Of these listed in Table 43-1, cigarette smoking is linked to an elevated risk for placental abruption (Eubanks, 2021). One metaanalysis of 1.6 million pregnancies in smokers found a twofold risk (Ananth, 1999). This risk was five- to eightfold if smokers had chronic hypertension, severe preeclampsia, or both. Similar findings are reported by others (Hogberg, 2007; Kaminsky, 2007). *Cocaine abuse* is linked, and in one series of 50 women who abused cocaine during pregnancy, eight had a stillbirth caused by placental abruption (Bingol, 1987).

Of potential serum markers, MSAFP, inhibin, and pregnancy-associated plasma protein in abnormal levels carry increased

risk (Ananth, 2017). Indeed, preliminary data shows that MSAFP levels >280 μg/L in the third trimester may be predictive (Ngai, 2012). Subclinical hypothyroidism or high levels of antithyroid antibodies have been associated with a two- to threefold higher risk for placental abruption (Abbassi-Ghanavati, 2010; Maraka, 2016). Lupus anticoagulant is associated with maternal floor infarction of the placenta but is less so with typical abruptions. Women affected by some of the thrombophilias have higher associated rates of thromboembolic events during pregnancy, however, no convincing evidence supports a link between thrombophilias and placental abruption (American College of Obstetricians and Gynecologists, 2019; 2020).

Diagnosis

The signs and symptoms of placental abruption can vary considerably. Classically, affected women have a sudden onset of abdominal pain, vaginal bleeding, and uterine tenderness. In an earlier study, 78 percent had vaginal bleeding, 66 percent had uterine tenderness or back pain, and 60 percent had a nonreassuring fetal status (Hurd, 1983). Other findings included frequent contractions and persistent hypertonus. However, in a fifth, preterm labor was diagnosed, and placental abruption was not suspected until fetal distress or death followed.

In some women, external bleeding can be profuse, yet placental separation may not be so extensive as to compromise the fetus. In others, external bleeding is absent, but the placenta is sufficiently sheared off to kill the fetus—a concealed abruption. In either case, bleeding can be massive and leads to hypovolemic shock. In an earlier report from Parkland Hospital, Pritchard and Brekken (1967) described 141 women with abruption so severe as to kill the fetus. Blood loss in these women often amounted to at least half of their pregnant blood volume.

Consumptive Coagulopathy

With placental abruption, some degree of intravascular coagulation is almost universal. Placental abruption is the most common cause of clinically profound consumptive coagulopathy in obstetrics and probably in all specialties (Cunningham, 2015). A primary consequence of intravascular coagulation is the activation of plasminogen to plasmin, which then lyses fibrin microemboli to maintain microcirculatory patency. With placental abruption severe enough to kill the fetus, pathological levels of fibrinogen–fibrin degradation products and D-dimers are almost always found in maternal serum (Erez, 2015). Their quantification is not clinically useful.

In a third of women with an abruption severe enough to kill the fetus, the plasma fibrinogen level will be <150 mg/dL. These levels are dependent on the maternal preabruption fibrinogen level, and thus higher levels are "protective" (Cunningham, 2015; Wang, 2016). Clinically significant low levels may cause troublesome surgical bleeding, and measurement of levels assists fibrinogen-replacement efforts. Levels of several other coagulation factors also are variably decreased. These are not specifically measured in DIC, but factors are replaced empirically with fresh frozen plasma as a part of massive transfusion protocols (Chap. 44, p. 772). In addition, thrombocytopenia, sometimes profound, may accompany severe hypofibrinogenemia and can be common after repeated blood transfusions. This "dilutional coagulopathy" is additive to DIC (Chap. 44, p. 772).

Consumptive coagulopathy is more likely with a concealed abruption because intrauterine pressure is higher. This forces more thromboplastin into the large veins draining the implantation site. With a partial abruption and a live fetus, severe coagulation defects are less common. Our experience has been that if serious coagulopathy develops, it is usually evident by the time abruption symptoms appear. In one unusual case, a woman cared for at Parkland Hospital presented with a nosebleed. She had no pain or vaginal bleeding, but her fetus was dead. Her blood did not clot, and the plasma fibrinogen level was 25 mg/dL. A total placental abruption was confirmed at delivery.

Couvelaire Uterus

At the time of cesarean delivery, it is not uncommon to find widespread extravasation of blood into the uterine musculature and beneath the serosa (Fig. 43-5). This phenomenon is named after Couvelaire, who in the early 1900s termed it *uteroplacental apoplexy*. These myometrial hemorrhages may incite uterine atony, but are not a sole indication for hysterectomy. Effusions of blood may collect beneath the tubal serosa, between the leaves of the broad ligaments, in the ovaries, or in the peritoneal cavity.

End-organ Injury

Acute kidney injury (AKI) is a general term describing renal dysfunction from many causes (Chap. 56, p. 1006). Delayed or incomplete treatment of hypovolemia is one. However, even with placental abruption complicated by severe DIC, prompt and vigorous treatment with blood and crystalloid solutions usually prevents significant renal dysfunction. The risk for renal injury with placental abruption rises when preeclampsia

FIGURE 43-5 Couvelaire uterus from total placental abruption after cesarean delivery. Blood markedly infiltrates the myometrium to reach the serosa. (Reproduced with permission from Dr. Steven Blaine Holloway.)

coexists (Alexander, 2015; Drakeley, 2002). Most cases of AKI are reversible, do not require dialysis, and generally have good long-term outcomes (Arazi, 2015). However, irreversible acute cortical necrosis occasionally stems from placental abruption (Gopalakrishnan, 2015).

Rarely, pituitary failure—*Sheehan syndrome*—follows severe intrapartum or early postpartum hemorrhage. Described in Chapter 61 (p. 1104), the exact pathogenesis is not well understood, especially because endocrine abnormalities are infrequent even in women who suffer catastrophic hemorrhage (Matsuwaki, 2014).

Differential Diagnosis

Severe placental abruption usually is obvious. However, less severe forms are not always recognized with certainty, and the diagnosis becomes one of exclusion. Unfortunately, no laboratory tests or other diagnostic methods accurately confirm lesser degrees of placental separation. Sonography has limited use because the placenta and fresh clots may have similar imaging characteristics. In a study of 149 women with a suspected placental abruption, the sensitivity for sonography was only 24 percent (Glantz, 2002). Thus, negative findings with sonographic examination do not exclude placental abruption. Conversely, magnetic resonance (MR) imaging is highly sensitive for placental abruption and should be considered if the diagnostic information would change management (Masselli, 2011). Last, elevated serum levels of D-dimers may be suggestive, but this has not been adequately tested.

Thus, in the woman with vaginal bleeding and a live fetus, placenta previa and other bleeding causes are sought with clinical and sonographic evaluation. It has long been taught—perhaps with some justification—that painful uterine bleeding signifies placental abruption, whereas painless uterine bleeding indicates placenta previa. The differential diagnosis is usually not this straightforward, and labor accompanying previa may cause pain that suggests placental abruption. Conversely, pain from placental abruption may mimic normal labor, or it may be painless, especially with a posterior placenta. At times, the vaginal bleeding source remains obscure even after delivery.

■ Management

Treatment varies depending on maternofetal clinical condition, gestational age, and amount of associated hemorrhage. With a living viable-aged fetus and with vaginal delivery not imminent, emergency cesarean delivery is chosen by most. In some women, fetal compromise will be evident as shown in Figure 43-6. When evaluating fetal status, sonographic confirmation of fetal heart activity may be necessary because sometimes an electrode applied directly to a dead fetus will provide misleading information by recording the maternal heart rate (Chap. 24, p. 447).

If the fetus has died or if it is not considered sufficiently mature to live outside the uterus, vaginal birth is preferable for the mother. In either case, prompt and intensive resuscitation with blood products and crystalloids is begun. These measures are lifesaving for the mother and hopefully for her fetus. If the diagnosis of placental abruption is uncertain and the fetus is alive and without evidence of compromise, close observation may be warranted provided that immediate intervention is available. Colón and coworkers (2016) performed a randomized trial and found no benefits to magnesium sulfate tocolysis given to women with a preterm "nonsevere" abruption at 24 to 34 weeks' gestation.

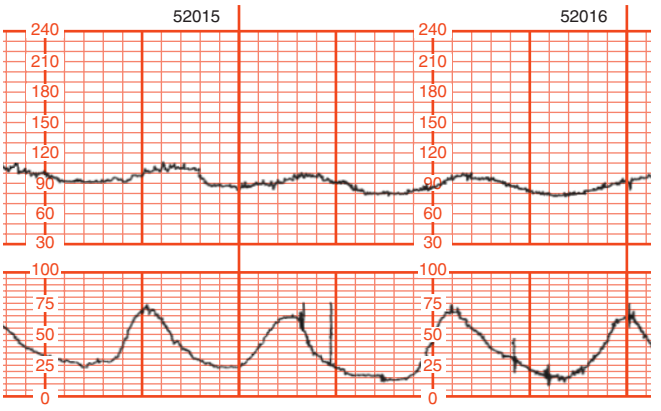

FIGURE 43-6 Placental abruption with fetal compromise. Lower panel: Uterine hypertonus with a baseline pressure of 20 to 25 mm Hg and frequent contractions peaking at approximately 75 mm Hg. Upper panel: The fetal heart rate demonstrates baseline bradycardia with repetitive late decelerations.

Cesarean Delivery

The compromised fetus is usually best served by cesarean delivery, and the speed of response is an important factor in perinatal outcomes. In one study of 33 singleton pregnancies with a clinically overt placental abruption and fetal bradycardia, 15 of the 22 neurologically intact survivors were delivered within a 20-minute decision-to-delivery interval (Kayani, 2003). However, eight of 11 infants who died or developed cerebral palsy were delivered after a 20-minute intervals. Onishi and colleagues (2019) also found a significant negative correlation between these intervals and cord arterial pH. At Parkland Hospital, placental abruption was one of the most powerful antecedents to body-cooling treatment for neonatal encephalopathy (Nelson, 2014).

A major hazard to cesarean delivery is imposed by clinically significant consumptive coagulopathy. Preparations include two large-bore intravenous catheters and plans for blood and component replacement. Measures of hemoglobin, platelet, and fibrinogen levels as well as protime (PT) and partial thromboplastin time (PTT) guide product replacement.

Vaginal Delivery

If the fetus has died, vaginal delivery is usually preferred. As reviewed earlier, hemostasis at the placental implantation site depends primarily on myometrial contraction and not blood coagulability. Thus, after vaginal delivery, uterotonic agents and uterine massage are used to stimulate myometrial contractions. Uterine muscle fibers compress placental site vessels and prompt hemostasis even if coagulation is defective. In some instances, vaginal delivery may not be preferable, even with a dead fetus. One example is brisk hemorrhage that cannot be successfully managed by vigorous blood replacement. Others

are the myriad obstetrical complications that prohibit vaginal delivery in general. In some women with extensive placental abruption, labor tends to be rapid because the uterus is usually persistently hypertonic (see Fig. 43-6). This can magnify fetal compromise. In some cases, baseline intraamnionic pressures reach 50 mm Hg or higher, and with contractions, pressures may attain levels exceeding 100 mm Hg. Overall, however, first- and second-stage labor does not appear to be shorter than usual (Downes, 2017).

Early amniotomy has long been championed in the management of placental abruption. This ostensibly achieves better spiral artery compression to diminish implantation site bleeding and reduce thromboplastin infusion into the maternal vascular system. Although evidence supporting this theory is lacking, membrane rupture may hasten delivery. However, if the fetus is small, the intact sac may be more efficient in promoting cervical dilation. If rhythmic uterine contractions are not superimposed on baseline hypertonus, oxytocin is given in standard doses. No data indicate that oxytocin augments thromboplastin escape into the maternal circulation to worsen coagulopathy. In light of hypertonus associated with placental abruption, misoprostol may be a less favored induction agent due to its association with uterine tachysystole.

In the past, some had set arbitrary time limits to permit vaginal delivery. Instead, experiences illustrate that maternal outcome depends on the diligence with which adequate fluid and blood replacement therapy are pursued rather than on the interval to delivery. Observations from Parkland Hospital described by Pritchard and Brekken (1967) are similar to those from the University of Virginia reported by Brame and associates (1968). Specifically, women with severe abruption who were transfused during 18 hours or more before delivery had similar outcomes to those in whom delivery was accomplished sooner.

Expectant Management

If possible, delaying delivery may benefit an immature fetus. In one series, 43 women with placental abruption before 35 weeks' gestation were expectantly managed, and 31 of them were given tocolytic therapy (Bond, 1989). The mean interval until delivery for all 43 approximated 12 days. Cesarean delivery was performed in 75 percent, and there were no stillbirths. As discussed earlier, women with a very early abruption may develop *chronic abruption–oligohydramnios sequence*. In one report, four women with an abruption at a mean gestational age of 20 weeks subsequently developed oligohydramnios and delivered at an average gestational age of 28 weeks (Elliott, 1998). In another description of 256 women with an abruption at <28 weeks' gestation, a mean of 1.6 weeks was gained (Sabourin, 2012). Of the group, 65 percent were delivered before 29 weeks, and half of all women underwent emergent cesarean delivery.

Unfortunately, even continuous fetal heart rate monitoring does not guarantee universally good outcomes. A normal tracing may precede sudden further separation with instant fetal compromise. In some of these, if the separation is sufficient, the fetus will die before it can be delivered. Tocolysis is advocated by some for suspected abruption if the fetus does not display compromise. Some investigators have observed that tocolysis improved outcomes in a highly selected cohort of women with preterm pregnancies (Bond, 1989; Combs, 1992). In another study, Towers and coworkers (1999) administered magnesium sulfate, terbutaline, or both to 95 of 131 women with abruption diagnosed before 36 weeks' gestation. The perinatal mortality rate was 5 percent in both groups with or without tocolysis. Similar results were reported from a randomized trial (Colón, 2016). A clinical consideration to the use of tocolytic agents, such as terbutaline, is that the drug-induced tachycardia may mask maternal compromise. We are of the opinion that suspected placental abruption contraindicates tocolytic agent use.

PLACENTA PREVIA

Classification

The Latin *previa* means going *before*, and in this sense, the placenta goes before the fetus into the birth canal. *Placenta previa* describes a placenta that is implanted somewhere in the lower uterine segment, either over or very near the internal cervical os. Because these anatomical relationships cannot always be precisely defined and because they frequently change across pregnancy, terminology can sometimes be confusing.

Terminology for placenta previa has evolved, and the National Institutes of Health (NIH)-sponsored Fetal Imaging Workshop (Reddy, 2014) recommends the following classification:

- Placenta previa: the internal os is covered partially or completely by placenta (Figs. 43-7 and 43-8). In the past, these were further classified as either total or partial previa.
- Low-lying placenta: implantation in the lower uterine segment is such that the placental edge does not cover the internal os but lies within a 2-cm wide perimeter around the os. A previously used term, *marginal previa*, described a placenta that was at the edge of the internal os but did not overlie it.

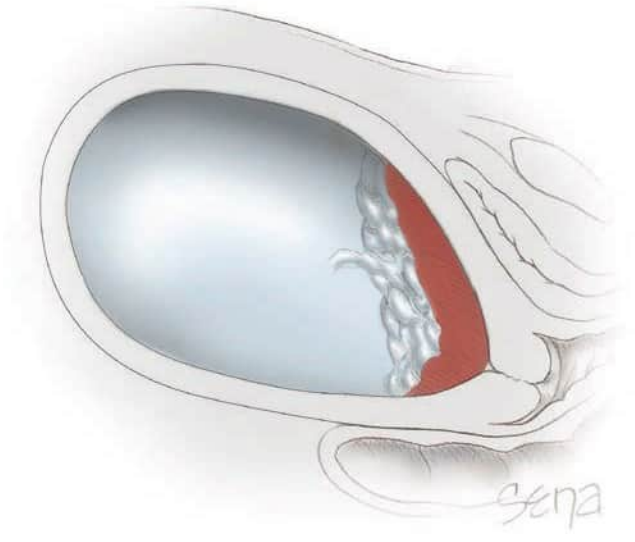

FIGURE 43-7 Placenta previa showing that copious hemorrhage could be anticipated with any cervical dilation.

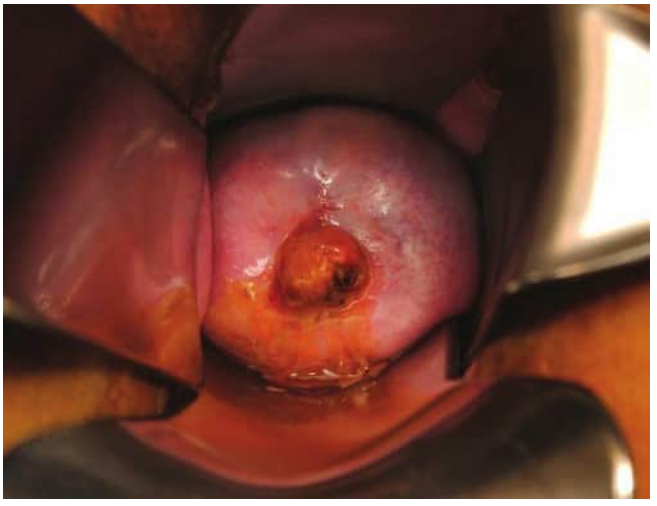

FIGURE 43-8 On speculum examination, placenta is visible protruding through the cervical os. (Reproduced with permission from Dr. Maureen E. Flowers.)

Clearly, the classification of some cases will depend on cervical dilation at the time of assessment. For example, a low-lying placenta at 2-cm dilation may become a partial placenta previa at 4-cm dilation because the cervix has opened to expose the placental edge. Conversely, a placenta previa that appears to be total before cervical dilation may become partial at 4-cm dilation because the cervical opening now extends beyond the edge of the placenta. *Digital palpation in an attempt to ascertain these changing relations between the placental edge and internal os as the cervix dilates usually causes severe hemorrhage!*

With any degree of placenta previa, a certain amount of spontaneous placental separation is inevitable during lower uterine segment remodeling and cervical dilation. Although this frequently causes bleeding and thus technically constitutes a placental abruption, this term is usually not applied in these instances.

Somewhat but not always related is *vasa previa*, in which fetal vessels course through membranes and present at the cervical os. Vasa previa has been reviewed by the Society for Maternal–Fetal Medicine (2015) and is discussed in Chapter 6 (p. 115).

Placental Migration

Beginning with the use of sonography in obstetrics, the term *placental migration* was coined to describe the apparent movement of the placenta away from the internal os (King, 1973). Obviously, the placenta does not actually move, and the mechanism of apparent movement is not completely understood. To begin with, migration is clearly a misnomer, because decidual invasion anchors chorionic villi.

Explanations of placental migration are likely additive. First, apparent movement of the low-lying placenta relative to the internal os is related to the imprecision of two-dimensional sonography. Second, as pregnancy progresses, growth of the lower and upper uterine segments differs. With greater blood flow in the upper uterus, placental growth toward this supply, termed *trophotropism*, is thus more likely directed toward the fundus. Many of those placentas that "migrate" most likely never were circumferentially implanted with true villous invasion that reached the internal cervical os. *Importantly, a low-lying placenta or placenta previa is less likely to "migrate" if there is a prior cesarean delivery scar*.

The frequency of placental migration has been quantified. In one study of 4300 women at midpregnancy, 12 percent had a low-lying placenta (Sanderson, 1991). Of placentas not covering the internal os, previa did not persist, and none subsequently had placental hemorrhage. Conversely, approximately 40 percent of placentas that covered the os at midpregnancy continued to do so until delivery. Thus, placentas that lie close to but not over the internal os until the early third trimester are unlikely to persist as a previa by term (Heller, 2014; Parrott, 2015). The chance that placenta previa persists increases with a hysterotomy scar (Kohari, 2012; Oyelese, 2006).

Incidence and Associated Factors

The incidence of placenta previa has risen during the past 30 years. Reported incidences average about 0.4 percent or 1 case per 250 to 400 deliveries (Hill, 2020). The frequency at Parkland Hospital from 1988 through 2003 for nearly 250,000 births was 2.6 cases per 1000. For the 2004 to 2020 epoch, it rose to 3.8 cases per 1000. Similar frequencies have been reported from Austria, Finland, and Israel (Kollmann, 2016; Räisänen, 2014; Rosenberg, 2011).

Several demographic factors may contribute to this higher rate of placenta previa. First, maternal age increases the frequency (Biro, 2012; Roberts, 2012). In the First- and Second-Trimester Evaluation of Risk (FASTER) trial, which included more than 36,000 women, the frequency of previa was 0.5 percent for women <35 years compared with 1.1 percent in those ≥35 years (Cleary–Goldman, 2005). At Parkland Hospital, the incidence ranged from a rate of approximately 0.65 cases per 1000 births for women ≤19 years to almost 10 cases per 1000 births for women older than 35.

Multiparity also elevates the rate of placenta previa (Räisänen, 2014). Obviously, the effects of advancing maternal age and parity are confounding. Still, Babinszki and colleagues (1999) reported that the 2.2-percent incidence in women with parity of five or greater was significantly higher than that of women with lower parity. The interpregnancy interval does not affect this rate (Fox, 2015).

Cigarette smoking increases the relative risk of placenta previa at least twofold (Usta, 2005). It has been postulated that carbon monoxide hypoxemia causes compensatory placental hypertrophy and greater surface area. Smoking may also be related to decidual vasculopathy.

Several clinical characteristics also raise placenta previa risks. Foremost, women with one or more *prior cesarean deliveries* are at greater risk for subsequent placental disorders that include placenta previa, placental abruption, or placenta accreta spectrum (PAS) (Gibbins, 2018; Klar, 2014). The cumulative risks for placenta previa that accrue with the increasing number of cesarean deliveries are extraordinary. In one MFMU Network study of 30,132 women undergoing cesarean delivery, the incidence was 1.3 percent for those with only one prior cesarean

delivery, but it was 3.4 percent if there were six or more prior cesareans (Silver, 2006). In a retrospective cohort of nearly 400,000 women who were delivered of two consecutive singletons, those with a cesarean delivery for the first pregnancy had a 1.6-fold greater rate for previa in the second pregnancy (Gurol-Urganci, 2011). These same investigators reported a 1.5-fold higher rate from six similar population-based studies. This risk is increased eightfold in women with parity greater than four and who have more than four prior cesarean deliveries (Gilliam, 2002).

Importantly, women with a prior uterine incision and placenta previa have an increased likelihood that cesarean hysterectomy will be necessary because of associated PAS (p. 761). In one study, 6 percent of women with a primary cesarean delivery for placenta previa required a hysterectomy. This rate was 25 percent for women with a placenta previa undergoing repeat cesarean delivery (Frederiksen, 1999).

Multifetal gestation raises placenta previa risk (Ananth, 2003a; Luke, 2017a). Compared with monochorionic twins, dichorionic ones show higher rates, which perhaps stems from having two implantation sites (Weis, 2012).

MSAFP levels, if abnormally elevated for otherwise unexplained reasons during prenatal screening, raise the risk for placenta previa and a host of other abnormalities. Moreover, women with a placenta previa and comorbid MSAFP level >2.0 multiples of the median (MoM) at 16 weeks' gestation were at greater risk for late-pregnancy bleeding and preterm birth (Chap. 17, p. 338).

Assisted reproductive technology (ART) used for conception elevates placenta previa rates. Some of this association may derive from overlapping effects. First, older women constitute a significant portion of patients electing ART (Luke, 2017b). Second, even adjusting for multifetal gestation, ART is still associated with higher previa rates (Karami, 2018). Last, in one systematic review including nearly 256,000 births, uterine leiomyomas were associated with higher placenta previa rates (Jenabi, 2019).

Clinical Features

Painless bleeding is the most characteristic event with placenta previa. Bleeding usually does not develop until near the end of the second trimester or later, but it can begin even before midpregnancy. Undoubtedly, some late abortions are caused by an abnormally located placenta. Initial bleeding from a previa usually begins without warning, and this *sentinel bleed* is rarely so profuse as to prove fatal. Usually it ceases, only to recur. However, in perhaps 10 percent of women, particularly those with a placenta implanted near but not over the cervical os, bleeding is delayed until labor onset. Bleeding at this time varies in degree, and it may mimic placental abruption.

In cases in which the placenta is located over the internal os, a specific sequence of events leads to bleeding. First, the uterine body remodels to form the lower uterine segment. With this, the internal os dilates, and some of the implanted placenta inevitably separates. Bleeding that ensues is augmented by the inherent inability of myometrial fibers in the lower uterine segment to contract and thereby constrict torn vessels. Similarly, bleeding from this lower-segment implantation site also frequently continues after placental delivery. Last, lacerations in the friable cervix and lower segment will bleed. These may be especially problematic following manual removal of a somewhat adhered placenta.

Cervical length may alter the clinical course. Stafford (2010) but not Trudell (2013), both with their associates, found that a placenta previa and a third-trimester cervical length <30 mm increased the risks for hemorrhage, uterine activity, and preterm birth. Similarly, Friszer (2013) but not Trudell (2013), both with their coworkers, showed that women admitted for bleeding had a greater chance of delivery in the subsequent 7 days when the cervical length measured <25 mm sonographically.

Placenta accreta spectrum is a frequent and serious complication associated with placenta previa. This abnormal placental attachment derives in part from poorly developed decidua that lines the lower uterine segment. Biswas and coworkers (1999) performed placental bed biopsies in 50 women with a placenta previa and in 50 control women. Infiltration of spiral arterioles by trophoblastic giant cells, rather than by the expected endovascular trophoblast cells, was found in half of specimens. In contrast, only 20 percent of biopsies from normally implanted placentas had these changes. In another study of 514 cases of placenta previa, abnormal placental attachment was identified in 7 percent (Frederiksen, 1999). As discussed, placenta previa overlying a prior cesarean incision conveys a particularly high risk for PAS.

Coagulopathy rarely complicate placenta previa, even when implantation site separation is extensive (Cunningham, 2015). Placental thromboplastin, which incites the intravascular coagulation seen with placental abruption, is presumed to readily escape through the cervical canal rather than be forced into the maternal circulation. The paucity of large myometrial veins in this area also may be protective.

Diagnosis

For uterine bleeding after midpregnancy, placenta previa and placental abruption are always considered. In one Canadian study, placenta previa accounted for 21 percent of women admitted from 22 to 28 weeks' gestation with vaginal bleeding (Sabourin, 2012). Previa should not be excluded until sonographic evaluation has clearly proved its absence. If sonography is not readily available, diagnosis by digital cervical examination is done in an operating room and with preparations in place for operative delivery. We call these preparations a *double set-up technique*. *Even the gentlest examination can cause torrential hemorrhage.*

Using standard sonographic techniques, quick and accurate placental localization can be accomplished (American Institute of Ultrasound in Medicine, 2018). This is usually done with transabdominal sonography. If the placenta clearly overlies the cervix or if it lies away from the lower uterine segment, the examination has excellent sensitivity and negative predictive value (Olive, 2006; Quant, 2014). Obese women may hinder clear viewing of the lower uterine segment. A full bladder may artificially elongate the cervix and compress the lower uterine

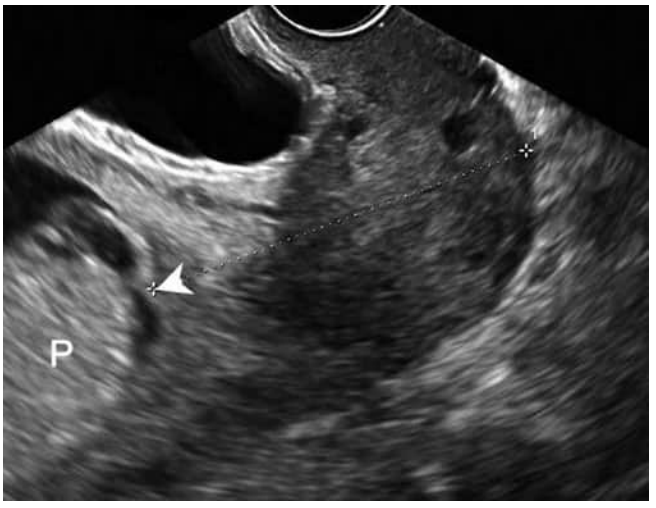

FIGURE 43-9 In this transvaginal image at 21 weeks' gestation, the posterior placenta (*P*) completely covers the internal cervical os (*arrowhead*). The dotted line represents the cervical canal.

segment to give the impression that the placenta overlies the cervix.

If placental location remains unclear, transvaginal sonography is the most accurate sonographic method and is safe even with vaginal bleeding (Fig. 43-9). In a comprehensive study, the internal os was visualized in all cases with transvaginal sonography but in only 30 percent with transabdominal sonography (Farine, 1988). As discussed, if the placental edge lies <2 cm from the internal os, but not covering it, the placenta is considered low lying (Reddy, 2014). In the absence of any other indication, sonography need not be frequently repeated simply to document placental position. At Parkland Hospital, women with placenta previa identified at 18 to 22 weeks' gestation and a prior cesarean delivery are reevaluated sonographically at 28 weeks and again at 32 weeks if it persists. Those with a placenta previa but without prior cesarean delivery undergo reimaging at 32 weeks. Restriction of activity is not necessary unless a previa persists beyond 28 weeks' gestation or if clinical findings such as bleeding or contractions develop before this time. At 32 weeks' gestation, if the placental edge is still <2 cm from the os, transvaginal sonography is repeated at 36 weeks' gestation.

Using MR imaging, several investigators report excellent visualization of placental abnormalities. However, it is unlikely that this modality will replace sonography for routine evaluation anytime soon given availability and cost differences compared with sonography. However, MR imaging is useful for evaluation of PAS (p. 761).

■ Management

Care with placenta previa is individualized, and three prominent factors include fetal maturity, associated labor, and bleeding severity. In one study of 214 women with a placenta previa, 43 percent had an emergency delivery, and half of these were preterm (Ruiter, 2015). Instead, if active bleeding subsides and the fetus is immature, close observation in an obstetrical unit is indicated. Data are sparse regarding tocolytic administration for uterine contractions. Although robust randomized trials are lacking, Bose and colleagues (2011) recommend that if tocolytics are given, they be limited to 48 hours of administration. As noted earlier, the physiological cardiovascular responses to tocolytic agents that include hypotension and tachycardia can mask maternal compromise. We categorically recommend against their use in this setting.

After bleeding has ceased for approximately 2 days and the fetus is judged to be healthy, a woman can usually be discharged home with instructions for "pelvic rest." The Society for Maternal–Fetal Medicine (2018) does not recommend routine cervical length screening in these women. Importantly, the woman and her family must appreciate the possibility of recurrent bleeding and be prepared for immediate transport back to the hospital. In other cases, prolonged hospitalization may be necessary.

The frequency of emergency delivery in women with placenta previa ranges from 25 to 40 percent (Erfani, 2019; Gibbons, 2018). In properly selected patients, however, long-term inpatient care does not appear to add benefits compared with outpatient management (Neilson, 2003). In one randomized study of 53 women who had a bleeding previa at 24 to 36 weeks' gestation, maternal or fetal morbidity rates did not differ between management methods (Wing, 1996). Of all study women, 60 percent had recurrent bleeding, and half eventually required expeditious cesarean delivery.

For women who are near term and who are not bleeding, plans are made for scheduled cesarean delivery. A planned delivery in a controlled setting is optimal, and timing balances fetal immaturity against antepartum hemorrhage. The American College of Obstetricians and Gynecologists and Society for Maternal–Fetal Medicine (2021) recommend delivery for otherwise uncomplicated placenta previa between $36^{0/7}$ and $37^{6/7}$ weeks. At Parkland Hospital, we usually perform elective cesarean delivery at $38^{0/7}$ weeks. Recommendations for delivery of women with PAS are outlined in that section.

■ Delivery

Practically all women with placenta previa undergo cesarean delivery. Some recommend a vertical laparotomy incision to provide rapid entry if bleeding is torrential or if generous operating space is required for hysterectomy. As discussed, cesarean delivery is emergently performed in more than half because of hemorrhage, for which about a fourth require blood transfusion (Sabourin, 2012). Although a low transverse hysterotomy is usually possible, this may cause fetal bleeding if the placenta is implanted anteriorly and the placenta is incised. In such cases, fetal delivery should be expeditious (Silver, 2015a). Thus, a vertical uterine incision may be preferable in some instances. In either case, even when the incision extends through the placenta, maternal or fetal outcomes are rarely compromised.

Following placental removal, the implantation site may bleed uncontrollably due to poorly contracted smooth muscle, which is characteristic of the lower uterine segment. If hemostasis at the placental implantation site cannot be obtained by uterotonic agent administration and pressure, it can be oversewn with no. 0 chromic sutures. Cho and associates (1991) described placing interrupted sutures at 1-cm intervals to form

a circle around the bleeding portion of the lower segment to control hemorrhage. Others have reported success with compression sutures that traverse and compress the anterior and posterior uterine wall (Mohamed, 2019; Sallam, 2019).

Of other methods, Bakri or Foley balloon tamponade used alone or coupled with compression sutures has been described (Albayrak, 2011; Diemert, 2012). Other surgical options are bilateral uterine or internal iliac artery ligation, illustrated in Chapter 44 (p. 779). Pelvic artery embolization also has gained acceptance. Yu and colleagues (2020) performed a randomized trial of perioperative prophylactic internal iliac artery balloon occlusion during cesarean delivery for placenta previa and found that deployment did not reduce postpartum hemorrhage or alter maternal or neonatal morbidity.

If these more conservative methods fail and bleeding is brisk, hysterectomy is necessary. Placenta previa—especially with PAS—currently is a common indication for peripartum hysterectomy at Parkland Hospital and other institutions (Jakobsson, 2015; Wong, 2011). In cases without PAS, the reported incidence of hysterectomy with placenta previa is 2 percent (Gibbins, 2018).

Thus, it is not possible to accurately estimate the effect on the hysterectomy rate from placenta previa alone without considering the associated PAS. *Again, for women whose placenta previa is implanted anteriorly at the site of a prior uterine incision, the likelihood of an associated morbidly adherent placenta and need for hysterectomy is increased.* In a study of 318 peripartum hysterectomies performed in the United Kingdom, 40 percent were done for abnormal placentation (Knight, 2007). At Parkland Hospital, 44 percent of cesarean hysterectomies were done for bleeding placenta previa or for PAS (Wortman, 2015). The technique for peripartum hysterectomy is described in Chapter 30 (p. 560).

■ Maternal and Perinatal Outcomes

Placenta previa and coexistent PAS both contribute substantively to maternal morbidity and mortality rates. The maternal mortality ratio is increased approximately threefold for women with a placenta previa (Gibbins, 2018). In a report of 5367 maternal deaths in the United States from 2006 to 2013, placenta previa alone accounted for nearly 3 percent of deaths from hemorrhage (Creanga, 2014, 2017).

The report from the Consortium on Safe Labor emphasizes the ongoing perinatal morbidity with placenta previa (Lai, 2012). In these cases, preterm delivery continues to be a major cause of perinatal death (Balachandar, 2020; Nørgaard, 2012; Salihu, 2003). Ananth and colleagues (2003b) reported a comparably elevated risk of neonatal death even for fetuses who delivered at term. This is at least partially related to the fetal anomaly rate, which is two- to threefold higher in pregnancies with placenta previa (Crane, 1999; Kancherla, 2015).

The association of fetal-growth restriction with placenta previa is likely minimal after controlling for gestational age. In a population-based cohort of more than 500,000 singleton births, most low-birthweight newborns associated with placenta previa resulted from preterm birth (Ananth, 2001). From their large metaanalysis, Balayla and coworkers (2019) found a slightly increased frequency of fetal-growth restriction. At least two other studies reported an elevated risk (Räisänen, 2014; Weiner, 2016). Apparently, fetal growth effects are similar with placenta previa and PAS (Jauniaux, 2019).

PLACENTA ACCRETA SPECTRUM

The term *placenta accreta spectrum (PAS)* describes aberrant placentation characterized by abnormally implanted, invasive, or adhered placenta. Derivation of accreta comes from the Latin *ac- + crescere*—to adhere or become attached to (Benirschke, 2012). It is also referred to as the morbidly adherent placenta, and in Europe it is referred to as a *pernicious placenta previa with accreta* and *abnormally adherent placenta*.

■ Etiopathogenesis

The major clinical problem is placental failure to separate normally from the myometrium after fetal delivery. This abnormal adherence stems in part from partial or total absence of the decidua basalis and imperfect development of the fibrinoid or Nitabuch layer, described in Chapter 5 (p. 85). If the decidual spongy layer is lacking either partially or totally, the physiological line of cleavage is absent, and some or all cotyledons are densely anchored. Microscopically, placental villi attach to smooth muscle fibers rather than to decidual cells. This decidual deficiency then prevents normal separation after delivery. The surface area involved at the implantation site and the depth of trophoblast ingrowth vary between women, but all affected placentas can potentially cause significant hemorrhage.

Data now suggest that PAS is not solely caused by the decidua's anatomical deficiency. Indeed, the cytotrophoblasts may control decidual invasion through factors such as angiogenesis (Duzyj, 2018; Goh, 2016). Moreover, some tissue specimens show immunologically mediated "hyperinvasiveness" (Harris, 2019). Some genes that code for remodeling and for adherence may be highly expressed (Matsukawa, 2019; Shainker, 2020). Myometrial fibers attached to the basal plate in an antecedent pregnancy are predictive markers for a subsequent PAS (Linn, 2015; Miller, 2016). This implies an antecedent "constitutional endometrial defect" in most cases. The greater risk conveyed by previous surgical uterine trauma may be partially explained by an enhanced vulnerability to trophoblast invasion (Einerson, 2020; Jauniaux, 2018).

This association with prior trauma is reinforced by the close relationship between *cesarean scar pregnancy (CSP)* and later development of PAS in the same pregnancy. Indeed, accruing evidence suggests that CSP and PAS lie on a spectrum and that CSP is a precursor (Happe, 2020; Timor-Tritsch, 2019). Described in Chapter 12 (p. 229), early rupture and hemorrhage with CSP are not uncommon, and women often elect pregnancy-terminating interventions to avoid these (Society for Maternal–Fetal Medicine, 2020; Timor-Tritsch, 2019).

■ Classification

Variants of PAS are classified by the depth of trophoblastic growth (Figs. 43-10 and 43-11). *Placenta accreta* indicates that

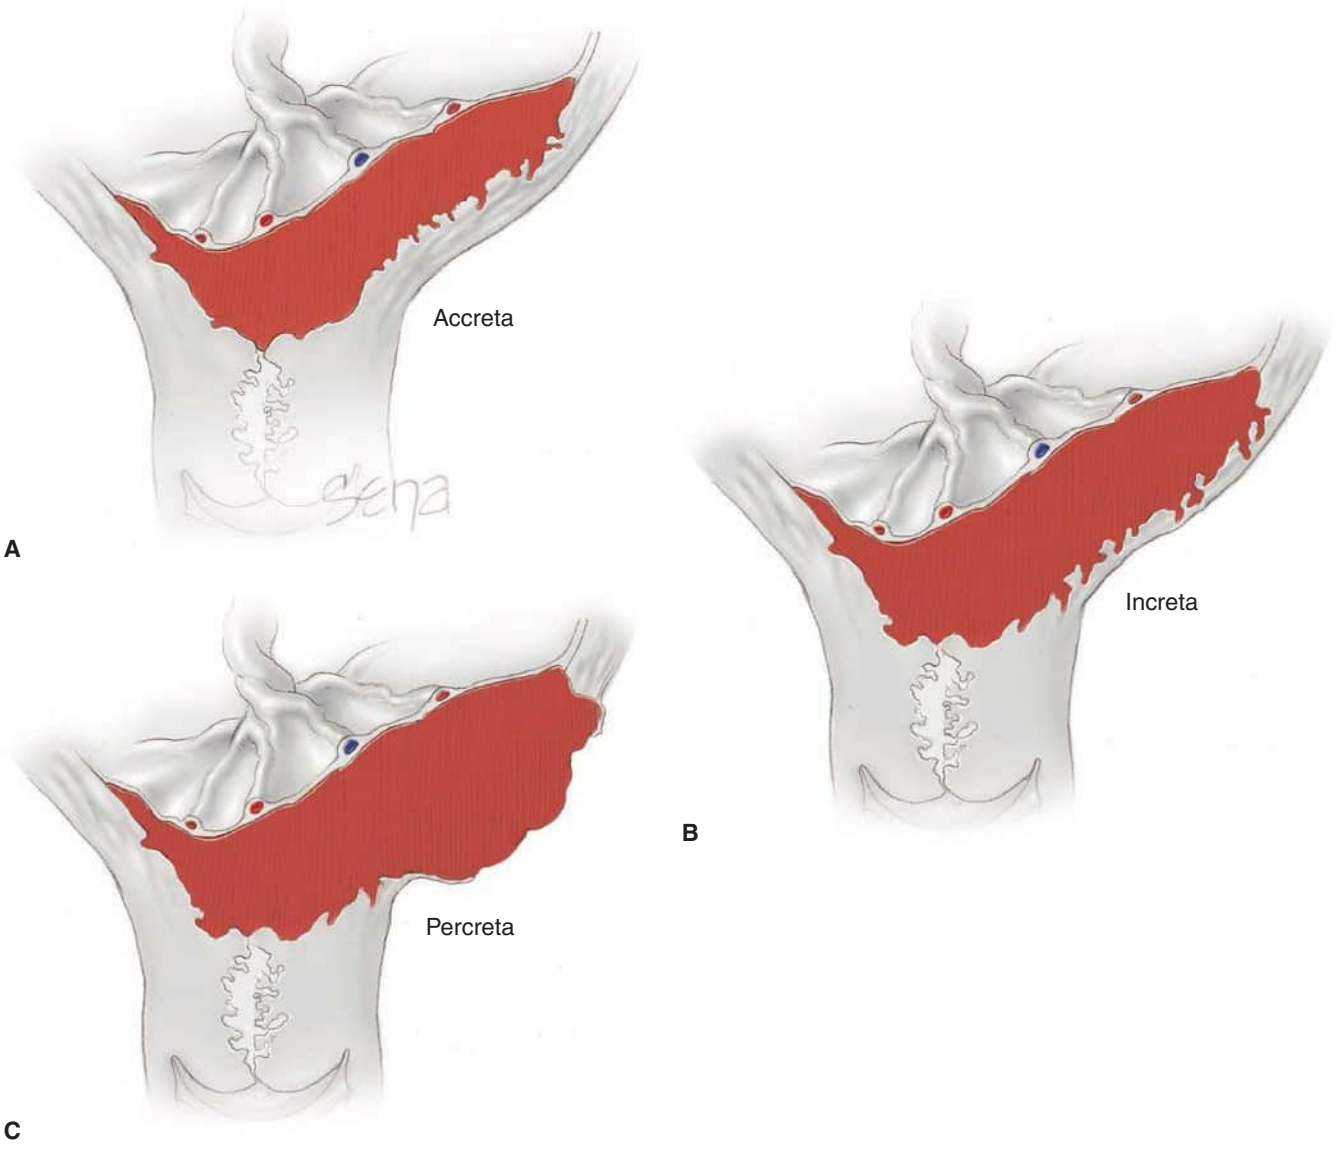

FIGURE 43-10 Placenta accreta spectrum. **A.** Placenta accreta. **B.** Placenta increta. **C.** Placenta percreta.

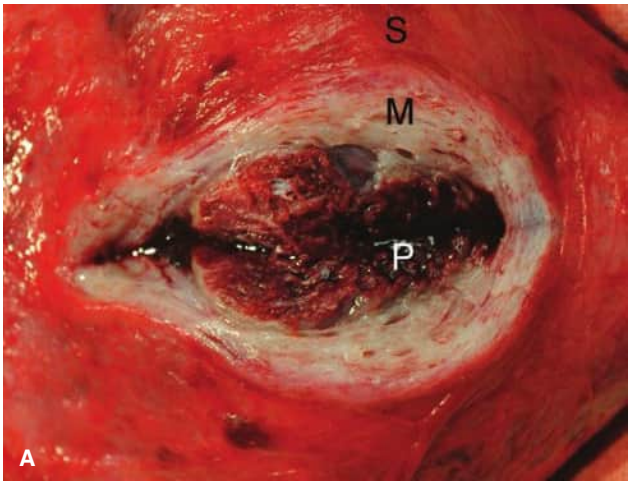
villi are attached to the myometrium. With *placenta increta*, villi actually invade the myometrium, and *placenta percreta* defines villi that penetrate through the myometrium and to or through the serosa (Silver, 2018). In clinical practice, these three variants are encountered in an approximate ratio of 80:15:5, respectively (Wong, 2008). At a referral center, however, the distribution was 22, 24, and 54 percent respectively (Birgani, 2020). In all three varieties, abnormal adherence may involve all lobules—*total placenta accreta*. If all or part of a single lobule is abnormally attached, it is described as *focal placenta accreta*. Histological diagnosis cannot be made from the placenta alone, and myometrial samples are necessary for confirmation (Jauniaux, 2021). Terminology for consistent classification has been lacking because of varying clinical criteria and lack of detailed pathological examinations. To alleviate this, the International Federation of Gynecology and Obstetrics (FIGO) has recently proposed a clinical classification system for PAS (Jauniaux, 2019).

Incidence and Risk Factors

Decades ago, the frequency of PAS was 1 in 20,000 births (McKeogh, 1951). As late as 1971, Hellman and Pritchard in the 14th edition of *Williams Obstetrics* described PAS as the subject of case reports. Since then, the incidence has grown remarkably in direct relationship to the rising cesarean delivery rate. For example, the incidence was 1 case in 2500 births in the 1980s, but it was 1 case per 731 births in a report from the MFMU Network comprising 115,502 women (Bailit, 2015). From the Nationwide Inpatient Sample, the PAS rate was an astounding 1 case in 270 births (Mogos, 2016).

This rising frequency has made PAS one of the most formidable problems in obstetrics. Of 5367 pregnancy-related maternal deaths in the United States from 2006 to 2013, 13 percent were due to hemorrhage caused by PAS (Creanga, 2015, 2017). In addition, PAS is a leading cause of hemorrhage and emergency peripartum hysterectomy (Awan, 2011; Eller, 2011; Rossi, 2010). The American College of Obstetricians and



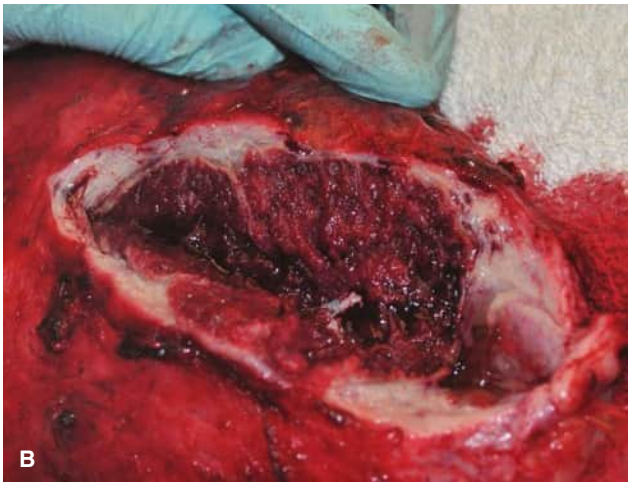


FIGURE 43-11 Varying degrees of myometrial invasion with placenta accreta spectrum disorders. Incisions begin on the serosal surface and extend through to the placenta. **A.** In this case, the myometrium (M) shows minimal invasion by the placenta (*P*). S = uterine serosa. **B.** A greater degree of myometrial invasion is seen here. **C.** In this example, the placenta (brackets) extends to the serosal edge, held by the surgeon's hand. No myometrium remains at this site. (Reproduced with permission from Dr. C. Edward Wells in Cunningham FG: Placenta previa and morbidly adherent placenta. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd edition. New York, McGraw Hill Education, 2017.)

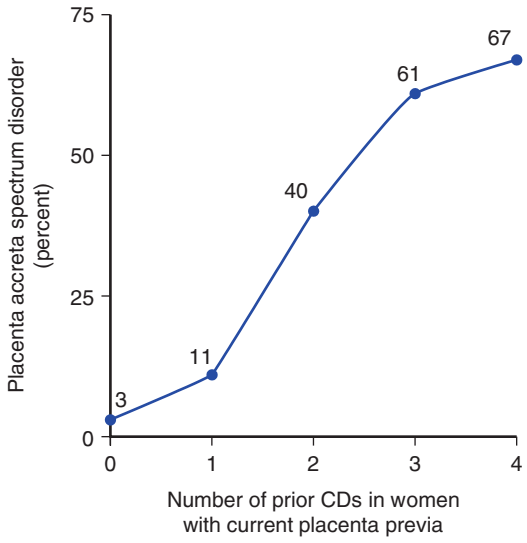

FIGURE 43-12 Frequency of placenta accreta spectrum in women with one to four prior cesarean deliveries (CDs) and now with a placenta previa.

Gynecologists and the Society for Maternal–Fetal Medicine (2018) have outlined optimal management. The International Society for Abnormally Invasive Placenta also has published guidelines (Collins, 2019).

In subsequent pregnancies following PAS, recurrence risks are high. Women in whom hysterectomy is avoided have an estimated 20-percent incidence of recurrence (Cunningham, 2016; Roeca, 2017). Some evidence shows that these women also have greater risks for placenta previa, uterine rupture, manual placental removal, preterm delivery, and hysterectomy (Baldwin, 2020; Eshkoli, 2013).

PAS risk factors are similar to those for placenta previa (p. 756). Shown in Figure 43-12, the two most important elements are an associated placenta previa, a prior cesarean delivery, or more likely both (Klar, 2014; Silver, 2006). A classical hysterotomy incision has a higher risk for subsequent PAS than a lower uterine segment one (Gyamfi-Bannerman, 2012). Of women with a prior cesarean delivery, almost half had myometrial fibers seen microscopically adhered to the placenta (Hardardottir, 1996; Miller, 2016). Dysfunctional decidua may also follow other myometrial trauma such as curettage or endometrial ablation (Baldwin, 2018; Gill, 2015). ART is an independent risk factor for PAS (Salmanian, 2020).

Other risk markers are prenatal MSAFP and human chorionic gonadotropin (hCG) used to screen for neural-tube defects and aneuploidies. In one study of more than 9300 women screened at 14 to 22 weeks' gestation, the risk for PAS was eightfold higher with MSAFP levels >2.5 MoM, and it was increased fourfold with maternal serum free β-hCG levels >2.5 MoM (Hung, 1999).

■ Diagnosis

With first- and second-trimester PAS, hemorrhage usually stems from a coexisting placenta previa. Such bleeding will typically prompt evaluation, and ideally sonography is used (Chantraine, 2013; Jauniaux, 2018).

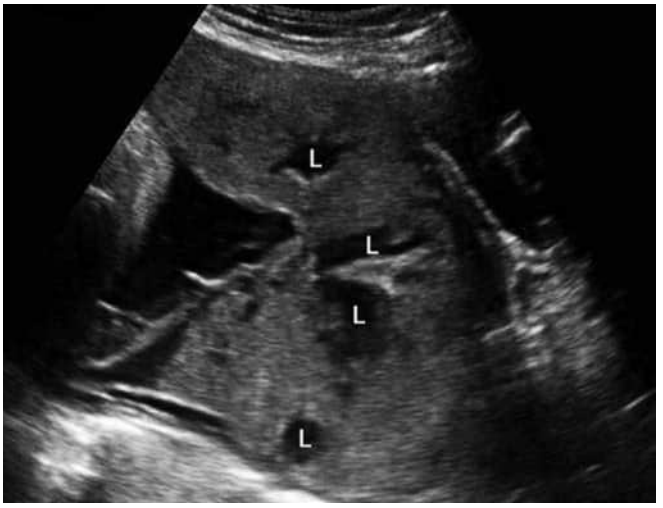

FIGURE 43-13 Transabdominal sonogram of placental percreta shows multiple and massive placental "lakes" or "lacunae" (*L*).

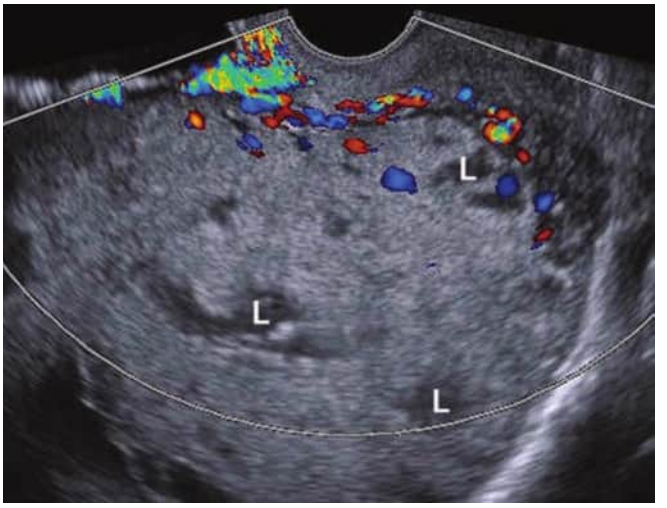

FIGURE 43-14 Transvaginal sonogram of placental invasion with a placenta percreta. Retroplacental vessels (color Doppler) invade the myometrium, and abnormal intraplacental venous lakes (*L*) are commonly seen in this setting.

With lesser degrees of bleeding, first-trimester measurement of the smallest myometrial thickness can help predict the later risk for peripartum hysterectomy with PAS (Happe, 2020). In a screening study of more than 22,000 singleton pregnancies at 11 to 13 weeks' gestation, 6 percent were at high risk for PAS (Panaiotova, 2019). However imaging was less than perfect to identify all of these placentas early. Subsequently, only 14 had a suspected clinical diagnosis, and 13 of these were confirmed at delivery.

Five characteristic sonographic findings suggest PAS: (1) placental lacunae; (2) thinning of the retroplacental myometrium; (3) disruption of the bladder-uterine serosal interface; (4) bridging vessels from the placenta to the bladder-serosal interface; and (5) placental bulge that pushes outward and distorts the contour of the uterus (Fig. 43-13). In a metaanalysis, the sensitivities of these criteria to identify placenta accreta, increta, and percreta were 91, 93, and 89 percent, respectively. Corresponding specificities were 97, 98, and 99 percent, respectively (Pagani, 2018).

These figures may be overestimated because of clinical bias and considerable interobserver variability (Silver, 2018). Some investigators report fewer spectacular results with sonography (Jauniaux, 2016; Primo, 2014). Bowman and colleagues (2014) described the sensitivity of sonography to be 54 percent; specificity, 88 percent; positive predictive value, 82 percent; negative predictive value, 65 percent; and accuracy, 65 percent. Location affects sonographic accuracy. Posterior placental location is associated with delayed diagnosis and increased surgical complications (Morgan, 2019; Tinari, 2021). In one study, the detection rate was 90 percent for anterior placenta accreta compared with 50 percent for posterior ones (Pilloni, 2016). Nageotte (2014) concluded that identification of PAS with sonography should be interpreted with clinical and operative findings.

Better results have been found by some using three-dimensional (3-D) sonography and power Doppler (Collins, 2015). We too have found that the addition of Doppler color flow mapping aids prediction of myometrial invasion (Fig. 43-14). Invasion is suspected if the distance between the uterine serosa–bladder wall interface and the retroplacental vessels measures <1 mm and if large intraplacental lacunae are seen (Rac, 2015a; Twickler, 2000). In another study, hypervascularity of the uterine serosa–bladder wall interface had the highest positive and negative predictive values for placenta percreta (Cali, 2013). Intracervical lakes also have been reported with placenta percreta (di Pasquo, 2020).

Yule and coworkers (2020) reported that the *placenta accreta index* was useful for diagnosis. This index incorporates the number of prior cesarean deliveries, placental location, lacunae, bridging vessels, and smallest myometrial distance. These investigators are also exploring first-trimester color mapping to develop a quantification algorithm (Yule 2021).

To further delineate anatomy, MR imaging can be added. We and others use it to identify invasion of adjacent structures (Chalubinski, 2013; Reddy, 2014). Interobserver variability was reported to be excellent to diagnose PAS and assess invasion depth. There was less agreement in assessing topography of invasion (Finazzo, 2020). Using MR imaging, Mori and colleagues (2020) described a high prevalence of pelvic parasitic arteries with PAS. However, not all investigators have found MR imaging to be beneficial (Einerson, 2018).

Although gadolinium is usually not added during pregnancy, this contrast may enhance images (Millischer, 2017). Lax and coworkers (2007) described three MR imaging findings that suggest PAS: uterine bulging, dark intraplacental bands on T2-weighted imaging, and heterogeneous signal intensity within the placenta indicative of lacunae. Some recommend MR imaging if sonography results are inconclusive or there is a posterior previa (American College of Obstetricians and Gynecologists, 2018; Silver, 2018).

Management

Preoperative assessment ideally begins once a possible PAS is recognized antenatally. *A major decision concerns the timing and the ideal facility for delivery.* Considerations include appropriate

TABLE 43-2. Criteria to Consider for Delivery of Placenta Accreta Spectrum (PAS) in a Center of Excellence

Sonogram findings suspicious for PAS
Placenta previa with abnormal ultrasound appearance
Placenta previa with 2 to 3 prior cesarean deliveries
Prior classical cesarean delivery and anterior placentation
Prior endometrial ablation or pelvic irradiation
Inability to adequately evaluate or exclude PAS
Any other reason to suspect PAS

surgical, anesthesia, intensive care, and blood banking capabilities. An obstetrical surgeon or gynecological oncologist and surgical, urological, and interventional radiological consultants should be available (Collins, 2019; Shamshirsaz, 2018). The American College of Obstetricians and Gynecologists (2018) and the Society for Maternal–Fetal Medicine recommend planned delivery in a tertiary-care facility. In some, specially designed teams have been assembled and are on call (Shamshirsaz, 2018). A metaanalysis described the improved maternal outcomes with such management (Bartels, 2018).

Silver and colleagues (2015b) have provided requisites for accreta centers of excellence and their criteria to consider transfer to a higher level-of-care hospital (Table 43-2). If possible, delivery is best scheduled for peak availability of all resources and team members. Even so, a third of cases require unscheduled delivery, and contingency plans should be ready (Pettit, 2019). Women who refuse blood or its derivatives pose especially difficult management dilemmas (Barth, 2011).

Delivery Timing

In one study, 40 percent of women with PAS had bleeding mandating unplanned delivery prior to 34 weeks' gestation. Timing balances fetal immaturity against adverse maternal consequences of hemorrhage and emergency cesarean delivery (Perlman, 2017; Pettit, 2019). The American College of Obstetricians and Gynecologists (2018; 2021) recommends individualization and suggests delivery between $34^{0/7}$ and $35^{6/7}$ weeks' gestation. They cite a decision-analysis study that justifies elective delivery without fetal lung maturity testing after 34 completed weeks (Robinson, 2010). The Society for Maternal–Fetal Medicine (2018) recommends delivery between 34 and 37 weeks. Two earlier surveys found that most practitioners do not deliver these women until 36 weeks or later (Esakoff, 2012; Wright, 2013). At Parkland Hospital, we generally schedule these procedures after 36 completed weeks but are prepared also to manage them in nonelective situations (Rac, 2015b).

In some cases, PAS is not recognized until laparotomy. If resources are inadequate to surgically manage the percreta and if the woman is stable and not bleeding, the fetus is not delivered. The abdominal incision is closed, and she is transferred to a tertiary-care facility.

Preoperative Prophylactic Catheterization

In cases that may involve the ureters, catheterization may aid their dissection or identification. However, these catheters overall do not lower urinary tract injury rates (Crocetto, 2021). Some, but not all, advocate preoperative ureteral catheterization (American College of Obstetricians and Gynecologists, 2018; Eller, 2011). The role of catheters for ureteral injury repair is outlined in Chapter 30 (p. 564).

With a*rterial catheterization*, balloon-tipped catheters aim to mitigate blood loss and thereby enhance surgical visibility. Catheters are advanced preoperatively into the internal iliac arteries and are inflated after fetal delivery to occlude pelvic blood flow (Ballas, 2012; Desai, 2012; Zhou, 2021). Some prefer an infrarenal aortic balloon occlusion catheter (Mei, 2020). Alternatively, the catheters can be used to deliver occluding emboli to bleeding arterial sites (Mei, 2018). Others have concluded that these procedures offer borderline efficacy and have serious risks (Chen, 2020; Makary, 2019; Mohr-Sasson, 2020). Rare complications have included thrombosis of the common iliac artery (Bishop, 2011). At this time, the American College of Obstetricians and Gynecologists (2018) concludes that a firm recommendation cannot be made for or against intra-arterial catheter use. Similarly, there are no obvious benefits to prophylactic internal iliac artery ligation in this setting (Po, 2012; Yu, 2020).

Cesarean Delivery and Hysterectomy

Before commencing with delivery, the risk of hysterectomy to prevent exsanguination should be estimated. Some of these abnormal placentations, especially if partial, may be amenable to placental delivery with hemostatic suture placement. Confirmation of a percreta or increta almost always mandates hysterectomy. Because the scope of invasion may not be apparent before delivery of the fetus, some complete a number of dissection steps early. This also minimizes blood loss during potentially tedious dissection after hysterotomy and if the placenta bleeds. Thus, an attempt can be made to create a wide bladder flap before making the hysterotomy incision (Cunningham, 2017). The round ligaments are divided, and the lateral edges of the peritoneal reflection are dissected downward. If possible, these incisions are extended to encircle the entire placental implantation site that visibly occupies the prevesical space and posterior bladder wall. Following this, a classical hysterotomy, transverse fundal, or high posterior incision is made to avoid the placenta (Kotsuji, 2013).

After fetal delivery, the extent of placental invasion is assessed without attempts at manual placental removal. In a report from the United Kingdom, attempts at partial or total placental removal prior to hysterectomy were associated with twice as much blood loss (Fitzpatrick, 2014). Generally speaking, with obvious percreta or increta, hysterectomy is usually the best course, and the placenta is left in situ. With more extensive placental ingrowth, bleeding may be minimal until manual placental removal is attempted. Unless there is spontaneous separation with bleeding that mandates emergency hysterectomy, the operation begins after full assessment is made. Cesarean hysterectomy is carried out as described in Chapter 30 (p.560).

With heavy bleeding, successful treatment depends on immediate blood replacement and other measures that can include uterine or internal iliac artery ligation, balloon occlusion, or

TABLE 43-3. Steps in Cesarean Hysterectomy for Management of Placenta Percreta

Midline vertical laparotomy and midline hysterotomy: enter uterus to avoid placenta

Superior devascularization: divide and ligate uteroovarian pedicles and round ligaments

Retroperitoneal dissection: incise down to paravesical space; consider cephalad dissection to expose ureters and bifurcation of common iliac arteries

Bladder dissection: progress lateral to medial and down to vaginal fornices; associated with troublesome venous bleeding

Colpotomy: inferior dissection of extremely vascular paravesical space may cause significant hemorrhage

embolization. In some cases, the operation is made easier by performance of a supracervical hysterectomy (Levin, 2020). Kingdom and colleagues (2020) have described a modified radical hysterectomy for PAS (Table 43-3). This technique is also detailed in *Cunningham and Gilstrap's Operative Obstetrics*, 3rd edition (Cunningham, 2017). Because of a high risk for postoperative venous thromboembolism, consideration is given for thromboprophylaxis (Silver, 2018).

Conservative Management

Occasionally, it may be possible to trim the umbilical cord, repair the hysterotomy incision, leave the placenta in situ, and not pursue hysterectomy (Sentilhes, 2021). This option may be used for women in whom abnormal placentation was not suspected before cesarean delivery and in whom uterine closure stops bleeding. After this, she can be transferred to a higher level-of-care facility for definitive management. Another consideration is the woman with a strong desire for fertility and who has received extensive counseling. Resection of the adherent placenta and underlying myometrium has been advocated as a uterine-sparing technique (Palacios-Jaraquemada, 2020).

Conservative management was reviewed by Perez-Delboy (2014) and Fox (2015) and their colleagues. In some of these cases, the placenta spontaneously resorbed between 1 and 12 months with a mean of 6 months. Numerous complications can occur and include sepsis, coagulopathy, pulmonary embolism, and arteriovenous malformation (Fox, 2015; Judy, 2015; Roach, 2015). In other cases, sutures are placed through the outside wall of the uterus overlying the placental bed. Shih and associates (2019) described this using a Nausicaa procedure.

In some of these women, a subsequent hysterectomy—either planned or prompted by bleeding or infection—is performed days to weeks postpartum when blood loss might be less (Al-Khan, 2014; Sentilhes, 2009, 2021; Zuckerwise, 2020). In some studies, 20 percent or fewer of women ultimately required hysterectomy (Bretelle, 2007; Kutuk, 2018). In other reports, however, up to 60 percent eventually required emergency hysterectomy (Clausen, 2013; Pather, 2014). Evidence that treatment with methotrexate aids resorption is lacking. Last, for women in whom the placenta is left in situ, serial serum β-hCG measurements are not informative, and serial sonographic or MR imaging is recommended (Timmermans, 2007; Worley, 2008).

At this time, we agree with the American College of Obstetricians and Gynecologists (2018) that leaving the placenta in situ should be considered investigational. Exceptions permit transfer to a higher level of care. Guidelines from the International Society for Abnormally Invasive Placenta are more permissive (Collins, 2019).

Pregnancy Outcomes

In sum, PAS can have disastrous outcomes for both mother and fetus. Although the depth of placental invasion does not correspond with perinatal outcome, it is of paramount maternal significance. Table 43-4 displays outcomes of women at tertiary-care hospitals and in whom the PAS diagnosis was usually made preoperatively. Despite these advantages, complications included hemorrhage, urinary tract injury, intensive care unit admission, secondary surgical procedures, and maternal death. Some of these same reports chronicle outcomes in a second cohort of women in whom care was not given at a tertiary-care facility or in whom the diagnosis of percreta was not made until delivery, or both. In these cohorts, morbidity and mortality rates were higher (Erfani, 2019).

CHAPTER 44

Management of Obstetrical Hemorrhage

Recognition of obstetrical hemorrhage severity is crucial to its management. However, visual estimates, especially when blood losses are excessive, are notoriously inaccurate. In many cases, true volume losses are often two to three times the clinical estimate. Moreover, in obstetrics, part and sometimes even all of the lost blood may be concealed. Estimation is further complicated in that peripartum hemorrhage also includes the pregnancy-augmented blood volume. After pregnancy hypervolemia is lost at delivery, blood loss can be estimated by calculating 500 mL loss for each 3 volume percent drop in hematocrit. Its nadir depends on the speed of resuscitation with intravenous crystalloids and blood products. *With ongoing blood loss, the real-time hematocrit is at its maximum whenever measured in the delivery, operating, or recovery room.*

Prudently, if blood loss is considered more than average, the hematocrit is determined, and plans are made for close observation for potential physiological deterioration. Blood loss determination as recommended by the American College of Obstetricians and Gynecologists (2019b) is discussed in detail in Chapter 42. Urine output measured hourly is one of the most important "vital signs." *Unless diuretic agents are given—and these are seldom indicated with active bleeding—accurately measured urine flow reflects renal perfusion. This in turn reflects perfusion of other vital organs.* The volume of urine output should be ≥30 mL/hr and preferably ≥50 mL/hr.

Another important factor to consider with management of hemorrhage is whether there are adequate procoagulants to achieve clot formation and stability. Many cases of severe obstetrical hemorrhage are further complicated by disseminated intravascular coagulation (DIC), in which blood has dysfunctional coagulation (p. 775).

MANAGEMENT OF HEMORRHAGE

Hypovolemic Shock

Shock from hemorrhage evolves through several stages (Cannon, 2018). Early, the mean arterial pressure, stroke volume, cardiac output, central venous pressure, and pulmonary capillary wedge pressure decline. Greater differences in arteriovenous oxygen content values reflect enhanced tissue oxygen extraction, although overall oxygen consumption falls.

Blood flow to capillary beds is controlled by arterioles, which are resistance vessels and partially controlled by the central nervous system (CNS). However, approximately 70 percent of total blood volume is contained in venules, which are passive resistance vessels controlled by humoral factors. Thus, the catecholamine release during hemorrhage prompts greater venular tone, and this provides an autotransfusion from this capacitance reservoir. This volume boost is accompanied by compensatory rises in heart rate, systemic and pulmonary vascular resistance, and myocardial contractility. At the same time, selective, CNS-mediated arteriolar constriction or relaxation, termed autoregulation, preferentially redistributes cardiac output and blood volume. Thus, more blood flow is diverted to the heart, brain, and adrenal glands, whereas perfusion to the kidneys, splanchnic beds, muscles, skin, and uterus is relatively diminished.

When the blood volume deficit exceeds approximately 25 percent, compensatory mechanisms usually are inadequate to maintain cardiac output and blood pressure. Importantly, additional small losses of blood will now cause rapid clinical

deterioration. Following an initial augmented total oxygen extraction by maternal tissue, maldistribution of blood flow results in local tissue hypoxia and metabolic acidosis. This creates a vicious cycle of vasoconstriction, organ ischemia, and cellular death.

Hemorrhage also activates lymphocytes and monocytes, which in turn prompts endothelial cell activation and platelet aggregation (Cannon, 2018). This endotheliopathy promotes release of vasoactive mediators that occlude small vessels and further impair microcirculatory perfusion. Comorbid preeclampsia or sepsis also leads to loss of capillary endothelial integrity, additional loss of intravascular volume into the extracellular space, and platelet aggregation. These then can incite DIC.

The pathophysiological events just described create important but often overlooked extracellular fluid and electrolyte shifts involved in both the genesis and successful treatment of hypovolemic shock. These include changes in the cellular transport of various ions such as sodium and water into skeletal muscle as well as potassium loss. Replacement of extracellular fluid and intravascular volume are both necessary. Patient survival rates are enhanced in acute hemorrhagic shock if blood plus crystalloid solution are given compared with blood transfusions alone.

Fluid Resuscitation

Whenever excessive blood loss is suspected, steps are simultaneously taken to identify the bleeding source and to begin resuscitation. Refer to the algorithm for hemorrhage management (Fig. 42-3, p. 735). If the woman is undelivered, restoration of blood volume benefits both mother and fetus. It also prepares for emergent delivery. If she is postpartum, immediately identifying uterine atony, retained placental fragments, or genital tract lacerations is essential. One or two large-bore intravenous infusion systems are ideally established promptly, crystalloid solutions are rapidly infused, and blood products are ordered. An operating room is readied, and a surgical and anesthesia team are quickly assembled. Specific management of hemorrhage is further dependent on its etiology. A neonatal resuscitation team is included if imminent delivery is planned.

Serious hemorrhage demands prompt and adequate refilling of the intravascular compartment with crystalloid solutions. These rapidly equilibrate into the extravascular space, and only 20 percent of crystalloid remains intravascular in critically ill patients after 1 hour (Zuckerbraun, 2010). *Because of this, initial fluid is infused in a volume two to three times the estimated blood loss.*

Crystalloid Versus Colloid Solutions

Resuscitation of hypovolemic shock with colloid versus crystalloid solutions has been debated. In a Cochrane review of resuscitation of nonpregnant critically ill patients, Lewis and coworkers (2018) found selection of colloids versus crystalloids probably makes little or no difference to mortality rates. Similar results were found in the Saline versus Albumin Fluid Evaluation (SAFE) randomized trial of almost 7000 nonpregnant patients (Finfer, 2004). At Parkland Hospital, acute volume resuscitation is preferably done with crystalloid solutions and blood.

Either a saline-based or a balanced crystalloid solution may be infused. The latter includes Ringer lactate and Plasma-Lyte solutions, which have electrolyte compositions similar to plasma. In some studies, but not in all, balanced crystalloid solutions were found to be superior to saline-based ones (Semler, 2018; Yule, 2020). Excessive saline-based crystalloid solution can theoretically lead to hyperchloremic acidosis. In comparisons, the difficulty lies in separating the effects of the underlying pathophysiology driving the acidosis.

Blood Replacement

Type and Screen Versus Crossmatch

A blood type and antibody screen should be performed for any woman at significant risk for hemorrhage. Because prediction of women at risk for postpartum hemorrhage is poor, we perform type and screen in all women upon admission to labor and delivery. Screening involves mixing maternal serum with standard reagent red cells that carry antigens to which most of the common clinically significant antibodies react. Instead, crossmatching involves the use of actual donor erythrocytes rather than the standardized red cells. This process is efficient, and only 0.03 to 0.07 percent of patients identified as having no antibodies are subsequently found to them (Boral, 1979). *Importantly, administration of screened blood rarely results in adverse clinical sequelae.*

Transfusion Thresholds

The hematocrit level or hemoglobin concentration threshold that mandates blood transfusion is controversial (Bienstock, 2021). Cardiac output does not substantively drop until the hemoglobin concentration falls to approximately 7 g/dL or when the hematocrit approximates 20 volume percent. Military combat trauma units have used a target hematocrit of 21 volume percent, and at this level, most experts recommend consideration of red cell transfusion (Carson, 2017; Kogutt, 2019). In general, with ongoing obstetrical hemorrhage, we recommend rapid blood infusion when the hematocrit is <25 volume percent. Other decision-modifying factors are whether the fetus is undelivered; surgery is imminent or ongoing operative blood loss is expected; or maternal hypoxia, vascular collapse, or other factors are present.

Limited data address these issues. In a study from the Canadian Critical Care Trials Group, nonpregnant patients were randomly assigned to restrictive red cell transfusions to maintain hemoglobin concentration >7 g/dL or to liberal transfusions to maintain the hemoglobin level at 10 to 12 g/dL. The 30-day mortality rate was similar—19 versus 23 percent—in the restrictive versus liberal groups, respectively (Hébert, 1999). Transfusion therapy in nonpregnant patients with septic shock had similar mortality rates when 7 g/dL was compared with 9 g/dL as targets for transfusions (Holst, 2014). *The number of units transfused in a given woman to reach a target hematocrit depends on her body mass and on the expectations of additional blood loss.*

Blood Component Products

The content and effects of transfusion of various blood components are shown in Table 44-1. Because whole blood is rarely available, most women with obstetrical hemorrhage and ongoing

TABLE 44-1. Blood Products Commonly Transfused in Obstetrical Hemorrhage

Product	Volume per Unit	Contents per Unit	Effect on Hemorrhage
Whole blood	About 50 mL: Hct ~40 percent	RBCs, plasma, 600–700 mg fibrinogen, no platelets	Restores blood volume and fibrinogen, increases Hct 3–4 volume percent per unit
Packed RBCs	250–300 mL: Hct ~55–80 percent	RBCs, minimal fibrinogen, no platelets	Increases Hct 3–4 volume percent per unit
FFP	About 250 mL; 30-minute thaw	Colloid, 600–700 mg fibrinogen, no platelets	Restores circulating volume and fibrinogen
Cryoprecipitate	About 15 mL, frozen	One unit has 200 mg fibrinogen, other clotting factors, no platelets	15–20 units or 3–4 g will increase baseline fibrinogen ~150 mg/dL
Platelets	About 50 mL, stored at room temperature	One unit raises platelet count ~5000/μL; single-donor apheresis bag preferable	6–10 units transfused; single-donor bag preferable to raise platelets ~50,000 μ/L

FFP = fresh-frozen plasma; Hct = hematocrit; RBCs = red blood cells.

massive blood loss are given packed red cells, crystalloid solutions, and blood components. As subsequently discussed, many institutions use *massive transfusion protocols (MTPs)* designed to anticipate all facets of massive obstetrical hemorrhage. These protocols commonly contain plasma, cryoprecipitate, and platelets in various ratios (Cunningham, 2015; Shields, 2011).

Several studies have assessed plasma:red cell ratios with MTPs used in civilian trauma units and military combat hospitals (Hardin, 2014; Rahouma, 2018). Patients receiving a massive transfusion—defined as 10 or more units of blood—had much higher survival rates as the ratio of plasma to red cell units neared 1:1.4, that is, one unit of plasma given for each 1.4 units of packed red cells. By way of contrast, the highest mortality group had a ratio of 1:8.

From the foregoing, when red cell replacement exceeds five units or so, evaluation of platelet count, clotting studies, and plasma fibrinogen concentration is reasonable (Bienstock, 2021; Pacheco, 2019). In the woman with obstetrical hemorrhage, the platelet count should be maintained >50,000/μL by the infusion of platelet concentrates. A fibrinogen level <150 mg/dL or a sufficiently prolonged PT or PTT in a woman with surgical bleeding is an indication for replacement. Fresh-frozen plasma is administered in doses of 10 to 15 mL/kg, or alternatively, cryoprecipitate is infused (see Table 44-1).

At Parkland Hospital, we use a standardized response to active hemorrhage. If whole blood is not available, the following escalation of blood products is applied: 2 units packed red blood cells, and if continued bleeding, 2 units packed red blood cells and 2 units fresh-frozen plasma are automatically ordered. Beyond this, MTP is initiated.

Whole Blood and Packed Red Blood Cells

Compatible whole blood is ideal for management of severe obstetrical hemorrhage. It has a shelf life of 40 days, and 70 percent of the transfused red cells function for at least 24 hours following transfusion. One unit raises the hematocrit by 3 to 4 volume percent. Important for obstetrical hemorrhage, whole blood replaces many coagulation factors needed in obstetrics—especially fibrinogen—and its plasma treats hypovolemia. A collateral derivative is that women with severe hemorrhage are resuscitated with fewer blood donor exposures than with packed red cells and components.

Experience at Parkland Hospital supports the preferable use of whole blood for massive hemorrhage (Alexander, 2009; Hernandez, 2012). Of more than 66,000 deliveries, women with obstetrical hemorrhage treated with whole blood had significantly lower incidences of severe maternal morbidity that included renal failure, acute respiratory distress syndrome, pulmonary edema, hypofibrinogenemia, intensive care unit admissions, or maternal death compared with those given packed red cells and component therapy. One unit of packed erythrocytes is derived from one unit of whole blood to have a hematocrit of 55 to 80 volume percent. One unit will increase the hematocrit by 3 to 4 volume percent depending on the size of the woman.

Dilutional Coagulopathy

A major drawback of massive hemorrhage treatment with crystalloid solutions and packed red blood cells is depletion of platelets and clotting factors. Discussed later, this can lead to a dilutional coagulopathy that is clinically indistinguishable from DIC (Cunningham, 2015; Hossain, 2013). Thrombocytopenia is the most frequent coagulation defect found with blood loss and multiple transfusions. In addition, packed red cells have only very small amounts of soluble clotting factors, and stored whole blood is deficient in platelets and in factors V, VIII, and XI. Thus, *hypofibrinogenemia* and prolongation of the prothrombin (PT) and partial thromboplastin times (PTT) are other sequelae. Because many causes of obstetrical hemorrhage also cause DIC, the distinction between dilutional and consumptive coagulopathy can be confusing. Fortunately, treatment for both is similar.

Platelets

Platelet transfusions are considered with ongoing obstetrical hemorrhage if the platelet count falls below 50,000/μL (Kenny,

2015). In the nonsurgical patient, bleeding is rarely encountered if the platelet count is 10,000/μL or higher (Murphy, 2010). The preferable source of platelets is one "bag" obtained by single-donor apheresis. This contains the equivalent of one unit each from six individual donors. Depending on maternal size, each single-donor-apheresis, six-unit bag raises the platelet count by approximately 20,000/μL. If these bags are not available, then individual-donor platelet units are used, and six to eight such units are generally transfused.

Importantly, the donor plasma in platelet units must be compatible with recipient erythrocytes. Further, because some red blood cells are invariably transfused along with the platelets, only units from D-negative donors should be given to D-negative recipients.

Fresh-frozen Plasma

This component is prepared by separating plasma from whole blood and then freezing it. Approximately 30 minutes are required for frozen plasma to thaw. It is a source of all stable and labile clotting factors, including fibrinogen. Thus, it is often used for treatment of women with consumptive or dilutional coagulopathy. *Plasma is not a suitable volume expander in the absence of specific clotting factor deficiencies.* It is considered in a bleeding woman with a fibrinogen level <150 mg/dL or with an abnormal PT or PTT.

An alternative to frozen plasma is *liquid plasma (LQP)*. This never-frozen plasma is stored at 1 to 6^0 C for up to 40 days, and its use compares favorably with fresh-frozen plasma (Backholder, 2017). Liquid plasma is not universally available in many centers.

Cryoprecipitate and Fibrinogen Concentrate

Each unit of cryoprecipitate is prepared from one unit of fresh-frozen plasma. Each 10- to 15-mL unit contains at least 200 mg of fibrinogen along with factor VIII:C, factor VIII:von Willebrand factor, factor XIII, and fibronectin (American Association of Blood Banks, 2017). It is usually given as a "pool" or "bag" using an aliquot of fibrinogen concentrate taken from 8 to 120 donors. Cryoprecipitate is an ideal source of fibrinogen when levels are dangerously low and surgical incisions show oozing. Because of transit time, the return of cryoprecipitate to transfusion services is often not feasible and is considered wastage if not deployed. Nearly 17 percent of ordered cryoprecipitate has been reported to be wasted in labor and delivery units, and this is the most commonly wasted product (Yee, 2019). Another alternative is virus-inactivated fibrinogen concentrate (Ng, 2020). These pooled fibrinogen products are marketed as *RiaSTAP* and *Fibryna*. Each gram of concentrate raises the plasma fibrinogen level approximately 40 mg/dL. These concentrates are used to treat congenital hypofibrinogenemia syndromes.

Recombinant Activated Factor VII

This synthetic vitamin K–dependent protein is available as *NovoSeven*. Recombinant activated factor VII (rFVIIa) binds to exposed tissue factor at the injury site to generate thrombin that activates platelets and the coagulation cascade. Since its introduction, rFVIIa has been used to help control hemorrhage from surgery, trauma, and obstetrical causes (Goodnough, 2016; Murakami, 2015). Many Level I trauma centers include it in MTPs. Importantly, rFVIIa will not be effective if the plasma fibrinogen level is <50 mg/dL or the platelet count is <30,000/μL.

One concern with rFVIIa is associated arterial—and to a lesser degree—venous thrombosis. In a review of 35 randomized trials, arterial thromboembolism developed in 55 percent (Levi, 2010). A second concern is that it has been found to have only marginal efficacy (Pacheco, 2019).

Tranexamic Acid

Normally, plasminogen binds with tissue plasminogen activator (tPA) to form plasmin. This binding degrades fibrin into fibrinogen–fibrin degradation products and leads to clot lysis. Instead, tranexamic acid (TXA) reversibly binds to plasminogen, and thereby blocks plasmin binding to fibrin. Fibrin strands are not broken, and a clot persists to slow down bleeding.

Ahmadzia and coworkers (2021) recently reported the pharmacodynamics of TXA at cesarean delivery using rotational thromboelastometry. TXA inhibited tPA-induced clot lysis in a dose-dependent manner. In the randomized WOMAN trial of gravidas with hemorrhage following vaginal birth or during cesarean delivery, mortality rates from obstetrical hemorrhage were 1.2 percent in those given a 1-g intravenous TXA dose plus traditional care for bleeding. This rate was statistically lower than the 1.7-percent death rate in women given traditional care alone (WOMAN Trial Collaborators, 2017). The trial was carried out in developing nations and because of the results, the drug is recommended by the World Health Organization (2017). In a large randomized trial of tranexamic acid given for *prophylaxis*, the drug did not decrease the rate of postpartum hemorrhage following vaginal delivery (Sentilhes, 2018). In the Tranexamic Acid for Preventing Postpartum Hemorrhage Following a Cesarean Delivery—TRAAP2 trial—women undergoing cesarean delivery who were given tranexamic acid prophylaxis had a lower incidence of red-cell transfusions (Sentilhes, 2021).

Gayet-Ageron and coworkers (2018) conducted a metaanalysis with more than 1000 patients with postpartum hemorrhage treated with TXA. They also analyzed data from two randomized trials that included more than 40,000 women treated with TXA. They concluded that treatment must be given soon after bleeding onset to reduce maternal mortality rates. Shakur and colleagues (2018) performed a Cochrane database review and also concluded that early TXA administration decreases maternal deaths.

Most of these studies were conducted in impoverished countries, and the American College of Obstetricians and Gynecologists (2019a) does not recommend TXA for either prophylaxis or first-line treatment of obstetrical hemorrhage. If used, administration within 3 hours of delivery is recommended.

Massive Transfusion Protocols

As noted, these protocols are initiated once four to five units of packed red cells have been given within 2 hours or so. These protocols speed blood product delivery to provide early resuscitation and help avoid dilutional coagulopathy. Once activated, packed red cells, plasma, platelets, and fibrinogen are given set ratios (Table 44-2). Some protocols include rFVIIa, TXA, or prothrombin complex concentrates (Jackson, 2018).

The data supporting the superiority of MTPs compared with traditional component replacement to improve survival

rates in obstetrical studies are limited. Most reports describe nonpregnant trauma victims, but some observational studies address obstetrical hemorrhage (Green, 2016; Pacheco, 2016).

Viscoelastic Assays

Thromboelastography (TEG) and *rotational thromboelastometry (ROTEM)* are point-of-care tests that assess coagulation in whole blood during massive transfusions. These tests work by analyzing both clot formation and breakdown in a whole blood sample from a given patient. Testing produces a profile of coagulation dynamics, and displayed values indicate the speed and quality of clot formation (Fig. 44-1). These assays provide information regarding time to clot formation, clot strength, and fibrinolysis (Arnolds, 2020). Currently, they guide blood product replacement in trauma, liver transplant, and cardiac surgery patients. Studies of TEG and ROTEM techniques in pregnant women have confirmed the hypercoagulable state of pregnancy and provide reference ranges for use in this population (Lee, 2021; McNamara, 2019; Pacheco, 2019).

Although promising, they also have several limitations. For example, they are less informative in a woman with torrential hemorrhage in whom clotting function would need to be measured minute-by-minute. They cannot be used to detect disorders of primary hemostasis (Solomon, 2012). A major drawback is the risk of misinterpretation when tests are used by inadequately trained personnel. Although use is gaining favor, we and others recommend further study before these tests are widely applied for obstetrical hemorrhage treatment (Amgalan, 2020). We have found this testing modality to be more applicable after initial management of hemorrhage and with intensive care recovery than during acute hemorrhage.

A15, A20: amplitude at 15 and 20 minutes. MCF: maximum clot firmness. LY30: amount of clot lysed at 30 minutes.

Cell Salvage and Autologous Transfusion

Preoperative patient phlebotomy and *autologous blood storage* for transfusion in obstetrics has been disappointing. Exceptions are women with a rare blood type or with unusual antibodies (Pacheco, 2013; Sullivan, 2019).

Intraoperative blood salvage with reinfusion is considered a safe intervention in obstetrical patients. This practice may aid women declining transfusion (Chap. 30, p. 549). Prior concern centered on amnionic fluid contamination and embolism (Dhariwal, 2014; Goucher, 2015). To evaluate benefits, one trial randomly assigned 3028 women at risk for hemorrhage and undergoing cesarean delivery either to routine care or to cell salvage. The rate of nonautologous donor blood transfusion was not significantly reduced in the cell salvage group—2.5 versus 3.5 percent (Khan, 2017). In another study, Sullivan and colleagues (2019) routinely set up most cesarean deliveries for autologous transfusions and reported a lower rate of nonautologous donor transfusion. Similar to prior reports, no cases of amnionic fluid embolism were reported in these two studies.

■ Transfusion Complications

Of serious known risks, *transfusion of an incompatible blood component* may result in acute hemolysis. If severe, this can cause DIC, acute kidney injury, and death. Preventable errors responsible for most of these reactions frequently include mislabeling of a specimen or incorrectly transfusing a patient not slated for those products.

The rate of such errors in the United States is estimated to be 1 case in 14,000 units, but these events are likely underreported (Lerner, 2010). A transfusion reaction is characterized by fever, hypotension, tachycardia, dyspnea, chest or back pain, flushing, severe anxiety, and hemoglobinuria. Immediate supportive measures include stopping the transfusion, treating hypotension and hyperkalemia, provoking diuresis, and alkalinizing the urine.

Transfusion-related acute lung injury (TRALI) and *transfusion-associated circulatory overload (TACO)* are the most common causes of transfusion-related mortality (Semple, 2019). Affected women characteristically have severe dyspnea, hypoxia, and pulmonary edema that develop within 6 hours of transfusion (Peters, 2015). Of the two, TACO is more common, and its incidence nears 1 percent. TRALI is estimated to complicate at least 1 in 12,000 transfusions (Carson, 2017). Although their pathogenesis is incompletely understood, injury to the pulmonary capillaries may arise from human leukocyte antigen (HLA) antibodies and human neutrophil antibodies (HNA) in donor plasma (McCullough, 2016). Management is supportive and may include mechanical ventilation (Chap. 50, p. 885).

Bacterial infection from transfusion of a contaminated blood component is unusual because organism growth is discouraged by refrigeration. The most often implicated contaminants of red cells include *Yersinia*, *Pseudomonas*, *Serratia*, *Acinetobacter*, and *Escherichia* species. The more important risk is from bacterial contamination of platelets, which are stored at room temperature. Current estimates are that 1 in 1000 to 2000 platelet units are contaminated. Death from transfusion-related sepsis is 1 case in 17,000 transfused single-donor platelets and 1 case in 61,000 transfused apheresis-donor packs (Lerner, 2010).

Viral infection risks from transfusion have been curtailed. The estimated risk of human immunodeficiency virus (HIV) or of hepatitis C virus infection in screened blood is 1 case in 1 to 2 million transfused units (Carson, 2017). The estimated hepatitis B transmission rate is <1 case in 100,000 transfused units (Jackson, 2003). Because of the high prevalence of the virus, cytomegalovirus-infected leukocytes are often transfused.

Risks for transmitting West Nile virus, parvovirus B19, human T-lymphotropic virus type 1, and toxoplasmosis are slight (American Association of Blood Banks, 2013; Foroutan-Rad, 2016). Although rare, Zika virus has emerged as another relevant transfusion-transmitted infection (Motta, 2016). Collection of all whole blood components now includes testing for Zika virus (Centers for Disease Control and Prevention, 2018). At this time, transmission of SARS-CoV-2 virus from a COVID-positive donor is hypothetical (Leblanc, 2020).

OBSTETRICAL COAGULOPATHIES

The terms *consumptive coagulopathy*, *defibrination syndrome*, and *disseminated intravascular coagulation (DIC)* are often used interchangeably, but distinctions are important. Actual consumption of procoagulants within the intravascular tree results in a consumptive coagulopathy. In contrast, massive loss of procoagulants from hemorrhage results in a dilutional coagulopathy. Semantics aside, consumptive coagulopathy culminates in a systemic intravascular activation that completely disrupts natural hemostasis. As a result, an ineffective balance of natural anticoagulant mechanisms leads to widespread fibrin deposition that can cause multiorgan failure (Levi, 2016).

Pregnancy-induced Coagulation Changes

During normal pregnancy, the balance between coagulation and fibrinolysis changes to create a procoagulant state. Changes that promote coagulation include appreciable elevation in the plasma concentrations of factors I (fibrinogen), VII, VII, IX, and X. A partial list of these normal values is found in the Appendix (p. 1228). Concurrently, levels of plasminogen, which lyses fibrin, rise considerably. However, plasminogen activator inhibitor 1 and 2 (PAI-1 and PAI-2) levels also increase. Thus, plasmin activity usually declines until after delivery (Hale, 2012; Hui, 2012). As shown in Figure 4-7, (p. 62), mean platelet count drops by 10 percent during pregnancy, and platelet activation is enhanced (Kenny, 2015; Reese, 2018).

The net results of these changes include greater levels of fibrinopeptide A, β-thromboglobulin, platelet factor 4, and fibrinogen–fibrin degradation products, which includes D-dimers. In addition to lower concentrations of the anticoagulant protein S, pregnancy-related hypercoagulability, and decreased fibrinolysis, there is augmented—yet compensated—intravascular coagulation that may function to maintain the uteroplacental interface.

Disseminated Intravascular Coagulation

Because of the many definitions and variable severity, the incidence of consumptive coagulopathy in gravidas varies and ranges from 0.03 to 0.35 percent (Erez, 2014; Rattray, 2012). For example, some degree of significant coagulopathy is found in virtually all cases of placental abruption and amnionic fluid embolism. Other instances in which frequently occurring but less recognized degrees of coagulation activation can be found include sepsis; thrombotic microangiopathies; acute kidney injury; acute fatty liver; severe preeclampsia; and hemolysis, elevated liver enzyme levels, low platelet count (HELLP) syndrome (Cunningham, 2015).

When consumptive coagulopathy is severe, the likelihood of maternal and perinatal morbidity and mortality rises. In one study of 49 cases, antecedent causes included those listed above, and 59 percent received blood transfusions, 18 percent underwent hysterectomy, 6 percent required renal dialysis, and three mothers died (Rattray, 2012). In this series, the perinatal mortality rate was 30 percent. From 2010 to 2011, DIC was the second most common severe maternal morbidity indicator (Creanga, 2014). DIC was associated with nearly a fourth of maternal deaths during this study period. Despite these statistics, consumptive coagulopathy as the sole cause of maternal death is uncommon and accounts for only 0.2 percent of pregnancy-related deaths in the United States (Creanga, 2015).

Activation of Normal Coagulation

Instead of the "waterfall" sequential activation of the clotting cascade, a current theory proposes that *tissue factor*—an integral membrane glycoprotein—serves as the principal initiator of coagulation (Levi, 2016). Coagulation then moves forward but incorporates a feedback loop. To begin, tissue factor forms complexes with factor VII/VIIa to activate factors IX and X. Tissue factor is found in highly vascularized organs such as the brain, lungs, and placenta; in amnionic fluid; and in certain other cells (Kuczyfiski, 2002; Østerud, 2006; Uszyfiski, 2001).

Tissue factor–factor VIIa complexes ultimately generate activated factor X (Xa) to initiate clotting. Subsequently, the previously labeled "intrinsic" pathway amplifies this process. Specifically, the initial thrombin produced directly activates factor XI by providing a feedback amplification loop (Fig. 44-2). The end result of this amplified coagulation process is fibrin formation. This is then counterbalanced by the fibrinolytic system, in which plasminogen is activated. Even this process is tied initially to tissue factor. The final product is fibrin degradation products, sometimes called fibrin split products, which include D-dimers.

Activation of Pathological Coagulation

With DIC, pathological entities prompt tissue factor release from subendothelial tissue and stimulated monocytes, which in

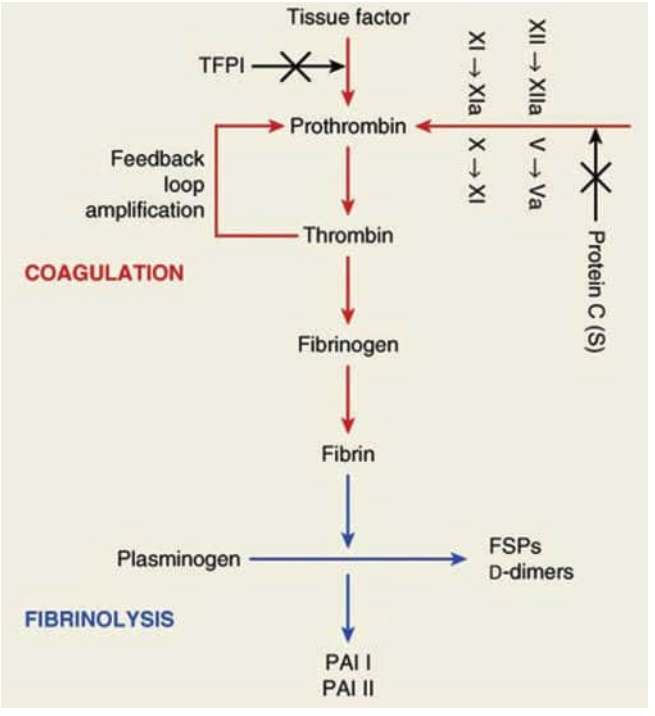

FIGURE 44-2 Coagulation pathway schematic. FSP = fibrin split products; PAI = plasminogen activator inhibitor; TFPI = tissue factor pathway inhibitor.

turn provoke cytokine release from the endothelium. With generalized endothelial activation, diffuse activation of coagulation follows. This pathological cycle of coagulation and fibrinolysis becomes clinically important when coagulation factors and platelets are sufficiently depleted to create consumptive coagulopathy.

Purpura fulminans is a severe—often lethal—form of consumptive coagulopathy. It is caused by microthrombi in small blood vessels leading to skin necrosis and sometimes vasculitis. Debridement of large areas of skin over the extremities and buttocks frequently requires treatment in a burn unit. Rarely, four-extremity amputation is required (Bhatti, 2019). Purpura fulminans usually complicates sepsis in women with heterozygous protein C deficiencies and low protein C serum levels (Bhatti, 2019; Levi, 2016). Importantly, homozygous protein C or S deficiency results in neonatal purpura fulminans, which is fatal (Chap. 55, p. 976).

Inciting Conditions

Several obstetrical syndromes can trigger consumptive coagulopathy. Of these, *placental abruption* is the most common cause of severe consumptive coagulopathy in obstetrics and is discussed more fully in Chapter 43 (p. 749). With *preeclampsia*, *eclampsia*, and *HELLP syndrome*, endothelial activation is a hallmark. Perhaps 10 percent of HELLP cases have some disseminated coagulation (Haram, 2017). In general, the clinical severity of preeclampsia is directly correlated with thrombocytopenia and fibrin degradation products (Gedik 2017; Kenny, 2015). That said, intravascular coagulation is seldom severe enough to be clinically worrisome (Pritchard, 1976). Acute fatty liver of pregnancy also causes intravascular coagulation in addition to decreased procoagulant synthesis (Chap. 58, p. 1034).

Amnionic fluid embolism is usually caused by intravenous embolization of meconium-laden amnionic fluid. It results in rapid cardiorespiratory collapse and profound consumptive coagulopathy. The Society for Maternal-Fetal Medicine (2021) has developed a checklist for the initial management of amnionic fluid embolism. It is discussed in Chapter 42 (p. 745).

Sepsis stemming from various infections can be accompanied by endo-or exotoxin release. Although a feature of sepsis syndrome includes activation of coagulation, seldom does sepsis alone cause massive procoagulant consumption. *Escherichia coli* bacteremia is frequently seen with antepartum pyelonephritis and puerperal infections, however, accompanying consumptive coagulopathy is usually not severe. Some notable exceptions are septicemia caused by exotoxins released from group A *Streptococcus pyogenes*, *Staphylococcus aureus*, or *Clostridium perfringens*, *C sordellii*, or *C novyi* (Herrera, 2016; Pritchard, 1971). Treatment of sepsis and septic shock is discussed in Chapter 50 (p. 889). *Septic abortion*—especially associated with these organisms—can incite coagulation and worsen hemorrhage.

Second-trimester induced abortions can stimulate intravascular coagulation even in the absence of sepsis. Ben-Ami and associates (2012) described a 1.6-percent incidence in 1249 late-second-trimester pregnancies terminated by dilation and evacuation. Two thirds were done for fetal demise, which may have contributed to coagulopathy (Kerns, 2019). Another source of intense coagulation is instillation of hypertonic solutions to effect midtrimester abortions. These are not commonly used currently for pregnancy terminations. The mechanism is thought to initiate coagulation by thromboplastin release into maternal circulation from the placenta, fetus, and decidua by the necrobiotic effect of hypertonic solutions.

Prolonged retention of a dead fetus is an unusual cause of consumptive coagulopathy today. Namely, fetal death can be easily confirmed, and highly effective methods for labor induction are available. Moreover, if the dead fetus is undelivered, most women enter spontaneous labor within 2 weeks and gross disruption of maternal coagulation rarely develops before 4 weeks (Pritchard, 1959, 1973). After 1 month, however, almost a fourth will develop consumptive coagulopathy.

Diagnosis

Bioassay is an excellent method to detect or suspect clinically significant coagulopathy. Excessive bleeding at sites of modest trauma characterizes defective hemostasis. Examples include persistent bleeding from venipuncture sites, nicks from preoperative shaving, trauma from bladder catheterization, and spontaneous bleeding from the gums, nose, or gastrointestinal tract. Purpura or petechiae at pressure sites such as sphygmomanometer cuffs or tourniquets suggest significant thrombocytopenia. Any surgical procedure provides the ultimate bioassay and elicits generalized oozing from abdominal wall layers, the retroperitoneal space, the episiotomy, or incisions and dissections for cesarean delivery or hysterectomy.

Of laboratory tests, fibrinogen and D-dimer levels can be informative. In late pregnancy, plasma fibrinogen levels typically have risen to 300 to 600 mg/dL. Thus, even with severe consumptive coagulopathy, levels may sometimes be

sufficiently high to protect against clinically harmful hypofibrinogenemia. For example, defibrination caused by a placental abruption might lower an initial fibrinogen level of 600 mg/dL to 250 mg/dL. Although this would indicate massive fibrinogen consumption, levels are still adequate to promote clinical coagulation. The clinically impactful threshold usually approximates 150 mg/dL. The effects of serious hypofibrinogenemia—less than 50 mg/dL—can be illustrated with clinical *thrombin clot test*. With low fibrinogen levels, the clot formed from whole blood in a glass phlebotomy tube will initially be soft and cannot retract in volume. Instead, during the next half hour, *platelet-induced* clot retraction ensues, and this causes a tighter clot to form.

As depicted in Figure 44-2, fibrinolysis cleaves fibrin into various fibrin degradation products, and one of the smaller ones is the D-dimer. Several sensitive assays contain monoclonal antibodies specific for D-dimers (Johnson, 2019). Assay values are almost always abnormally high with clinically significant consumptive coagulopathy. At least in obstetrical disorders, quantification does not correlate with outcomes. Examples of the magnitude of fibrin split product elevations in various obstetrical coagulopathies are shown in Figure 44-3.

Thrombocytopenia is likely if petechiae are abundant or if clotted blood fails to retract within an hour or so. Confirmation is provided by a low platelet count. If severe preeclampsia syndrome is comorbid, qualitative platelet dysfunction may coexist (Chap. 40, p. 696).

Prothrombin time (PT) and *partial thromboplastin time (PTT)* are standard coagulation tests. Prolongation may stem from very low fibrinogen concentrations, from appreciably reduced levels of the procoagulants needed to generate thrombin, or from large amounts of circulating fibrinogen–fibrin degradation products.

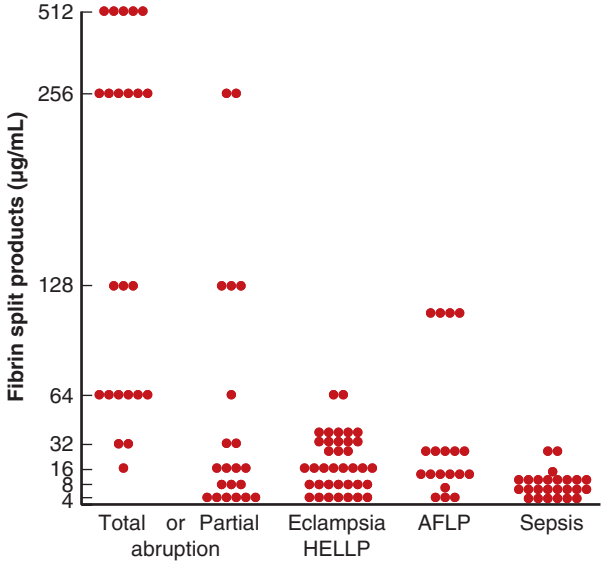

FIGURE 44-3 Quantification of fibrin split products in various obstetrical syndromes that cause disseminated intravascular coagulation. AFLP = acute fatty liver of pregnancy; HELLP = hemolysis, elevated liver enzyme levels, low platelet count. (Reproduced with permission from Cunningham FG, Nelson DB: Disseminated intravascular coagulation syndromes in obstetrics. Obstet Gynecol. 2015 Nov;126(5):999–1011)

Thromboelastometry and *thromboelastography* are point-of-care tests used as adjuncts to conventional laboratory studies (McNamara, 2019; Pacheco, 2019). Their current role may serve to guide blood product replacements as discussed earlier (p. 774). Using many of these tests, several organizations have attempted to establish a more uniform definition of DIC. One is the International Society on Thrombosis and Haemostasis (ISTH) scoring system. The score is used only after a condition known to cause intravascular coagulation is identified and is calculated using a combination of laboratory tests. Composite ISTH-DIC scores <5 suggest nonovert DIC, whereas scores ≥5 are compatible with overt DIC. A scoring system for nonovert DIC has been developed by Alhousseini and coworkers (2020). These scoring systems have not been applied widely in obstetrics (Hizkiyahu, 2019; Jonard, 2016; Nelson, 2014).

General Management

To halt ongoing defibrination, identifying and removing the inciting source is a priority. With incisions or extensive lacerations accompanied by severe hemorrhage, rapid replacement of procoagulants is usually indicated. Vigorous restoration and maintenance of the circulation to treat hypovolemia cannot be overemphasized. Adequate perfusion restores hepatic and endothelial synthesis of procoagulants and permits prompt removal of activated coagulation factors, fibrin, and fibrin degradation products by the reticuloendothelial system.

Aside from these fundamental steps, few other agents have proved soundly effective. Although its use is seemingly counterintuitive, unfractionated heparin has now been abandoned. Other agents not recommended for first-line use include tranexamic acid or epsilon-aminocaproic acid, both antifibrinolytic agents (American College of Obstetricians and Gynecologists, 2019a; Pacheco, 2017). This is because the fibrinolytic system is necessary for dissolution of widespread fibrin thromboses caused by generalized intravascular coagulation (Levi, 2016). Discussed earlier (p. 773), recombinant factor VIIa (rFVIIa) can be used to help control severe obstetrical hemorrhage from other causes. However, current clinical evidence is insufficient to make firm recommendations on its administration for obstetrical coagulopathies.

SURGICAL MANAGEMENT OF HEMORRHAGE

Several invasive procedures can help to arrest severe postpartum hemorrhage. A report from the Agency for Healthcare Research and Quality concluded that most studies addressing these methods are of poor quality (Likis, 2015). In one study of 6660 women with postpartum hemorrhage, 4 percent underwent an invasive procedure, and 1 percent had a hysterectomy (Kayem, 2016). The failure rate of conservative surgical and embolization procedures was 15 percent.

Of specific methods, use of uterine balloon tamponade for treatment of atony has doubled in the past decade (Merriam, 2020; Suarez, 2020). It is described in Chapter 42 (p. 737).

For low-pressure bleeding, topical hemostatic agents can be used to control persistent surgical oozing. These were

reviewed by Stachowicz and colleagues (2020). Other than for cesarean hysterectomy, these are seldom used in obstetrical hemorrhage.

Uterine Compression Sutures

This surgical technique uses a no. 2 chromic suture to compress the anterior and posterior uterine walls together (B-Lynch, 1997). Because they give the appearance of suspenders, they are also called braces (Fig. 44-4). Several modifications of the B-Lynch technique have been described (Gilmandyar, 2019; Matsubara, 2013; Nelson, 2007).

B-Lynch sutures are mainly used to treat atony. These may help diminish DIC-associated bleeding, while coagulation is corrected by transfusion. Success rates vary by indication. For example, B-Lynch (2005) cited 948 cases with only 7 failures. Conversely, in other series, overall failure rates were 20 to 25 percent (Kaya, 2016; Kayem, 2011).

Some unique complications can rarely follow compression sutures (Matsubara, 2013). Most involve variations of

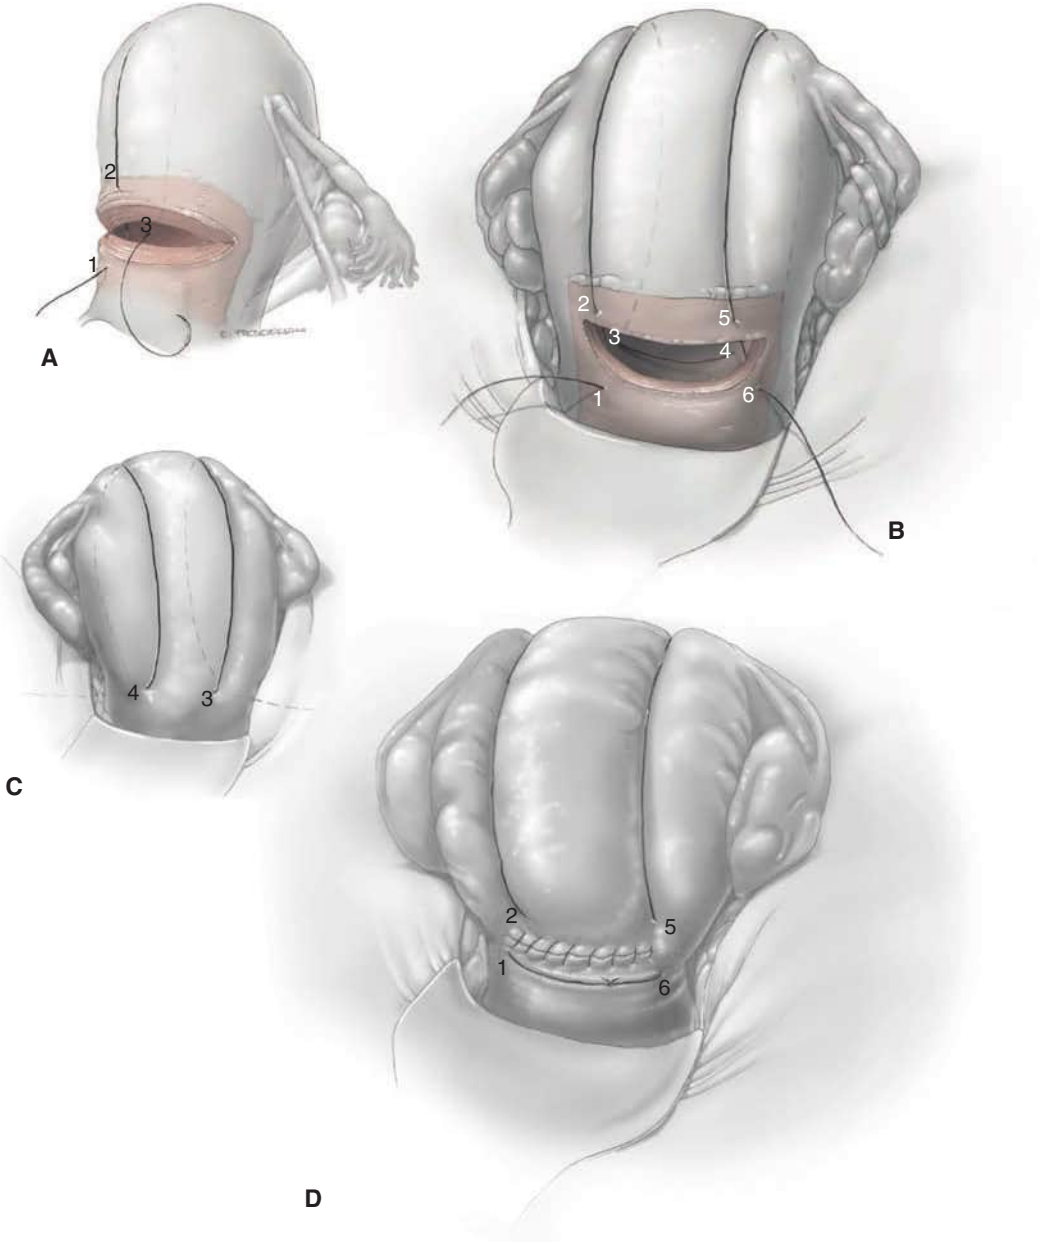

FIGURE 44-4 Uterine compression suture or "brace." The B-Lynch suture technique is illustrated from an anterior view of the uterus in Figures **A**, **B**, and **D** and a posterior view in Figure **C**. The numbers denote the sequential path of the suture and are shown in more than one figure. **Step 1.** Beginning below the incision, the needle pierces the lower uterine segment to enter the uterine cavity. **Step 2.** The needle exits the cavity above the incision. The suture then loops up and around the fundus to the posterior uterine surface. **Step 3.** The needle pierces the posterior uterine wall to reenter the uterine cavity. The suture then traverses to the opposite side within the cavity. **Step 4.** The needle exits the uterine cavity through the posterior uterine wall. From the back of the uterus, the suture loops up and around the fundus to the front of the uterus. **Step 5.** The needle pierces the myometrium above the incision to reenter the uterine cavity. **Step 6.** The needle exits below the incision, and the sutures at points 1 and 6 are tied below the incision. The hysterotomy incision is then closed in the usual fashion.

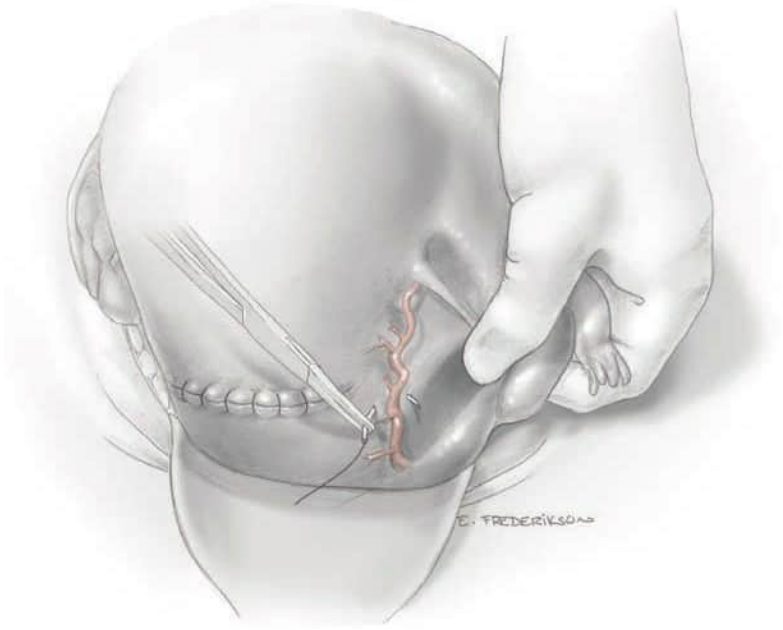

FIGURE 44-5 Uterine artery ligation. The suture goes through the lateral uterine wall anteriorly, curves posteriorly, and then re-enters anteriorly. When tied, it encompasses the uterine artery.

uterine ischemic necrosis with peritonitis (Gottlieb, 2008; Joshi, 2004; Treloar, 2006). In most cases, subsequent pregnancies are uneventful if compression sutures are used (An, 2013). A few women with B-Lynch sutures, however, developed uterine wall defects or uterine cavity synechiae (Akoury, 2008; Alouini, 2011; Ibrahim, 2013).

Artery Ligation

Ligation of arterial blood flow to the uterus can halt or diminish obstetrical hemorrhage. Common indications include uterine hysterotomy incision laceration, uterine atony, and abnormal placentation.

Uterine artery ligation may be unilateral or bilateral and is used mainly for lacerations at the lateral part of a hysterotomy incision (Fig. 44-5). In our experiences, this procedure is less helpful for other hemorrhage etiologies. In rare cases with torrential hemorrhage from placenta accreta syndrome, a tourniquet wrapped around the lower uterine segment may slow bleeding sufficiently while resuscitation ensues and dissection for hysterectomy is performed.

Internal iliac artery ligation may also be unilateral or bilateral. For years, ligation has been used to reduce pelvic hemorrhage. However, the procedure may be technically difficult and is successful in only half of cases (American College of Obstetricians and Gynecologists, 2019a; Bienstock, 2021). Wei and colleagues (2019) reported it to be successful for improved hemostasis with placenta previa. It is not particularly helpful for abating hemorrhage with postpartum atony (Clark, 1985).

For internal iliac ligation, adequate exposure is obtained by opening the peritoneum over the common iliac artery and dissecting down to the bifurcation of the external and internal iliac arteries (Fig. 44-6). Branches distal to the external iliac arteries are palpated to verify pulsations at or below the inguinal area. Ligation of the internal iliac artery at a point 5 cm distal to the common iliac bifurcation will usually avoid the internal iliac artery's posterior division branches (Bleich, 2007). The areolar sheath of the artery is incised longitudinally, and a right-angle clamp is carefully passed just beneath the artery from lateral to medial. Care must be taken not to perforate contiguous large veins, especially the internal iliac vein. Suture—usually nonabsorbable—is passed under the artery with a clamp, and the vessel is then securely ligated.

The most important mechanism of action with internal iliac artery ligation is an 85-percent reduction in pulse pressure in those arteries distal to the ligation (Burchell, 1968). This converts an arterial pressure system into one with pressures approaching those in the venous circulation. This creates vessels more amenable to hemostasis via pressure and clot formation.

Even bilateral internal iliac artery ligation does not appear to interfere with subsequent reproduction. Nizard and colleagues (2003) reported subsequent pregnancy in 17 such women. From a total of 21 pregnancies, 13 were normal, 3 ended with miscarriage, 3 were terminated, and 2 were ectopic.

Angiographic Embolization

This modality is now used for many causes of intractable hemorrhage when surgical access is difficult. Its use has increased remarkably in the past decade (Merriam, 2020). In more than

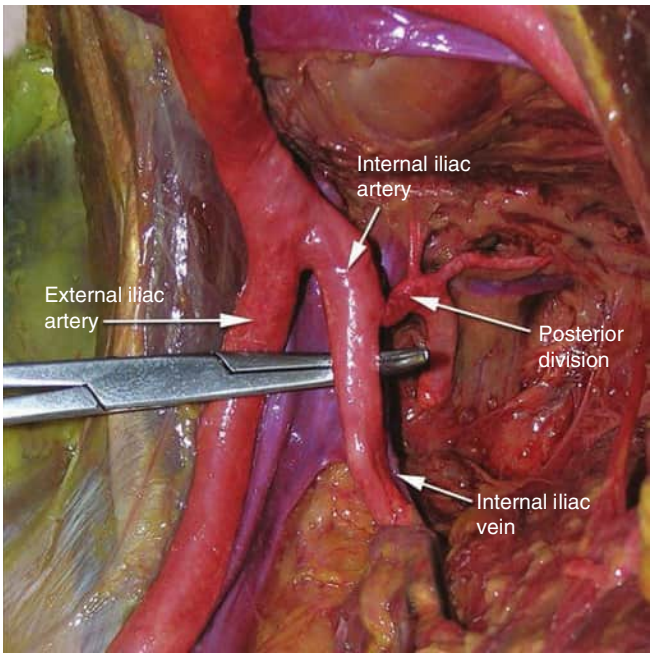

FIGURE 44-6 Ligation of the right internal iliac artery. Unembalmed cadaveric dissection shows the right-angle clamp passing underneath the anterior division of the internal iliac artery just distal to its posterior division. (Reproduced with permission from Dr. Marlene Corton.)

500 pregnancy-related cases, embolization was effective in 90 percent (Grönvall, 2014; Lee, 2012; Poujade, 2011; Zhang, 2015). After his review, Rouse (2013) concluded that embolization can be used to arrest refractory postpartum hemorrhage. Other reports have been less enthusiastic. Fertility is not impaired, and many subsequent successful pregnancies have been reported (Fiori, 2009; Kolomeyevskaya, 2009). *An important caveat for these procedures is that women with hemodynamic instability related to active bleeding should not be removed from the operating room*.

Complications are relatively uncommon but can be severe. Case reports detail instances of iatrogenic iliac artery rupture, uterine ischemic necrosis, and uterine infection (Grönvall, 2014; Katakam, 2009; Nakash, 2012). A rare case of massive buttock necrosis and paraplegia followed bilateral internal iliac artery embolization (Al-Thunyun, 2012). A myometrial defect in subsequent pregnancy also has been reported (Choo, 2019).

In a few instances, massive blood loss and difficult surgical dissection is anticipated. The use of balloon-tipped catheters preoperatively inserted into the iliac or uterine arteries is described in management of placenta accreta spectrum (Chap. 43, p. 759).

Aortic Compression

Prophylactic use of an aortic balloon occlusion device has been reported to reduce blood loss and the need for hysterectomy (Chen, 2019). Also known as *resuscitative endovascular balloon occlusion of the aorta* (*REBOA*), such occlusion lowers the perfusion pressure distally, increases cardiac afterload, and redistributes blood volume to the heart and brain (Cannon, 2018). Prolonged occlusion can result in lower limb ischemia requiring amputation. Whittington and colleagues (2020) described its successful prophylactic use in 11 women with placenta accreta spectrum disorders.

Instead, manual compression of the aorta above the sacral promontory can be used in cases in which pelvic hemorrhage is torrential. If the abdomen is closed, pressure placed above the umbilicus reduces blood pressure distally (Barbieri, 2018).

Pelvic Packing

If hysterectomy fails to curtail hemorrhage, then pelvic packing with gauze and termination of the operation may be considered (Pacheo, 2018; Touhami, 2018). Rolls of gauze are packed to provide constant local pressure. In some cases, this may serve as a temporizing step prior to interventional embolization. In other cases, packing alone may be left for 48 to 72 hours. If the patient is stable and bleeding appears to have stopped, packing is removed. In one review of 104 cases, the success rate was 79 percent. Packing failed in 24 patients, and 13 of these women died, yielding an overall mortality rate of 13 percent (Touhami, 2018).

The *umbrella* or *parachute pack* uses a similar concept (Logothetopulos, 1926). Although seldom used today, it can be lifesaving if all other measures have failed, especially in low-resource areas (Dildy, 2006; Touhami, 2018). The pack is constructed of a sturdy sterile plastic bag that is filled with gauze rolls that are unwound and knotted together. Sufficient rolls are used to provide adequate volume in the bag to fill the pelvis. The pack is introduced transabdominally with the stalk exiting the vagina. Mild traction is applied by tying the stalk to a 1-liter fluid bag, which is hung over the foot of the bed. The umbrella pack is removed vaginally after 24 hours.

CHAPTER 45

Preterm Birth

Preterm birth is a substantial global health issue with significant consequences to the newborn, family, and society. Preterm delivery affects nearly 15 million births worldwide, is the leading cause of death in children younger than 5 years, and remains a prominent issue in obstetrics (Chawanpaiboon, 2019). Although the burden of preterm birth is clear, defining the biology of human parturition and identifying strategies to reduce preterm birth rates remain elusive.

DEFINITION OF PRETERM BIRTH

Preterm birth is delivery before 37 completed weeks, that is, before $36^{6/7}$ weeks. Subdivisions vary among organizations. According to the American College of Obstetricians and Gynecologists (2021b), births occurring between 34 and 36 completed weeks are considered *late preterm*. The Centers for Disease Control and Prevention recognizes this late preterm definition but also labels births before $33^{6/7}$ weeks as *early preterm* (Martin, 2021). Instead, the World Health Organization (2018) defines births before 28 completed weeks as *extremely preterm*, those from 28 to 32 weeks as *very preterm*, and from 32 to 37 weeks as *moderate to late preterm*.

These definitions lack a functional basis and should be distinguished from the concept of *prematurity*, which represents incomplete development of various organ systems at birth. For example, the lungs are particularly affected and may be susceptible to the respiratory distress syndrome (Chap. 34, p. 615). Similarly, neonates born before term can be small or large for gestational age but are still preterm by definition. *Low birthweight* refers to neonates weighing 1500 to 2500 g; *very low birthweight* describes those between 1000 and 1500 g; and *extremely low birthweight* refers to those <1000 g (World Health Organization, 2019).

PRETERM BIRTH RATE TRENDS

In the United States, the preterm birth rate rose from 10.02 percent in 2018 to 10.23 percent for 2019. When interpreting these data, important factors and trends merit discussion. First, during the past two decades, the percentage of preterm neonates fell from 2007 to 2014 but has since risen (Martin, 2021). Some argue that the rate drop reflected changes in obstetrical dating criteria rather than true declines (Frey, 2016). Specifically, beginning in 2014, the National Center for Health Statistics transitioned to a new standard for estimating newborn gestational age for birth certificate completion (Martin, 2015). The new measure, which is the *obstetrical estimate* of gestational age at delivery, replaced calculations based on the date of the *last menstrual period*. These measures differ and do not provide equivalent absolute numerical comparisons of preterm

birth rates. *Thus, current national data are now not directly comparable to previously reported preterm birth rates.*

Although the percentage of neonates born early preterm rose slightly, the rise in the overall preterm rate from 2018 to 2019 was due primarily to the increase in late-preterm births. Rates of these preterm births have gradually risen since 2013 (Martin, 2021). Notably, national data do not separate spontaneous preterm births from those that may be prompted for medical indication.

One disturbing aspect of preterm birth rate trends in the United States is persistent disparities. Rates of preterm birth among black women are markedly elevated above those for white and Hispanic women (Martin, 2021). Some investigators attribute this to differing socioeconomical circumstances (Collins, 2007; Leveno, 2009). The rates of preterm birth in the United States are also higher compared with those in other industrialized countries (Ananth, 2009; Delnord, 2017). Internationally, preterm birth rates also are rising (Chawanpaiboon, 2019).

Last, births in singleton pregnancies should be analyzed separately from *all* births. Namely, multifetal gestations have a shorter average gestational length and raise preterm birth rates (Martin, 2021).

PRETERM NEWBORN MORBIDITY AND MORTALITY

In 2018 in the United States, 21,498 infants died in their first year of life, and 66 percent of infant deaths were among those born preterm. Gestational age at delivery and the risk of neonatal morbidity and mortality are inversely related. Namely, neonates born in the early-preterm period make up the smallest proportion of births, but these infants experience disproportionately higher rates of prematurity-related complications, including death (Table 45-1) (Ely, 2020). For context, the infant mortality rate in those born at less than 28 weeks' gestation was *186 times higher* than in those born at 37 to 41 weeks in the United States in 2018.

TABLE 45-1. Infant Mortality Rates in the United States in 2018

	Live Births	Infant Deaths
Total infants	3,791,712	21,498
Gestational age (weeks)		
<34	104,031	12,004
34–36	275,746	2263
<37	379,777	14,267
37–38	1,005,405	3135
39–41	2,292,705	3843
≥42	11,318	61

The joint effect of gestational age and infant condition at birth also has been examined. Data from the Swedish Medical Birth Register correlated Apgar scores at 5 and 10 minutes in preterm neonates across gestational ages. The relative risk of death consistently increased with decreased Apgar scores (Cnattingius, 2020). Low Apgar scores in preterm newborns may reflect biological immaturity rather than fetal depression. However, Apgar scores and changes in the score between 5 and 10 minutes were associated with neonatal mortality among preterm newborns.

Preterm neonates who survive are at risk for a range of short- and long-term morbidities, largely due to organ system immaturity (Table 45-2) (Eichenwald, 2008). That said, remarkable strides have been made in neonatal survival for those born preterm. In a study of more than 18,000 newborns weighing between 400 and 1500 g or aged between 22 and

TABLE 45-2. Major Short- and Long-Term Problems in Very-Low-Birthweight Infants

Organ or System	Short-Term Problems	Long-Term Problems
Pulmonary	Respiratory distress syndrome, air leak, bronchopulmonary dysplasia, apnea of prematurity	Bronchopulmonary dysplasia, reactive airway disease, asthma
Gastrointestinal or nutritional	Hyperbilirubinemia, feeding intolerance, necrotizing enterocolitis, growth failure	Failure to thrive, short-bowel syndrome, cholestasis
Immunological	Hospital-acquired infection, immune deficiency, perinatal infection	Respiratory syncytial virus infection, bronchiolitis
Central nervous system	Intraventricular hemorrhage, periventricular leukomalacia, hydrocephalus	Cerebral palsy, hydrocephalus, cerebral atrophy, neurodevelopmental delay, hearing loss
Ophthalmological	Retinopathy of prematurity	Blindness, retinal detachment, myopia, strabismus
Cardiovascular	Hypotension, patent ductus arteriosus, pulmonary hypertension	Pulmonary hypertension, systemic hypertension, hypertension in adulthood
Renal	Water and electrolyte imbalance, acid-base disturbances	Hypertension in adulthood
Hematological	Iatrogenic anemia, need for frequent transfusions, anemia of prematurity	
Endocrinological	Hypoglycemia, transiently low thyroxine levels, cortisol deficiency	Impaired glucose regulation, increased insulin resistance

32 weeks' gestation, survival rates were analyzed as a function of both birthweight *and* gestational age (Fanaroff, 2007). After achieving a birthweight ≥1000 g, a gestational age ≥28 weeks for females, or age ≥30 weeks for males, survival rates reach 95 percent.

Threshold of Viability

Births once considered to be "abortuses" because the fetus weighed <500 g are now classified as live births. In the United States in 2019, 5189 live births weighed <500 g (Martin, 2021). Fortunately, perinatal and neonatal care has advanced tremendously for these births. As a result, the *threshold of viability,* which is the lower limit of fetal maturation compatible with extrauterine survival, has been reassessed. Currently, the threshold of viability lies between $20^{0/7}$ and $25^{6/7}$ weeks' gestation. Neonates born in this *periviable period* are vulnerable because of their immature organ systems. Complications include brain injury and sepsis, both described in Chapter 34, (p. 618). To guide obstetrical decision-making and care of these fetuses, a national perinatal workshop convened in 2013 (Raju, 2014). The executive summary statement from this meeting served as the foundation for an Obstetric Care Consensus document (American College of Obstetricians and Gynecologists, 2019d).

Periviable Neonatal Survival

Delivery before 23 weeks' gestation often results in death, and survival rates approximate 5 to 10 percent (Fig. 45-1). Among survivors, morbidity is significant. Practices regarding active resuscitation vary between institutions and may explain the differing perinatal outcomes among these. Neonatal survival rates also vary among international comparisons, and rates at 24 weeks' gestation range from 35 to 84 percent (Helenius, 2017).

A retrospective analysis of infants born at the University of Iowa from 2006 to 2015 at 22 to 25 weeks' gestation underscores this issue (Watkins, 2020). After excluding anomalous fetuses, death in the delivery room, and parental request for palliation, the neurodevelopmental outcomes were analyzed for 169 of 214 survivors at 18 to 22 months. Active management was defined as antenatal corticosteroids and resuscitation when desired by the parents. The survival rate was lower in neonates born at 22 to 23 weeks' than at 24 to 25 weeks' gestation. However, mild or no neurodevelopmental impairment was reported in 64 percent of the surviving 22- to 23-week infants.

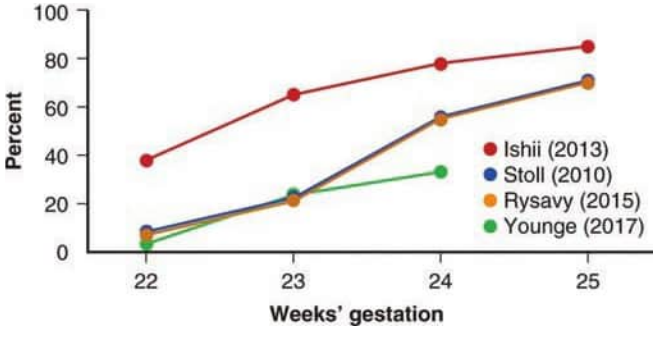

FIGURE 45-1 Neonatal survival rates according to condition at birth and gestational age. Ishii (2013) data curve reflects liveborn survival rates; Stoll (2010) curve reflects liveborn survival rates; Rysavy (2015) curve reflects overall survival rates; Younge (2017) curve reflects survival and neurodevelopmental outcomes.

An important caveat when examining perinatal outcomes, however, is ascertainment bias. For example, the mean survival rate is 45 percent if the denominator is all live births compared with 72 percent if the denominator is only newborns admitted to neonatal intensive care (Guillen, 2011). Another source of bias is use of multicenter datasets with considerable differences in obstetrical and early neonatal interventions (Stoll, 2010).

To evaluate contemporaneous outcomes of neonates born at 22 to 24 weeks, the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network reported both survival and neurodevelopmental outcomes across consecutive birth-year epochs of 2000 to 2003, 2004 to 2007, and 2008 to 2011 in infants aged 18 to 22 months (Younge, 2017). The percentage of infants who survived rose significantly from 30 percent in 2000 to 2003 to 36 percent in 2008 to 2011. The percentage of infants who survived without neurodevelopmental impairment also significantly grew from 16 percent to 20 percent during the same time period. Although rates of survival without neurodevelopmental impairment increased over time for those born at 23 and 24 weeks, only 1 percent of infants born at 22 weeks survived without neurodevelopmental impairment (Younge, 2017).

Somewhat similar results were published from Sweden. This report details a national population-based study of all neonates born at 22 to 26 weeks. Rates of survival to 1 year from 2004 to 2007 were compared with rates from 2014 to 2016. Survival rates at 1 year among live-born neonates at 22 to 26 weeks' gestation significantly improved during the later period (Table 45-3) (Norman, 2019).

Clinical Management

The Periviable Birth Obstetric Care Consensus document also addresses management options based on the clinical characteristics of a given pregnancy. Nonmodifiable factors are fetal gender, weight, and plurality. Potentially modifiable antepartum and intrapartum factors include the location of delivery, intent to intervene by cesarean delivery, and administration of antenatal corticosteroids (Table 45-4). Postnatal management addresses the initiation or withdrawal of intensive care after birth.

Cesarean delivery at the threshold of viability is controversial. If the fetus-neonate is perceived to be too immature for aggressive support, cesarean delivery for common indications such as breech presentation or nonreassuring fetal heart rate patterns might be preempted. Moreover, observational studies have been inconsistent in demonstrating a benefit of cesarean delivery for the sole indication of periviability. Moreover, cesarean delivery may predispose the gravida to adverse intraoperative events and morbidity (Bertholdt, 2018; Blanc, 2019).

In a study of 2906 singletons between $24^{0/7}$ and $31^{6/7}$ weeks eligible for attempted vaginal birth, 84 percent of cephalic presenting fetuses were delivered vaginally (Reddy, 2012). Neonatal mortality rates did not differ compared with those associated with planned cesarean delivery. For *breech*

CD for fetal indication	Not recommended	Not recommended	Consider	Consider[a]/recommended

[a]CD is considered for fetuses $24^{0/7}$– $24^{6/7}$ but recommend for those $25^{0/7}$ weeks and older.
CD = cesarean delivery; CS = corticosteroid; GBS = Group B streptococcus; MS = magnesium sulfate; PPROM = preterm prelabor rupture of membranes.

presentations, however, relative risk for mortality was threefold higher with attempted vaginal delivery. In another study, Werner and colleagues (2013) analyzed 20,231 newborns delivered at 24 to 34 weeks. Cesarean delivery did not protect against poor outcomes such as neonatal death, intraventricular hemorrhage, seizures, respiratory distress, and subdural hemorrhage.

From these findings, the Obstetric Care Consensus proposes that cesarean delivery be *considered* for fetal indications at $23^{0/7}$ to $24^{6/7}$ weeks. However, before 22 weeks, this route is reserved only for maternal indications. As emphasized by the authors of the Iowa report cited earlier, providing active management—such as antenatal corticosteroids—can be uncoupled from the decision of cesarean in the periviable period (Watkins, 2020). That said, the frequency of cesarean in the 23rd week has increased in the United States following publication of the perinatal workshop executive summary in 2014 (Rossi, 2019).

It is difficult to summarize the current practices of obstetrical care in the management of the periviable pregnancy given its continued rapid evolution. Moreover, it appears that maternal and neonatal interventions are shifting during the 22- to 23-week gestational age period. Data from the National Center for Health Statistics show that rates of at least one maternal or neonatal intervention were 38.9 percent and 78.3 percent for 22 and 23 weeks' gestation, respectively (Hajdu, 2020).

In this uncertain environment, individualized, patient-centered care with a multidisciplinary team remains essential. This is particularly relevant given that nearly 20 percent of women may have serious morbidity with delivery during the periviable period (Rossi, 2018).

For cases with threatened periviable delivery, neonatal and perinatal consultation aids informed decision-making and helps form expectations for the family. For fetuses with a life-limiting condition, such as extreme prematurity, *perinatal palliative care* is a strategy that emphasizes comfort (American College of Obstetricians and Gynecologists, 2019c). Care team members can include obstetric and neonatal professionals, chaplaincy, and mental health specialists.

Late-preterm Birth

As discussed, neonates born between 34 and 36 weeks' gestation account for more than 70 percent of all preterm births (Fig. 45-2) (Martin, 2021). Most of the increase in the total preterm birth rate for the United States 2018 to 2019 was among neonates born at 34 to 36 weeks. To estimate the risks associated with late-preterm births, investigators analyzed neonatal mortality and morbidity rates at 34, 35, and 36 weeks compared with those of births at term at Parkland Hospital (McIntire, 2008). Approximately 3 percent of all births during the study period were between 24 and 32 weeks, and 9 percent were during the late-preterm period. Thus, and similar to the national rates, late-preterm births accounted for three fourths of all preterm births. Approximately 80 percent of these resulted from idiopathic spontaneous preterm labor or prematurely ruptured membranes (Fig. 45-3). Other obstetrical complications were implicated in the remaining 20 percent of cases. Rates of morbidity and mortality were greater in these late-preterm newborns compared with rates in term ones (Table 45-5) (McIntire, 2008). Similarly, Tomashek (2007) reported higher neonatal mortality rates for late-preterm newborns. Rates of adverse neurodevelopment outcomes also are increased in these late-preterm infants (Petrini, 2009). Taken together, these findings suggest that a health-care focus on prematurity should include these late-preterm births.

CAUSES OF PRETERM BIRTH

Four direct causes for preterm births in the United States include (1) spontaneous unexplained preterm labor with intact membranes, (2) idiopathic preterm prelabor rupture of membranes, (3) delivery for maternal or fetal indications, and (4) twins and higher-order multifetal births. Of all preterm births, 30 to 35 percent are indicated, 40 to 45 percent are due to spontaneous preterm labor, and 30 to 35 percent follow preterm membrane rupture (Goldenberg, 2008). More than

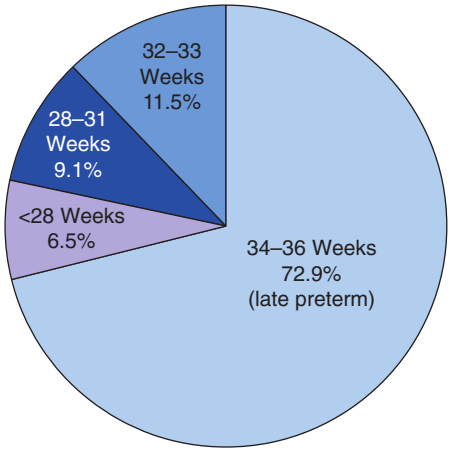

FIGURE 45-2 Distribution of preterm births by gestational age in the United States in 2019.

98 percent of triplets and 60 percent of twins are born preterm (Martin, 2021).

At term, a common parturition pathway is activated physiologically and leads to labor. For preterm labor, several disease processes are thought to activate one or more of the components of this common pathway (Romero, 2014). Put another way, preterm labor is not simply labor that starts too soon. This paradigm is supported by the rationale that causes of preterm birth have multiple, often interacting, antecedents and contributing factors that lead to a heterogenous syndrome (Deindl, 2020; Esplin, 2016). Analogous to other complex disease processes, multiple coexistent genetic alterations, bacterial and viral colonization, and diverse environmental factors may lead to preterm birth (Bayar, 2020; Mekonnen, 2021; Volozonoka, 2020). These multiple factors continue to pose challenges in identifying predictive biomarkers in blood, urine, or cervicovaginal fluid, despite significant technical advances in multiomic approaches (Ghaemi, 2021; Jehan, 2020; Peterson, 2020; Parry, 2020).

■ Spontaneous Preterm Labor

Pregnancies with spontaneous preterm labor yet intact fetal membranes must be distinguished from those complicated by ruptured membranes. Even so, spontaneous preterm labor does not constitute a homogeneous group. Evidence suggests it is a syndrome attributable to multiple pathological processes (Romero, 2014). Among the more common associated findings

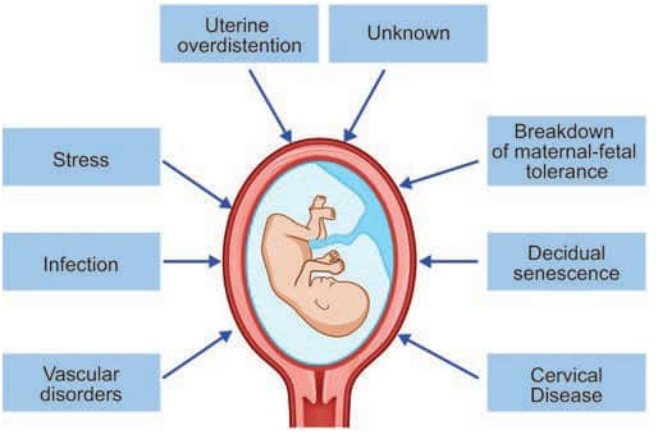

FIGURE 45-4 Proposed mechanisms of disease implicated in spontaneous preterm labor. Genetic and environmental factors are likely contributors to each mechanism.

are multifetal pregnancy, intrauterine infection, bleeding, placental infarction, premature cervical dilation, cervical insufficiency, hydramnios, uterine fundal abnormalities, and fetal anomalies. Severe maternal illness from infections, autoimmune diseases, and gestational hypertension also elevate preterm labor risks.

These processes culminate in a common end point of premature cervical dilation, effacement, and activation of uterine contractions. Importantly, the actual process of preterm labor should be considered a final step stemming from progressive or acute changes that could be initiated days or even weeks before labor onset. Diverse pathways to instigate parturition exist and are dependent on the etiology of preterm birth (Fig. 45-4) (Romero, 2014). Major causes include uterine overdistention, premature cervical changes, infection, and maternal–fetal stress. Genetic and environmental factors likely contribute to each mechanism.

Uterine Overdistention

Multifetal pregnancy and hydramnios are well-recognized risks for preterm birth. With these, *uterine overdistention* imparts greater stress on the myometrium. In nonhuman primates, inflation of intraamnionic balloons can stimulate uterine contractility, preterm labor, and an "inflammatory pulse." Similar inflammatory responses have been observed in the amnion of women with polyhydramnios and twins (Adams Waldorf, 2015).

Early uterine overdistention likely acts to initiate expression of contraction-associated proteins in the myometrium. These genes include those coding for gap-junction proteins, oxytocin receptors, and prostaglandin synthase (Korita, 2002; Lyall, 2002; Sooranna, 2004). Excessive uterine distention also leads to early activation of the placental–fetal endocrine cascade (Chap. 21, p. 407). Taken together, mechanical stress-induced distension and activation of endocrine cascades both lead to premature activation of inflammatory responses that result in uterine contractile activation (Gomez-Lopez, 2014; Stephen, 2015). A possible compensatory response to uterine distention is tissue remodeling and muscle growth (Adams Waldorf, 2015).

Cervical Dysfunction

In most cases, premature cervical remodeling precedes labor onset. In some instances, cervical dysfunction of the epithelia or its stromal extracellular matrix is the underlying cause (Nallasamy, 2017). Importantly, an intact cervical epithelial barrier is critical to prevent ascending infection. For example, loss of hyaluronan in cervical epithelia or colonization of group B streptococcus (GBS) enhances risk of preterm birth (Akgul, 2014; Coleman, 2021). GBS has the unique ability to synthesize the hyaluronan-degrading enzyme hyaluronidase to aid bacterial ascension (Vornhagen, 2017). Second, the mechanical competence of the cervix can be reduced. Genetic mutations in components of collagen and elastic fibers or proteins required for their assembly can be risk factors for cervical insufficiency and preterm birth (Nallasamy, 2017; Volozonoka, 2020).

Infection

Of all the mechanisms listed in Figure 45-4, only intraamnionic infection has been causally linked to spontaneous preterm delivery (Romero, 2014). Bacteria can gain access to intrauterine tissues through (1) transplacental transfer of maternal systemic infection, (2) flow of infection via the fallopian tubes, or (3) ascending infection with bacteria from the vagina and cervix. Because the lower pole of the fetal membrane–decidual junction is contiguous with the cervical canal orifice, this anatomical arrangement provides a passageway for microorganisms. Ascending infection is considered to be the most common entry route where microorganisms colonize the cervix, decidua, and possibly the membranes, and then may enter the amnionic sac.

Colonization with an infectious agent has been detected in 25 to 40 percent of all preterm deliveries (Goldenberg, 2008). In some instances, histological evidence of microbial inflammation is found in the fetal membranes, decidua, or umbilical cord. Other cases are deemed sterile intraamnionic inflammation. Despite the substantial association of infection with preterm birth, the cellular and molecular mechanisms underlying inflammation-driven preterm birth remain undefined (Cappelletti, 2020; Purisch, 2017).

Current data suggest that microbial invasion of the reproductive tract is sufficient to induce infection-mediated preterm birth. The level and kinetics of inflammation can vary between a polymicrobial or single-microbe exposure (Tong, 2021). Affected women are more likely to develop clinical chorioamnionitis and rupture of membranes compared with women whose cultures are sterile. Moreover, their neonates are also more likely to have perinatal complications such as neonatal sepsis (Villamor-Martinez, 2020). Although the clinical course is more severe when intraamnionic infection is obvious, inflammation in the absence of detectable intraamnionic microorganisms—termed *sterile intraamnionic inflammation*—is also a risk factor for an inflammatory response (Motomura, 2021). In sum, the earlier the onset of preterm labor, the greater the likelihood of underlying infection (Goldenberg, 2000; Goncalves, 2002).

Paradoxically, the incidence of culture-positive amnionic fluid collected by amniocentesis during spontaneous labor at term is similar to that with preterm labor (Gomez, 1994; Romero, 1993). It has been suggested that at term, amnionic fluid is infiltrated by bacteria as a consequence of labor, whereas in preterm pregnancies, bacteria represent an inciting cause. Thus, fetal infection, as defined by bacteria detected within amnionic fluid, has differing etiologies and consequences.

With chorioamnionitis, microbes may invade only maternal tissue and not amnionic fluid. Despite this, endotoxins can stimulate amnionic cells to secrete cytokines that enter amnionic fluid. This scenario may serve to explain the apparently contradictory observations concerning an association between amnionic fluid cytokines and preterm labor in cases in which microbes are not detected in the amnionic fluid.

Inflammatory Responses. These responses drive the pathogenesis of infection-induced preterm labor. Lipopolysaccharide (LPS) or other toxins elaborated by bacteria are recognized by receptors such as *toll-like receptors (TLRs)* (Janssens, 2003). These receptors are present on mononuclear phagocytes, decidual cells, cervical epithelia, and trophoblasts (Gonzalez, 2007; Holmlund, 2002). The expression of TLRs on maternal immune cells is necessary to recognize inflammatory stimuli in inflammation-mediated preterm birth (Cappelletti, 2020). Activation of TLRs induces a signaling cascade that activates production of chemokines such as interleukin 8 (IL-8) and cytokines such as IL-1β. Activation also recruits immune cells into the reproductive tract. Cytokines are produced by immune cells and by cells within the cervix, decidua, membranes, or fetus itself.

LPS-induced production of IL-1β in turn promotes a series of responses that include (1) increased synthesis of others, that is, IL-6, IL-8, and tumor necrosis factor alpha (TNF-α); (2) proliferation, activation, and migration of leukocytes; (3) modifications in extracellular matrix proteins; and (4) mitogenic and cytotoxic effects such as fever and acute-phase response (El-Bastawissi, 2000). In many tissues, including myometrium, decidua, and amnion, IL-1β also promotes prostaglandin formation that induces cervical ripening and loss of myometrial quiescence (Challis, 2002; Keelan, 2003). The importance of prostaglandins to infection-mediated preterm birth is supported by the observation that prostaglandin inhibitors can reduce the rate of LPS-induced preterm birth in both the mouse and nonhuman primate (Gravett, 2007; Timmons, 2014). Inhibition of cyclooxygenase 2 prevents inflammation-mediated preterm labor in the mouse. For these reasons, clinical approaches described on page 806 are being explored.

Proteases such as matrix metalloproteinases (MMPs) also are induced by inflammatory cytokines and function to break down extracellular matrix components such as collagen or elastic fibers. This disrupts the structural integrity of fetal membranes or the cervix. Current evidence from animal and human studies suggests that many aspects of infection-mediated preterm birth differ from pathways that regulate term parturition (Hamilton, 2012; Shynlova, 2013a,b; Willcockson, 2018).

Origin of Cytokines. Secretion of uterine cytokines is likely important for preterm labor. Cytokines produced in maternal decidua and myometrium have effects confined to that side, whereas cytokines produced in the membranes or in cells within the amnionic fluid will not be transferred to maternal tissues.

In general, resident and invading leukocytes produce the bulk of cytokines in cases of inflammation resulting from infection.

The presence of cytokines in amnionic fluid and their association with preterm labor is well documented. But, their exact cellular origin—with or without recoverable microorganisms—is not well defined. Amnionic fluid cytokines are most likely secreted by mononuclear phagocytes or neutrophils activated and recruited into the amnionic fluid (Tong, 2020). Thus, the amount of amnionic fluid IL-1β would be determined by the number of leukocytes recruited, their activational status, or the effect of amnionic fluid constituents on their IL-1β secretion rate.

Microbiota. Mucosal immunity and barrier function of the cervicovaginal epithelia, the vaginal microbiota composition, and their interplay among differing populations are major research topics (Elovitz, 2019; Fettweis, 2019; Serrano, 2019). To explore these, advanced genomic analysis techniques are used and show that the nonpregnant vagina hosts a complex microbial community (Gajer, 2012; White, 2011). And, the vaginal microbiome changes during normal pregnancy (Stout, 2017). Specifically, the diversity of microbe populations are reduced during pregnancy and become more stable.

Some but not all studies report an increased population of certain microbes—for example, *Gardnerella vaginalis* and *Ureaplasma urealyticum*—in women with preterm birth (Donders, 2009; Nelson, 2014). In contrast, Schuster and coworkers (2020) reported that asymptomatic vaginal *Candida* colonization was not associated with preterm birth. Differences in populations studied, preterm birth definitions, and data analysis complicate interpretation of these data. Currently, the strongest evidence for the role of the microbiome in preterm birth relates to the vaginal microbiota. The most consistent finding across almost all studies is the benefit of a vaginal microbiota characterized by *Lactobacillus crispatus* (Bayar, 2020).

Aagaard and colleagues (2014) suggested that the placenta contains a microbiome akin to the oral microbiome. Subsequent studies, however, have failed to confirm this (Lauder, 2016; Theis, 2019). Recently, de Goffau and associates (2019) found no evidence of bacteria in most of 537 placental samples from both complicated and uncomplicated pregnancies. Almost all samples pointed to acquisition of bacteria during labor and delivery or to contamination of laboratory reagents with the exception of *Streptococcus agalactiae*. *Thus, the human placenta does not appear to have a relevant microbiome* (Bayar, 2020).

■ Preterm Prelabor Rupture of Membranes

Previously referred to as preterm *premature* rupture of membranes, preterm *prelabor* rupture of membranes (PPROM) defines spontaneous membrane rupture before 37 completed weeks and before labor onset (American College of Obstetricians and Gynecologists, 2020g). Such rupture likely has various causes, but intrauterine infection, oxidative stress–induced DNA damage, and premature cellular senescence are major predisposing events (Dutta, 2016; Mercer, 2003). Associated risk factors are similar to those at term and include lower socioeconomical status, low body mass index, nutritional deficiencies, and cigarette smoking. Women with PPROM carry an enhanced risk for recurrence during a subsequent pregnancy (Bloom, 2001). Despite these known risk factors, none are identified in many cases.

Bacterial cultures of amnionic fluid support a role for infection in PPROM. One review of 18 studies and almost 1500 women with PPROM found that bacteria were isolated from amnionic fluid in a third of cases (Goncalves, 2002). Microbiome-mediated preterm birth and PPROM are current research areas (Bayar, 2020). One goal is to identify early risk markers for PPROM.

Molecular Changes

In pregnancies with PPROM, the amnion exhibits a higher degree of cell death and more apoptosis markers than in term amnion (Arechavaleta-Velasco, 2002; Fortunato, 2003). In vitro studies indicate that apoptosis is likely regulated by bacterial endotoxin, IL-1β, and TNF-α. In addition, oxidative stress initiated by events other than infection can induce DNA damage, premature senescence, and subsequent inflammation and proteolysis that leads to PPROM (Menon, 2020).

With membrane rupture, thrombin activity rises, which activates MMPs and prostaglandin synthesis. Studies by Mogami (2013) provide a mechanism by which bacterial endotoxin or TNF-α elicits release of fetal fibronectin (fFN) by amnion epithelial cells. The fFN then binds toll-like receptor 4 in the amnion mesenchymal cells to activate signaling cascades. These result in augmented prostaglandin E (PGE_2) synthesis and elevated activity of MMPs. Increasing prostaglandin levels promote cervical ripening and uterine contractions. Greater MMP concentrations allow collagen breakdown in the fetal membranes, resulting in premature rupture. Last, proteins involved in collagen synthesis or promoting its tensile strength are altered in membranes with premature rupture (Wang, 2006). Recently, Blois and associates (2020) introduced the concept of *galectins*, a family of glycan-binding proteins. They may serve as a mediator in fetal-maternal immune tolerance and work to prevent microbial infections that lead to preterm birth.

Both preterm labor and PPROM arise from distinct pathophysiological pathways but share inflammation as a common underlying mechanism. Excellent reviews are presented by Menon (2020) and Diemert (2020) and their coworkers.

■ Maternal-Fetal Stress

In this context, stress is defined as a condition that disturbs the normal physiological or psychological functioning of an individual. Since the 1940s, the association of maternal stress with birth outcomes has been explored. Results vary partly because of methodological difference in measuring stress (Hong, 2021). Quantitative measure is difficult, but considerable evidence shows that psychosocial stress in the form of racial discrimination—especially in black populations—results in poor health outcomes, including preterm birth (Salow, 2018). Psychological duress can include childhood stress, depression, or posttraumatic stress syndrome (Gillespie, 2017; Goldstein, 2017; Venkatesh, 2016). In one review of more than 50 studies, a significant link was found between low birthweight and preterm

birth in women impacted by intimate partner violence (Donovan, 2016).

One potential mechanism for stress-induced preterm birth is premature activation of the placental–adrenal endocrine axis. Another mechanism by which stress may translate to preterm birth is premature cellular senescence. As part of normal physiology, aging of fetal and decidual cells precipitates release of uterotonic signals for uterine activation at term. The interplay between preterm birth and maternal stress was recently reviewed by Hong and colleagues (2021).

CONTRIBUTING FACTORS

Several factors associated with preterm birth include pregnancy factors, lifestyle and behaviors, genetic and demographic features, and aspects of obstetrical history (Table 45-6). Disentangling association from causation remains a dilemma.

Prior Preterm Birth

The most important risk factor for preterm labor is a prior preterm birth. Data from nearly 16,000 women delivered at Parkland Hospital are instructive (Bloom, 2001). Namely, the recurrent preterm delivery risk for women with a preterm first delivery was threefold greater than that of women whose first neonate was born at term. More than a third of women whose first two newborns were preterm subsequently delivered a third preterm newborn. Most—70 percent—of the recurrent births occurred within 2 weeks of the gestational age of the prior preterm delivery. The causes of prior preterm delivery also recurred. Although women with prior preterm births are clearly at risk for recurrence, they represented only 10 percent of the total preterm births. Expressed another way, 90 percent of the preterm births at Parkland Hospital could not be predicted based on a history of preterm birth. Others have confirmed the importance of prior *spontaneous* preterm birth (Laughon, 2014). Moreover, prior *indicated* preterm birth was strongly associated with subsequent spontaneous preterm birth. Variable definitions of spontaneous and indicated may explain this association.

Ultimately, risk of recurrent preterm birth is influenced by three factors: the frequency of prior preterm deliveries, severity as measured by gestational age, and the order in which the prior preterm delivery occurred (McManemy, 2007). That is, an individual woman's risk for recurrent preterm birth is influenced by her past number and sequence of preterm and term births. For example, a risk of recurrent preterm birth for a gravida 3 para 2 woman with a prior preterm birth followed by a term birth is less than that for a woman with a prior term birth followed by preterm birth. Thus, the influence of reproductive history has a profound prognostic significance for risk of recurrence. This may also influence the supposed benefit attributed to interventions described later.

TABLE 45-6. Factors That May Contribute to the Genesis of Preterm Labor

Factor	Examples
Prior preterm birth	Spontaneous, indicated
Lifestyle	Smoking, poor diet, illicit drug use, stress, heavy physical activity
Genetic	Recurrent, familial, ethnoracial, immunoregulatory genes
Infection	*Mycoplasma* spp., bacterial vaginosis
Periodontal disease	Gingivitis
Interpregnancy interval	Long or short

Pregnancy Factors

Of these, *threatened abortion* in early pregnancy is associated with higher rates of later adverse outcomes. Weiss (2004) reported outcomes in nearly 14,000 women with vaginal bleeding at 6 to 13 weeks' gestation. Both light and heavy bleeding were associated with subsequent preterm labor, placental abruption, and pregnancy loss before 24 weeks. *Birth defects* in the fetus also may predispose to preterm birth. In a secondary analysis of data from the First- and Second-Trimester Evaluation of Risk (FASTER) trial, birth defects were associated with preterm birth and low-birthweight neonates (Dolan, 2007). Multifetal gestation is another well-recognized associate. Importantly, preterm delivery continues to be the major cause of the excessive perinatal morbidity and mortality for these pregnancies.

Lifestyle Factors

Extremes of maternal weight—both underweight and obese mothers—have an enhanced risk of preterm birth (Cnattingius, 2013; Girsen, 2016). Other maternal factors implicated include young or advanced maternal age, poverty, short stature, and vitamin C deficiency (Casanueva, 2005; Goldenberg, 2008; Leveno, 2009). Cigarette smoking, inadequate maternal weight gain, and illicit drug use affect the incidence and outcome of low-birthweight neonates (Chap. 47, p. 825).

Studies of work and physical activity related to preterm birth have yielded conflicting results (Goldenberg, 2008). Some evidence suggests that working long hours, fixed night shifts, and hard physical labor are probably linked to a higher risk of preterm birth (Cai, 2020). However, aerobic exercise in normal-weight women with uncomplicated singleton pregnancies appears to be safe and not associated with preterm birth (American College of Obstetricians and Gynecologists, 2020f; Di Mascio, 2016). One metaanalysis of physical activity found that leisure-time physical activity was associated with a reduced risk of preterm birth (Aune, 2017).

Because of the observational nature of many of the studies with the potential for confounding, the American College of Obstetricians and Gynecologists (2020b) has offered guidance for employment considerations during pregnancy. It is emphasized that accommodations that allow a woman to keep working are the most reliable way to guarantee pay, benefits, and job protection.

Genetic Factors

Evidence for a genetic component to preterm birth is supported by familial recurrent preterm births (Crider, 2005).

Genome-wide studies have identified genetic variants associated with gestational duration and preterm birth (Zhang, 2017). Common variants in *EBF1*, *EEFSEC*, and *AGTR2* genes have an association with preterm birth. Data sets, however, included only women with European ancestry, and thus future efforts will ideally include other populations. Recent large-scale transcriptome studies have identified additional loci associated with gestation length (Marinić, 2021; Sakabe, 2020).

Periodontal Disease

Gingivitis is a chronic anaerobic inflammation that affects as many as 50 percent of pregnant women in the United States (Goepfert, 2004). One metaanalysis of 17 studies showed that periodontal disease was significantly associated with preterm birth (Vergnes, 2007). To better study this relationship, 813 pregnant women between 13 and 17 weeks' gestation who had periodontal disease were randomly assigned to treatment during pregnancy or postpartum. Treatment during pregnancy improved periodontal disease, however, it failed to significantly alter preterm birth rates (Michalowicz, 2006). A workshop of the European Federation of Periodontology and the American Academy of Periodontology reaffirmed this position (Sanz, 2013).

Interpregnancy Interval

In one metaanalysis, intervals <18 months and >59 months were associated with greater risks for both preterm birth and small-for-gestational-age newborns (Conde-Agudelo, 2006). The causal effect of short interpregnancy intervals, however, has been questioned (Ball, 2014). A recent cohort study of more than three million births across four countries, including the United States, found that associations between interpregnancy intervals and preterm birth are modified by whether the previous pregnancy was preterm (Marinovich, 2021).

Infection

Antimicrobial Prophylaxis

As discussed on page 789, a link between some cases of preterm birth and infection seems irrefutable (Goldenberg, 2008). In several studies, antimicrobial treatment has been given to prevent preterm labor that was thought to stem from microbial invasion. Some of these strategies have targeted *Mycoplasma* species.

First, Andrews and associates (2006) reported results of a randomized trial in which they provided a course of azithromycin plus metronidazole every 4 months to 241 nonpregnant women whose last pregnancy resulted in spontaneous delivery before 34 weeks. Approximately 80 percent of the women with subsequent pregnancies had received study drug within 6 months of their subsequent conception. Such interconceptional antimicrobial treatment did not reduce the rate of recurrent preterm birth. From a subgroup analysis of this data, Tita and coworkers (2007) concluded that such use of antimicrobials may be harmful.

In another randomized study, 2661 women were given placebo or metronidazole plus erythromycin between 20 and 24 weeks' gestation followed by ampicillin plus metronidazole during labor (Goldenberg, 2006). This antimicrobial regimen did not reduce the rate of preterm birth or histological chorioamnionitis. As discussed later, antibiotic prophylaxis to prevent preterm birth is not currently recommended in women with preterm labor and intact membranes (Flenady, 2013).

Bacterial Vaginosis

In this condition, normal, hydrogen peroxide–producing, lactobacillus-predominant vaginal flora is replaced with anaerobes. For nearly 40 years, bacterial vaginosis has been recognized to be associated with spontaneous abortion, preterm labor, rupture of membranes, chorioamnionitis, and amnionic fluid infection (Gravett, 1986; Hillier, 1995). Unfortunately, screening and treatment have not prevented preterm birth (Haahr, 2016). Moreover, microbial resistance or antimicrobial-induced change in the vaginal flora results from regimens intended to eliminate bacterial vaginosis (Beigi, 2004; Carey, 2005).

COVID-19

Early reports suggested an increase in rates of preterm birth in pregnant women with COVID-19. However, population-level data show conflicting results on the changes, if any, in preterm birth rates (Berghella, 2020; Hedermann, 2021; Main, 2021). At Parkland Hospital, Adhikari and colleagues (2020) did not identify higher rates of preterm birth in 252 women with COVID-19 compared with 3122 gravidas who tested negative. However, women with severe infection are often delivered preterm for maternal indications (Pierce-Williams, 2020).

DIAGNOSIS

Symptoms

Contractions, pelvic pressure, menstrual-like cramps, watery vaginal discharge, and lower back pain are typical symptoms of preterm labor. These can also be seen with normal pregnancy and may be minimized by patients and providers. Early differentiation between true and false labor is difficult—especially before demonstrable cervical effacement and dilation. Uterine activity alone can be misleading because of *Braxton Hicks contractions* (Chap. 4, p. 52). Accordingly, the American College of Obstetricians and Gynecologists (2020e) defines preterm labor to be regular contractions accompanied by a change in cervical dilation, effacement, or both or to be regular contractions and cervical dilation of at least 2 cm at initial presentation.

Chao (2011) prospectively studied 843 women with a singleton fetus who presented to Parkland Hospital with preterm labor symptoms between $24^{0/7}$ and $33^{6/7}$ weeks, intact membranes, and cervical dilation <2 cm. Those whose cervix remained <2 cm were sent home with a diagnosis of false preterm labor. When analyzed against the general obstetrical population, women sent home had a similar rate of birth before 34 weeks—2 versus 1 percent. However, these women did have significantly higher rates of birth between 34 and 36 weeks—5 percent compared with 2 percent. Women with cervical dilation of 1 cm at discharge were significantly more likely to

deliver before 34 weeks compared with women without cervical dilation—5 percent versus 1 percent. Almost 90 percent of the 1-cm group delivered within 21 days of the initial presentation.

Cervical Change

Asymptomatic cervical dilation after midpregnancy is suspected to be a preterm delivery risk factor. Multiparity alone is not sufficient to explain cervical dilation discovered early in the third trimester. Cook (1996) longitudinally evaluated cervical status with transvaginal sonography between 18 and 30 weeks' gestation in nulliparas and multiparas who all subsequently gave birth at term. Cervical length and diameter were identical in both groups throughout these critical weeks. In a study from Parkland Hospital, routine digital cervical examinations were performed between 26 and 30 weeks in 185 asymptomatic women. Approximately 25 percent of women whose cervix was dilated 2 or 3 cm delivered before 34 weeks (Leveno, 1986a). Other investigators have verified cervical dilation as a predictor of increased preterm delivery risk (Copper, 1995).

Although women with dilation and effacement in the third trimester are at greater risk for preterm birth, detection does not necessarily improve pregnancy outcome. In one randomized study, 2719 women undergoing routine cervical examinations at each prenatal visit were compared with 2721 gravidas in whom serial examinations were not performed. Knowledge of antenatal cervical dilation did not affect any pregnancy outcome related to preterm birth or the frequency of interventions for preterm labor (Buekens, 1994). Thus, it seems that prenatal cervical examinations in asymptomatic women are neither beneficial nor harmful. Numerous cervical imaging technologies are under investigation for early, accurate prediction of cervical changes associated with preterm birth (Pizzella, 2020).

Ambulatory Uterine Monitoring

An external tocodynamometer belted around the abdomen and connected to an electronic waist recorder allows a woman to ambulate while uterine activity is recorded. Results are transmitted via telephone daily. Women are educated concerning signs and symptoms of preterm labor, and clinicians are kept apprised of their progress. The 1985 approval of this monitor by the U.S. Food and Drug Administration (FDA) prompted its widespread clinical use. Subsequently, it was proven that this expensive and time-consuming system did not reduce preterm birth rates (Collaborative Home Uterine Monitoring Study Group, 1995; Iams, 2002). Despite technology improvements, use of such monitoring is discouraged (American College of Obstetricians and Gynecologists, 2021c).

Biomarkers

Because clinical symptoms alone are not predictive of preterm birth, surrogate biomarkers have been evaluated. These include fetal fibronectin (fFN), phosphorylated insulin-like growth factor–binding protein 1 (phIGFBP-1), and placental alpha microglobulin 1 (PAMG-1). Their performance varies between studies and is influenced by demographic and other factors (Melchor, 2018).

Fetal Fibronectin

This glycoprotein is produced in 20 different molecular forms by various cell types, including hepatocytes, fibroblasts, endothelial cells, and fetal amnion cells. Present in high concentrations in maternal blood and amnionic fluid, fFN is thought to function in intercellular adhesion during implantation and in maintenance of placental adherence to uterine decidua (Leeson, 1996). Detected in cervicovaginal secretions in women who have normal pregnancies with intact membranes at term, fFN appears to reflect stromal remodeling of the cervix before labor. Qualitative and quantitative fFN levels are measured using enzyme-linked immunosorbent assays, and values exceeding 50 ng/mL are considered positive. Sample contamination by amnionic fluid and maternal blood should be avoided. Interventional studies based on fFN screening results in asymptomatic women have not demonstrated improved perinatal outcomes (Andrews, 2003; Esplin, 2017). The American College of Obstetricians and Gynecologists (2021c) does not recommend screening with fFN tests. In one review of 16 trials involving management based upon fFN results, the low quality of existing evidence and need for cost-effectiveness analyses were noted (Berghella, 2019).

Cervical Length Measurement

Progressively shorter cervical canals assessed sonographically are associated with increased rates of preterm birth (Iams, 1996). The sonographic technique is described in Chapter 14 (p. 254). The Society for Maternal-Fetal Medicine (2016b) has provided guidance for proper cervical length measurement and recommends that sonographers and practitioners obtain specific training through accreditation programs in the acquisition and interpretation of cervical length images.

Transvaginal cervical sonography is not affected by maternal obesity, cervix position, or shadowing from the fetal presenting part. Because of the inability to easily distinguish the lower uterine segment from the cervix in early gestation, transvaginal cervical length assessment is typically performed after 16 weeks' gestation. Such interrogation is currently limited to singleton gestations and not recommended for multifetal gestations outside of research trials (American College of Obstetricians and Gynecologists, 2021c).

Indications for cervical length measurement are controversial. For those women with a history of prior spontaneous preterm birth, the Society for Maternal-Fetal Medicine (2016b) recommends transvaginal cervical length screening. And, the American College of Obstetricians and Gynecologists (2021c) now also recommends screening for this indication. In women with singleton pregnancies but without a history of prior preterm birth, the Society for Maternal-Fetal Medicine and the College view cervical length screening as reasonable yet acknowledges that this remains an area of debate.

Biomarkers have been incorporated with hopes to improve screening performance. Esplin and colleagues (2017) prospectively studied 9410 nulliparas with singleton pregnancies. Universal screening of sonographically measured cervical length and quantitative measurement of vaginal fFN levels were evaluated as predictors of women who would spontaneously

deliver before 37 weeks. These measures had poor predictive performance as a screening test. Based on these findings, routine use of these screening tests in a low-risk population is not recommended. Of other markers, PAMG-1 has emerged as superior to predict potential preterm birth compared with fFN, particularly among symptomatic women (Nikolova, 2018; Pirjani, 2019; Wing, 2017). Incorporating results of cervicovaginal fluid proteomic markers and microRNAs obtained from peripheral blood also has been assessed (Parry, 2020; Winger, 2020). Although evidence seems promising, any firm recommendations should await larger clinical trials (Jones, 2020). This is particularly important given the challenges with accuracy and utility of screening, especially in low-risk women, who represent most of the population with preterm birth.

A second concern with screening is the efficacy of interventions to improve perinatal outcomes once cervical length screening, biomarkers, or both have isolated at-risk women. Cervical cerclage or vaginal progesterone have been evaluated, and their efficacy is described in the next section.

Bloom and Leveno (2017) subsequently critiqued the use of transvaginal cervical length screening in low-risk women and the promulgation of consensus guidelines. They highlighted the staggering costs encumbering the healthcare system in the United States as a result of such strategies. Similar concerns were raised by Kuusela and associates (2021) who evaluated cervical length screening among 11,456 asymptomatic gravidas.

PRETERM BIRTH PREVENTION

Prevention of preterm birth remains an elusive goal. Yet, experts continue to debate the optimal strategies to prevent or manage preterm birth (Medley, 2018). Dietary supplementations, for example, have not shown benefit (Makrides, 2019; Palacios, 2019). Still, recent reports suggest that prevention in selected populations may be achievable (Breslin, 2020; Goodfellow, 2021).

Cervical Cerclage

Cerclage placement may be used to prevent preterm birth in at least three circumstances. First, the procedure may benefit women who have a history of recurrent second-trimester loss and who are diagnosed with cervical insufficiency. A second instance is the woman identified during sonographic examination to have a short cervix. The third indication is a "rescue" cerclage, done emergently when cervical incompetence is recognized in women with threatened preterm labor. Cerclage placement in twin pregnancies for clinical indications is an evolving area (Li, 2019; Roman, 2020). In this chapter, however, cerclage placement will be in the context of a singleton pregnancy.

An accurate history is critical for management decisions. For recurrent abortion from cervical incompetence, historical clues are outlined in Chapter 11 (p. 205). For women with a short cervix incidentally detected by sonography, the benefit of cerclage placement appears directly related to whether the woman has a history of prior preterm birth. In those without a prior preterm birth, cerclage for a sonographically detected short cervix alone offers no advantage (Berghella, 2017). To and associates (2004) screened 47,123 women and randomly assigned the 253 women with a cervix measuring <15 mm, with or without a history of preterm birth, to cerclage or no cerclage groups. The frequency of preterm delivery before 33 weeks did not differ significantly between the two cohorts.

In contrast, women with a sonographically diagnosed short cervix *and* a history of preterm birth may benefit. Owen and colleagues (2009) randomly assigned 302 women with prior preterm birth plus a short cervix—defined as length <25 mm—to cerclage or no-procedure groups. The primary study outcome was not supported by the intervention. However, women with a cervical length <15 mm delivered before 35 weeks significantly less often following cerclage compared with women with no cerclage—30 versus 65 percent. This study suggested that recurrent preterm birth could be prevented in a subset of women with asymptomatic singleton gestations with both previous preterm birth and short cervical length.

These findings prompted a reassessment by Berghella and coworkers (2011), who performed a metaanalysis using individual patient data (Fig. 45-5). The primary outcomes from the included trials did not support cerclage placement. However, these investigators concluded that cerclage significantly prevented preterm birth and improved composite perinatal mortality and morbidity outcomes in women with prior spontaneous preterm birth, singleton gestation, and cervical length <25 mm.

One caveat in the interpretation of this cerclage data is the influence of obstetrical history. For example, all of the trials comprising the metaanalysis included preterm birth as early as 16 to 17 weeks' gestation. Defining these early second-trimester losses as preterm births, rather than cervical incompetence, is problematic. Thus, it is difficult to distinguish whether these women were treated in the context of cervical incompetence or of preterm labor at 16 weeks. Nonetheless, based on these findings, the American College of Obstetricians and Gynecologists (2021c) concluded that in women with a singleton pregnancy, prior spontaneous preterm birth, cervical length <25 mm, and gestational age <24 weeks, cerclage placement may be considered versus vaginal progesterone (p. 797).

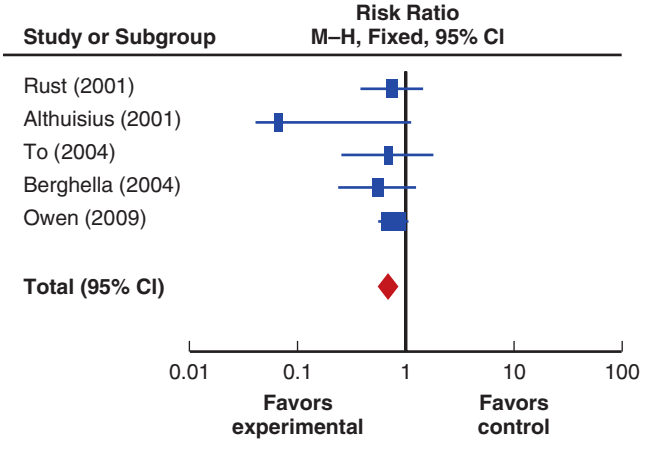

FIGURE 45-5 Cerclage versus no cerclage for prevention of recurrent preterm birth in women with a cervical length <25 mm. Forest plot analysis of composite perinatal mortality and morbidity. CI = confidence interval; M-H = Mantel-Haenszel.

Technique

The operative placement of cervical cerclage is shown in Chapter 11 (p. 206). Several emerging trends, however, merit comment. For example, indication for cerclage placement may influence selection of suture material (Battarbee, 2019). Tocolysis and antibiotics with cerclage placement is another controversy (Eleje, 2020). In a retrospective report of 142 cases, 72 received perioperative prophylaxis, which consisted of perioperative cefazolin and indomethacin, during physical examination–indicated cerclage placement. This practice was associated with a significant prolongation in gestational latency (Premkumar, 2020). At Parkland Hospital, we have not adopted such practices. Last, for women with a history of a failed cerclage, transabdominal cerclage appears to be superior to vaginal cerclage (Shennan, 2020).

Prophylaxis with Progestogen Compounds

In most mammals, *progesterone withdrawal* is considered to be a parturition-triggering event. During human parturition, however, maternal, fetal, and amnionic fluid progesterone levels remain elevated. It has been proposed that human parturition involves functional progesterone withdrawal mediated by decreased activity of progesterone receptors (Chap. 21, p. 406). It follows conceptually that progesterone administration may prevent preterm labor. This hypothesis has stimulated several studies of both 17-alpha hydroxyprogesterone caproate and vaginally administered progesterone in women with varying risks for preterm birth.

At present, reported benefits of either progestogen therapy are largely limited to women with singleton pregnancies. Progestogen prophylaxis specifically in multifetal gestations has not lowered preterm birth rates (Caritis, 2009; Dodd, 2019; Rehal, 2020; Rouse, 2007). Accordingly, both the American College of Obstetricians and Gynecologists (2021c) and the Society for Maternal-Fetal Medicine (2020b) support the use of progestogen therapy for prevention of preterm birth in select women with singleton pregnancies despite the challenges chronicled (Nelson, 2021). Either a history of prior preterm birth or no prior preterm birth but a sonographically identified short cervix is a criterion.

Prior Preterm Birth and Progestogen Compounds

The synthetic progestogen 17-alpha-hydroxyprogesterone caproate (17-OHPC) is the focus of current controversy. It remains the first, and only, drug approved by the FDA for prevention of recurrent preterm birth. This therapy was originally approved in 2011 through an accelerated process for orphan drugs and based on the findings of Maternal-Fetal Medicine Units (MFMU) Network study, described next. However, this approval and justification for continued use is now disputed (Chang, 2020; Food and Drug Administration, 2019, 2020; Greene, 2020; Nelson, 2021).

Maternal-Fetal Medicine Units Network Trial

In the MFMU Network trial, 463 women with a prior preterm birth were randomly assigned to receive weekly intramuscular injections of inert oil placebo or 17-OHPC from 16 through 36 weeks' gestation (Meis, 2003). Recurrence of preterm birth rates were 36 percent in women receiving 17-OHPC and 55 percent in those given placebo. This study was challenged because of the unexpectedly high preterm delivery rate in the placebo arm (Romero, 2013). One explanation for this high rate was asymmetry in the risks of recurrence. Indeed, 41 percent of the placebo group had ≥2 prior preterm births compared with only 28 percent in the 17-OHPC group. Another concern was that the injection dosage of 17-OHPC, which was 250 mg weekly, was empirically chosen (Caritis, 2012, 2014). Because of these reported challenges, the FDA granted approval but called for a confirmatory randomized clinical trial before final FDA approval (Food and Drug Administration, 2019). The multicenter, international, randomized trial was launched in 2009 but required 9 years to complete (Blackwell, 2020).

Pricing Concerns

Following the accelerated approval, drug-overpricing claims prompted concern (Cohen, 2011; Romero, 2013). In 2011, the FDA gave temporary approval to KV Pharmaceutical to market 17-OHPC under the brand name *Makena*. Because regulations prohibited compounding, there was no competitor for this relatively inexpensive drug, and *Makena* was priced at $1500 per injection. This caused widespread concern because the cumulative cost of *Makena* would be more than $30,000 per pregnancy.

Parkland Hospital, given these pricing concerns, contracted a local compounding pharmacy to provide 250-mg, single-dose vials of 17-OHPC in sesame oil at a cost of $25 per dose. Nelson and colleagues (2017) reported their findings from this program in a prospective study of 430 women given this compounded 17-OHPC. It was ineffective for prevention of recurrent preterm birth at 35 weeks or less compared with a historical cohort from Parkland Hospital. Moreover, 17-OHPC did not significantly reduce the rates of recurrent preterm birth regardless of prior preterm birth number or sequence. Moreover, plasma concentrations of 17-OHPC were not different at 24 weeks or 32 weeks between women delivered at ≤35 weeks and those delivered later.

Metabolism

Despite its widespread use, the mechanism of action for 17-OHPC remains unknown. Sharma and associates (2008) reported that the metabolism of 17-OHPC was predominantly mediated by the CYP3A enzymatic system. Thus, other agents that induce or inhibit this system or hepatic impairment may alter drug levels. They also showed that 17-OHPC is not converted after administration to the progesterone metabolite 17α-hydroxyprogesterone. The relative binding affinity of 17-OHPC to progesterone receptors approximates only 30 percent of that by progesterone (Attardi, 2007).

Caritis and colleagues (2012) examined 61 women receiving 17-OHPC therapy and found that the half-life was relatively long (median 16.2 days). Pharmacokinetic parameters were affected by maternal body habitus and varied widely between subjects. In addition, 17-OHPC crossed the placental barrier and was detectible in cord plasma 44 days after the

last maternal injection (Caritis, 2012). Despite this, evidence to date suggests that 17-OHPC is safe for the fetus (Food and Drug Administration, 2019). No abnormalities, including abnormal genitalia, were found in a 48-month follow-up study of infants exposed in the 2003 MFMU Network trial (Northen, 2007). Simons and coworkers (2021) also reported no effect of progestogens on child development in a systematic review comprising numerous developmental measurements.

PROLONG Trial

The FDA-required confirmatory trial was the PROLONG trial and completed in October 2018. A total of 1708 women were randomly assigned in a 2:1 ratio to receive 17-OHPC or placebo. This trial had two primary endpoints, which were birth <35 weeks' gestation and a neonatal composite. Data were analyzed for 1651 of the liveborn neonates (Table 45-7) (Blackwell, 2020). Progesterone was not effective in preventing recurrent preterm birth. In the analysis of various secondary outcomes, 17-OHPC treatment also lacked efficacy.

TABLE 45-7. Perinatal Outcomes of PROLONG Trial

Outcomes	17-OHPC n = 1130	Placebo n = 578	Relative Risk
Number assessed	1,113	574	0.95
PTB <$35^{0/7}$ wk	122 (11.0)	66 (11.5)	
Spontaneous	93 (8.4)	51 (8.9)	0.93
Indicated	28 (2.5)	14 (2.4)	1.03
Number assessed	1,112	572	
PTB <$37^{0/7}$ wk	257 (23.1)	125 (21.9)	1.06
Spontaneous	209 (18.8)	98 (17.1)	1.10
Indicated	46 (4.1)	26 (4.5)	0.91
Number assessed	1,116	574	0.92
PTB <$32^{0/7}$ wk	54 (4.8)	30 (5.2)	
Spontaneous	38 (3.4)	22 (3.8)	0.88
Indicated	15 (1.3)	7 (1.2)	1.11
Composite M&M	61 (5.6)	28 (5.0)	1.12
Death	6 (0.5)	3 (0.5)	0.98
BPD	6 (0.5)	1 (0.2)	3.02
RDS	54 (4.9)	26 (4.7)	1.06
NEC	2 (0.2)	2 (0.4)	0.5
IVH, grade 3 or 4	2 (0.2)	1 (0.2)	0.99
Sepsis	5 (0.5)	3 (0.5)	0.84

17-OHPC = 17-hydroxyprogesterone caproate; BPD = bronchopulmonary dysplasia; IVH = intraventricular hemorrhage; M&M = mortality and morbidity; NEC = necrotizing enterocolitis; PTB = preterm birth; RDS = respiratory distress syndrome.

FDA Recommendations

In October 2019, the FDA convened an Advisory Committee meeting to review 17-OHPC and the new data. Efficacy, side effects, and several subgroup analyses were studied, and none supported 17-OHPC efficacy (Fig. 45-6). The FDA concluded that the PROLONG trial did not demonstrate a treatment benefit of 17-OHPC in reducing the neonatal composite index or the rate of spontaneous preterm birth prior to 35 weeks' gestation. The Advisory Committee recommended to withdraw approval. In November 2020, the Center for Drug Evaluation and Research proposed that *Makena* (17-OHPC) be withdrawn from the market (Food and Drug Administration, 2020).

Response to the FDA position has been mixed. Both the American College of Obstetricians (2019a, 2021a) and Society for Maternal-Fetal Medicine (2020b) have issued statements endorsing continued use of 17-OHPC for prevention of recurrent preterm birth in women with singleton pregnancies. Endorsements by these organizations continue after publication of a metaanalysis by the Evaluating Progestogens for Preventing Preterm birth International Collaborative (EPPPIC)

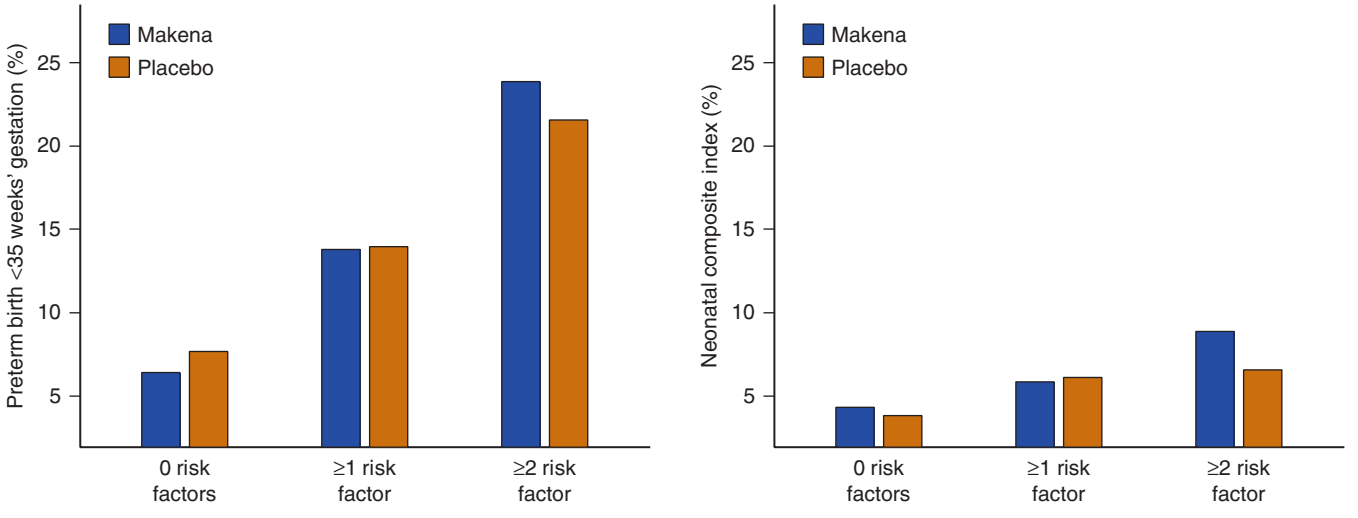

FIGURE 45-6 In analysis of co-primary endpoints for the PROLONG Trial, five of the included defining risk factors were noted to be different from those in the Maternal-Fetal Medicine Units Network trial (see text). These are black race, >1 prior spontaneous preterm birth, single or without a partner, substance use during pregnancy, and ≤12 years of formal education. The three groups examined in this post-hoc composite risk profile analysis were those with no risk factors, those with ≥1 risk factor, and those with ≥2 risk factors. Makena is the brand name of 17-OHPC.

Group (2021). These investigators summarized that vaginal progesterone and 17-OHPC both reduced birth rates before 34 weeks' gestation in high-risk singleton pregnancies. Notably, the findings for 17-OHPC did not reach statistical significance. Moreover, this metaanalysis grouped together trials of patients with differing risk profiles. It combined women with and without a prior preterm birth as well as women with and without a short cervix.

These positions have stimulated several dueling commentaries regarding its use (Chang, 2020; Godlewski, 2020; Greene, 2020; Sibai, 2020). At this time, the FDA has not withdrawn the accelerated approval. If formally withdrawn, however, a consequence may be continued "off-label" use, with the caveat that insurers may not provide payment coverage.

Progesterone Prophylaxis with Shortened Cervix

Three randomized trials are at the center of whether progestogen therapy should be used in women without prior preterm births but who have a shortened cervix (Table 45-8). In the first trial, 250 women with short cervices measuring ≤15 mm identified during routine prenatal care were nightly given 200-mg micronized progesterone vaginal capsules or placebo from 24 to 34 weeks' gestation (Fonseca, 2007). The rate of spontaneous delivery <34 weeks was significantly reduced by progesterone therapy. Importantly, this trial included nulliparas and also those with twins or prior preterm birth.

In the second trial, 465 women with a short cervix—10 to 20 mm—were given vaginal progesterone gel, 90 mg daily, or placebo (Hassan, 2011). Those receiving progesterone had significantly lower rates of preterm birth <33 weeks. This trial also included nulliparas and women with prior preterm births. According to Likis and colleagues (2012), the heterogeneity of these first two studies that included women with varied indications for progestogen treatment, combined with the fact that outcomes were not reported by risk factors such as nulliparity, made it impossible to interpret the efficacy of progesterone for specific indications.

The third study randomly assigned administration of 17-OHPC intramuscular injection or placebo between 16 and $22^{3/7}$ weeks' gestation to nulliparas with a singleton gestation and a cervical length <30 mm detected sonographically (Grobman, 2012). Treatment with 17-OHPC did not reduce the frequency of preterm birth <37 weeks. Regardless of cervical length, 17-OHPC was ineffective.

From these, vaginal progesterone, but not intramuscular 17-OHPC, appears to benefit women with a sonographically measured short cervix. Romero and Stanczyk (2013) provided a review to explain the conflicting evidence and argued that naturally occurring progesterone, which is used in the vaginal preparations, is not the same as synthetic 17-OHPC. Likewise, Furcron and coworkers (2015) found that 17-OHPC did not have local antiinflammatory effects at the maternal-fetal interface or cervix. Further, 17-OHPC did not protect against endotoxin-induced preterm birth.

From all these studies, the American College of Obstetricians and Gynecologists (2021c) concluded that universal cervical length screening in women without a prior preterm birth is not mandatory. However, this screening strategy could be considered in the context of treatment with vaginal progesterone.

Because of the preliminary results suggesting success of vaginally administered progesterone, the OPPTIMUM study was carried out—does progesterone prophylaxis to prevent preterm labor improve outcome? (Norman, 2016). High-risk women were defined as those with a prior spontaneous birth ≤34 weeks or with a cervical length ≤25 mm or a positive fFN test result combined with other clinical risk factors for preterm birth.

The primary outcomes of OPPTIMUM were unique in that both immediate obstetrical and childhood outcomes were examined. These were fetal death or birth <34 weeks; a composite of death, brain injury, or bronchopulmonary dysplasia; and a standardized cognitive score at age 2 years. Contrary to earlier reports, vaginal progesterone was not associated with a lower risk of preterm birth or composite neonatal adverse outcomes. In children at 2 years, vaginal progesterone had no long-term benefit or harm.

Progestogens Summary

Thus, evidence remains conflicting as to the efficacy of progestogens across various indications. Some have attempted to

TABLE 45-8. Randomized Trials of Progestogen Compounds Given Prophylactically to Prevent Preterm Labor

Investigator	Women Randomized	Cervical Length[a]	Progestogen Compound	Progestogen vs Placebo
Fonseca (2007)	n = 250; 5% nulliparous, 10% twins, 15% prior PTB; 8 hospitals: UK, Greece, Brazil, Chile	<15 mm	Progesterone, 200-mg vaginal capsules daily	Delivery <34 weeks: 19% vs 34%, $p = .02$
Hassan (2011)	n = 465; singletons only; 55% nulliparous; 13% prior PTB; 44 hospitals in 10 countries	10–20 mm	Progesterone, 90-mg vaginal gel daily	Delivery <33 weeks: 9% vs 16%, $p = .02$
Grobman (2012)	n = 657; singletons only; nulliparous only; 14 centers across US	<30 mm	17-OHPC, 250 mg IM weekly	Delivery <37 weeks: 25% vs 24%, p = NS

[a]Determined sonographically.
17-OHPC = 17-hydroxyprogesterone caproate; IM = intramuscularly; NS = nonsignificant; PTB = preterm birth; UK = United Kingdom; US = United States.

resolve these issues through systematic review and metaanalysis (Conde-Agudelo, 2018; da Fonseca, 2020; Jarde, 2019; Prior, 2017; Romero, 2018). However, virtually all evidence supporting progestogen use for a specific indication can be challenged in some way. At this time, we agree with Norman and colleagues (2016) that the results of recent studies should prompt a major review of progesterone use for preterm birth prophylaxis, a search to identify specific women who might benefit, and a redoubling of efforts to find alternative strategies to prevent preterm birth in women at risk.

Geography-based Public Health-care Programs

A well-organized prenatal system can lower preterm birth rates in high-risk indigent populations (Creasy, 1980). For example, in the Parkland Hospital prenatal clinic system, a declining preterm birth rate between 1988 and 2006 coincided with a substantial rise in prenatal visit attendance (Fig. 45-7) (Leveno, 2009). In the early 1990s, a concerted effort was made to improve access by creating seamless care that began with antenatal enrollment and extended through delivery and the puerperium. Prenatal clinics were placed strategically throughout Dallas County to provide convenient access for patients. Prenatal protocols are used by nurse practitioners at all clinic sites to guarantee homogeneous care. Women with high-risk pregnancy complications are referred to a hospital-based central clinic system. Here, maternal-fetal medicine clinics operate each weekday and are staffed by residents and midwives who are supervised by fellows and faculty.

A similar obstetrical care system for indigent women at the University of Alabama at Birmingham also has produced salutary results (Tita, 2011). Given the recent emphasis on access to care, especially among underserved minorities, these experiences remain relevant (United States Congress, 2019).

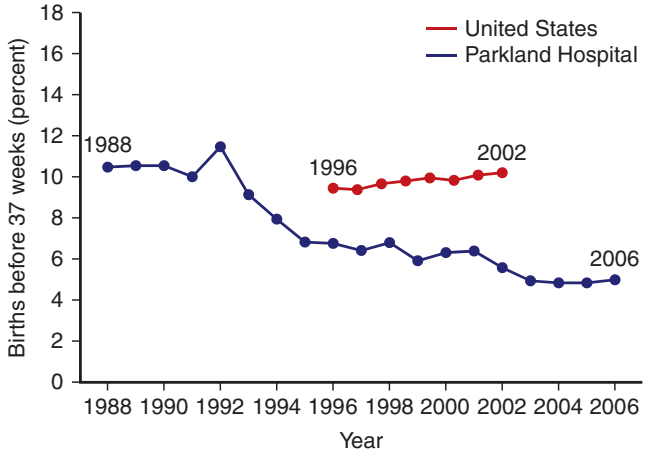

FIGURE 45-7 Percentage of births before 37 weeks' gestation at Parkland Hospital from 1988 to 2006 compared with that in the United States from 1996 to 2002. Analysis in both cohorts was limited to singleton liveborn infants ≥500 g who received prenatal care. (Reproduced with permission from Leveno KJ, McIntire DD, Bloom SL, et al: Decreased preterm births in an inner-city public hospital. Obstet Gynecol. 2009 Mar;113(3):578–584.)

Prenatal care is an important component of a comprehensive public health-care system that at least partially affects the preterm birth rate.

Aspirin

Acetylsalicylic acid (ASA) is a cyclooxygenase inhibitor with antiinflammatory and antiplatelet properties that has been used in pregnancy most commonly to prevent or delay onset of preeclampsia (Chap. 41, p. 705). Data now suggest that low-dose aspirin may also reduce spontaneous preterm birth rates (Andrikopoulou, 2018). In one randomized study of 11,976 nulliparas in six low- and middle-income countries, women were randomly assigned to receive low-dose aspirin (81 mg) or placebo initiated between $6^{0/7}$ and $13^{6/7}$ weeks' gestation (Hoffman, 2020). Low-dose aspirin decreased the incidence of birth <37 weeks and reduced the perinatal mortality rate. Although this trial did not differentiate spontaneous from indicated preterm birth, it requires replication in high-resource settings. The American College of Obstetricians and Gynecologists (2020c) does not recommend low-dose aspirin prophylaxis to prevent spontaneous preterm birth in the absence of preeclampsia risk factors.

MANAGEMENT OF PRETERM PRELABOR RUPTURE OF MEMBRANES

Methods used to diagnose ruptured membranes are detailed in Chapter 22 (p. 426). A history of vaginal leakage of fluid, either as a continuous stream or a gush, should prompt a speculum examination to visualize gross vaginal pooling of amnionic fluid, clear fluid from the cervical canal, or both. Confirmation of rupture of membranes is usually accompanied by sonographic examination to assess amnionic fluid volume, to identify the presenting part, and if not previously determined, to estimate gestational age. Once PPROM is identified, the general scheme shown in Table 45-9 can guide management.

Natural History

The time from PPROM to delivery is inversely related to the gestational age at which rupture occurs. Very few days are gained if membranes rupture during the third trimester compared with midpregnancy (Fig. 45-8) (Carroll, 1995).

In an earlier study from Parkland Hospital, 298 consecutive women with spontaneously ruptured membranes between 24 and 34 weeks' gestation were analyzed (Cox, 1988). PPROM constituted 1.7 percent of pregnancies during the study period. At the time they presented, 76 percent of the women were already in labor, and 5 percent were delivered for other complications. Thus, only 19 percent initially were suitable for expectant management. Ultimately, delivery was delayed 48 hours or more after membrane rupture in only 7 percent of the total study cohort. None of the neonates in this group died. This contrasted with a neonatal death rate of 8 percent in preterm newborns delivered within 48 hours of membrane rupture. Others have reported similar results (Nelson, 1994).

TABLE 45-9. Management of Prelabor Rupture of Membranes

$37^{0/7}$ weeks' gestation or older
- Deliver
- GBS prophylaxis as indicated (Table 67-3, p. 1195)
- Treat any intraamnionic infection

$34^{0/7}$–$36^{6/7}$ weeks' gestation
- Expectant management or deliver
- Neonatal consultation
- Consider single course of corticosteroids:
  - No prior corticosteroids
  - No chorioamnionitis
  - ≥24 hr anticipated from administration to delivery
  - <7 d anticipated from administration to delivery
- For delivery, GBS prophylaxis as indicated; For expectant care, GBS screening
- Treat any intraamnionic infection and deliver

$24^{0/7}$–$33^{6/7}$ weeks
- Expectant management, if no maternofetal indications favoring delivery
- Neonatal and perinatal consultations
- Single course of corticosteroids; rescue course suitable but not supported by robust data
- GBS screening on admission; for delivery, GBS prophylaxis as indicated
- Antibiotics recommended to prolong latency
- For pregnancies $<32^{0/7}$ weeks, magnesium sulfate for neuroprotection before anticipated delivery
- Treat any intraamnionic infection and deliver

Periviable: See Table 45-4

GBS = group B streptococcus.
American College of Obstetricians and Gynecologists 2019b; 2020g,h.

Hospitalization

Most clinicians hospitalize women with PPROM. Concerns regarding the costs of lengthy hospitalizations are usually moot, because most women enter labor within a week or less after membrane rupture. Carlan and coworkers (1993) randomly assigned 67 women with PPROM at <37 weeks' gestation to home or hospital management. The mean gestational age was 31 weeks. No benefits were found for hospitalization, and maternal hospital stays were reduced by 50 percent in those sent home—14 versus 7 days. Importantly, the investigators emphasized that this study was too small to conclude that home management was safe in regard to umbilical cord prolapse.

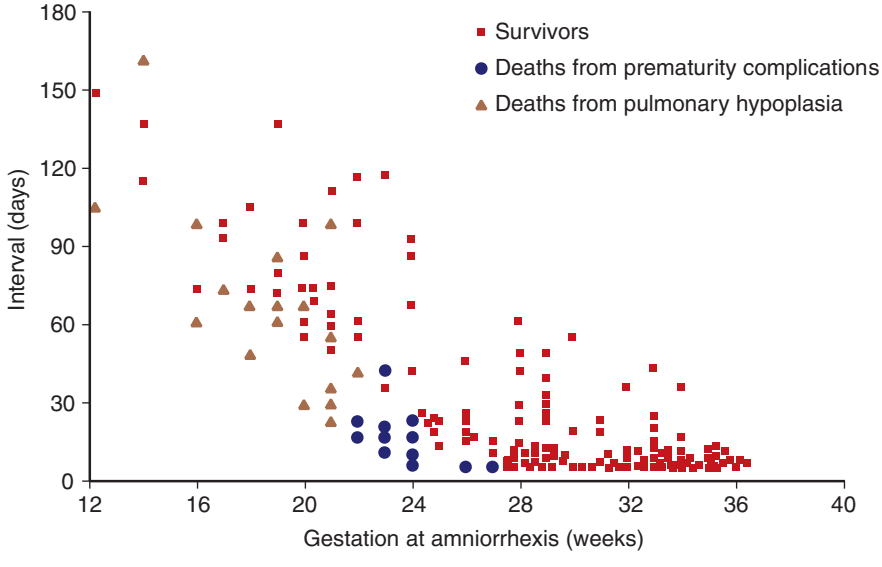

FIGURE 45-8 Relationship of time between preterm membrane rupture and delivery in 172 singleton pregnancies. (Reproduced with permission from Carroll SG, Blott M, Nicolaides KH: Preterm prelabor amniorrhexis: Outcome of live births. Obstet Gynecol 1995 Jul;86(1):18–25.)

If hospitalization is chosen, no consensus guides the optimal frequency of inpatient assessment. The American College of Obstetricians and Gynecologists (2020g) notes that an acceptable strategy would include periodic sonograms for fetal growth, fetal heart rate monitoring, and clinical surveillance for maternal infection—particularly fever. During the periviable period and at gestation ages before interventions would be planned, a short period of initial observation and consideration of outpatient monitoring in select cases is reasonable. Hospitalization would then be practiced at the time of viability.

Intentional Delivery

Before the mid-1970s, labor was usually induced in women with PPROM because of sepsis fears. Maternal infection risk and fetal prematurity risk vary according to the gestational age at membrane rupture, and management decisions incorporate this data. With periviable pregnancy, Morales (1993b) expectantly managed 94 singleton pregnancies with PPROM before 25 weeks. The average time gained was 11 days. Although 41 percent of infants survived to age 1 year, only 27 percent of the original cohort were neurologically normal. Similar results were reported by Farooqi (1998) and Winn (2000) and their colleagues. Management of these early pregnancies is discussed on page 785.

For PPROM in general, two randomized trials in the 1990s compared labor induction with expectant management (Cox, 1995; Mercer, 1993). In both of these studies, the balance of risk and benefit was difficult to ascertain, as neither immediate delivery nor expectant management was superior for neonatal outcomes. Lieman and associates (2005) found that neonatal outcomes did not improve with expectant management beyond 33 weeks. McElrath and coworkers (2003) found that prolonged latency after membrane rupture was not associated with a greater incidence of fetal neurological damage. An important correlate is that infection—specifically chorioamnionitis—is a recognized risk factor for neonatal neurological injury (Gaudet, 2001; Wu, 2000).

Bond and colleagues (2017) compared planned early birth with expectant management for women with PPROM before 37 weeks' gestation. They evaluated 12 randomized trials totaling 3617 women and 3628 newborns. No clinically important differences in the incidence of neonatal sepsis between women who immediately delivered and those managed expectantly were identified. Although the incidence of chorioamnionitis was lower, neonates of women randomized to early birth were more likely to be born at an earlier gestational age and encountered attendant perinatal sequelae. The authors concluded that in women with rupture of membranes before 37 weeks' gestation without contraindications to continuing the pregnancy, a policy of expectant management with careful monitoring was associated with better outcomes for both the mother and newborn. A subsequent metaanalysis of late-preterm prelabor rupture of membranes by Quist-Nelson and coworkers (2018) noted that immediate delivery and expectant management resulted in comparable rates of the composite of adverse neonatal outcomes.

Because of conflicting data and the controversies of immediate delivery compared with expectant management, the American College of Obstetricians and Gynecologists (2020g) cannot make firm recommendations. Clearly, gestational age is an important consideration. At $24^{0/7}$ to $33^{6/7}$ weeks, expectant management in the absence of nonreassuring fetal status, clinical chorioamnionitis, or placental abruption is recommended. At $34^{0/7}$ to $36^{6/7}$ weeks' gestation, delivery was once recommended, however, it is now considered reasonable to offer either expectant management or immediate delivery following consideration of risks and benefits, counseling, and shared decision-making. Expectant management should not go beyond $37^{0/7}$ weeks' gestation. Based upon limitations of access to care and resources, our current practices at Parkland Hospital continue to favor immediate delivery after 34 weeks' gestation.

Expectant Management

Several considerations arise during expectant management of PPROM (Boettcher, 2020; Shaddeau, 2020). One is digital cervical examination. Alexander and colleagues (2000) analyzed findings in women with membrane rupture expectantly managed between 24 and 32 weeks' gestation. They compared those who had one or two digital cervical examinations with women who were not examined. Those who were examined had a rupture-to-delivery interval of 3 days compared with 5 days in those not examined. This difference did not worsen maternal or neonatal outcomes. At Parkland Hospital, digital cervical examination is used judiciously in PPROM cases.

Rupture of membranes following second-trimester amniocentesis is uncommon (Chap. 17, p. 345). Compared with women with spontaneous rupture during the second trimester, Borgida and associates (2000) found that pregnancies complicated by PPROM after genetic amniocentesis resulted in significantly better perinatal outcomes. The perinatal survival rate was 91 percent. After counseling, affected women are typically managed expectantly as outpatients with serial surveillance of amnionic fluid volume and self-assessment of temperature (American College of Obstetricians and Gynecologists, 2020g). In the series cited above, the mean time to documentation of a normal amnionic fluid volume after amniocentesis approximated 2 weeks.

Tocolysis given with PPROM has been reported in few studies. In women with ruptured membranes and lack of labor, prophylactic tocolysis does not improve neonatal outcomes but is associated with greater chorioamnionitis rates (Mackeen, 2014). Similarly, therapeutic tocolysis—for those with ruptured membranes and labor—has not provided significant perinatal benefit (Garite, 1987).

Management of PPROM in the woman who has undergone cervical cerclage is complex (American College of Obstetricians, 2020g). McElrath and associates (2002) studied 114 women with a cerclage in place who later had ruptured membranes before 34 weeks. They were compared with 288 controls. Pregnancy outcomes were equivalent in both groups. Cerclage retention for more than 24 hours after PPROM may be associated with pregnancy prolongation, however, intrauterine infection and its consequences are risks (Giraldo-Isaza, 2011; Laskin, 2012). At Parkland Hospital, cerclage retention in the absence of infection or labor is currently practiced with close clinical surveillance in those with PPROM.

With PPROM in pregnancies before 26 weeks, the volume of amnionic fluid remaining after rupture appears to have prognostic importance (Carroll, 1995; Hadi, 1994). Although varied by report, current rates of pulmonary hypoplasia with PPROM before 24 weeks among surviving neonates can be as high as 30 percent (Kiver, 2018). This suggests that 23 weeks reflects a threshold for lung hypoplasia development (Chap. 7, p. 131). Further, when contemplating early expectant management, oligohydramnios and resultant limb compression deformities are influencing considerations.

For neonates born to women who have active herpetic lesions and who are expectantly managed, the infectious morbidity risk appears to be outweighed by risks associated with preterm birth (Chap. 68, p. 1216) (Major, 2003). Lewis and associates (2007) found that expectant management of women

with PPROM and noncephalic presentation was associated with a higher rate of umbilical cord prolapse, especially before 26 weeks.

Tissue sealants are often used to gain surgical hemostasis. Limited reports describe their use for repair of fetal membranes (Chap. 11, p. 203). Crowley and coworkers (2016) concluded that available data are currently insufficient to assess the value of sealing procedures for PPROM. We do not use these agents for this indication.

Clinical Chorioamnionitis

Infection is a major concern with membrane rupture. Although some cases remain subclinical, if chorioamnionitis is diagnosed, prompt efforts to effect delivery, preferably vaginally, are initiated. Because maternal leukocytosis alone is not a consistent finding, *fever is the only reliable indicator for the diagnosis of chorioamnionitis*. Institutional practices and protocols vary in defining the temperature threshold. Traditionally, a temperature ≥38°C (100.4°F) accompanying ruptured membranes has implied infection. At Parkland Hospital, we still adhere to this criterion.

In 2015, a workshop sponsored by the NICHD was convened and suggested renaming this condition *intraamnionic infection and inflammation—triple I* (Higgins, 2016). The merits of this terminology have been questioned (Barth, 2016). Nonetheless, the American College of Obstetricians and Gynecologists (2019b) revised both the definitions and temperature thresholds for intraamnionic infection. Using these new definitions, the diagnosis of suspected intraamnionic infection is made when the maternal temperature is ≥39.0°C or when the maternal temperature is 38.0 to 38.9°C and one additional clinical risk factor is present. The latter include low parity, multiple digital examinations, internal uterine and fetal monitors, meconium-stained amnionic fluid, and the presence of certain genital tract pathogens, such as group B streptococcus (GBS) and sexually transmitted agents. Isolated maternal fever is defined as any maternal temperature between 38.0°C and 38.9°C with no additional risk factors present, and with or without persistent temperature elevation.

With chorioamnionitis, fetal and neonatal morbidity are substantively increased. Alexander and colleagues (1998) studied 1367 very-low-birthweight neonates delivered at Parkland Hospital. Approximately 7 percent were born to women with overt chorioamnionitis, and their outcomes were compared with similar newborns without clinical infection. Those in the infected group had higher incidences of sepsis, respiratory distress, early-onset seizures, intraventricular hemorrhage, and periventricular leukomalacia. Yoon and colleagues (2000) found that intraamnionic infection in preterm neonates was associated with increased rates of cerebral palsy. In one study of more than 11 million singleton live births in the United States from 1995 to 1997, 1.6 percent of gravidas had fever during labor. This was a strong predictor of infection-related death in both term and preterm neonates (Petrova, 2001).

Antimicrobial Therapy

Various antimicrobials have been evaluated to forestall preterm delivery. Mercer and associates (1995) reviewed 13 randomized trials that evaluated antibiotics for PPROM before 35 weeks. Their metaanalysis indicated that only three of 10 outcomes were *possibly* benefited: (1) fewer women developed chorioamnionitis, (2) fewer newborns developed sepsis, and (3) pregnancy was more often prolonged 7 days in women given antibiotics. However, rates of other neonatal outcomes, including survival and respiratory distress, were unaffected.

In an MFMU Network trial, women with membrane rupture between 24 and 32 weeks' gestation were randomly assigned to expectant management combined with placebo or to a 7-day antibiotic regimen. Treatment included intravenous ampicillin plus erythromycin every 6 hours for 48 hours, which was followed by oral amoxicillin plus erythromycin, every 8 hours for 5 days. Neither tocolytics nor corticosteroids were given. Antimicrobial-treated women had significantly fewer newborns with respiratory distress, necrotizing enterocolitis, and composite adverse outcomes (Mercer, 1997). The latency period was also significantly longer. Specifically, 50 percent of women given an antimicrobial regimen remained undelivered after 7 days of treatment compared with only 25 percent of those given placebo. Also, a significantly greater number of treated pregnancies were undelivered at 14 and 21 days. Cervicovaginal GBS colonization did not alter these results.

Other studies have examined the efficacy of shorter treatment lengths and different antimicrobial combinations. Three-day treatments compared with 7-day regimens using either ampicillin or ampicillin-sulbactam appear equally effective in regard to perinatal outcomes (Lewis, 2003; Segel, 2003). Similarly, erythromycin compared with placebo offered a range of significant neonatal benefits. The substitution of azithromycin for erythromycin does not appear to impact maternal or neonatal outcomes, and the former has an improved side-effect profile (Dotters-Katz, 2020). An amoxicillin-clavulanate regimen is not recommended, however, because of its association with an increased incidence of neonatal necrotizing enterocolitis (Kenyon, 2004).

Some predicted that prolonged antimicrobial therapy in such pregnancies might have unwanted consequences (Carroll, 1996; Mercer, 1999). Stoll and associates (2002) studied 4337 neonates weighing from 400 to 1500 g and born from 1998 to 2000. Their outcomes were compared with those of 7606 neonates of similar birthweight born from 1991 to 1993 and prior to the practice of antibiotic prophylaxis. The overall rate of early-onset sepsis did not change between these two epochs. But, the rate of GBS sepsis dropped from 5.9 per 1000 births in the earlier group to 1.7 per 1000 births in the later group. Comparing these same epochs, the rate of *Escherichia coli* sepsis, however, rose from 3.2 to 6.8 per 1000 births. Almost 85 percent of isolates from the more recent cohort were resistant to ampicillin. Neonates with early-onset sepsis were more likely to die, especially if they were infected with coliforms. Long term, Kenyon and coworkers (2008a) found that antimicrobials given for women with PPROM had no effect on the health of children at age 7 years.

Corticosteroid Therapy

A single course of corticosteroids is recommended for pregnant women with PPROM between $24^{0/7}$ and $34^{0/7}$ weeks' gestation

(American College of Obstetricians and Gynecologists, 2020g). A single course of corticosteroids as early as $23^{0/7}$ weeks in those at risk for preterm delivery within 7 days may be considered. A similar controversy is found at the other end of the gestational age spectrum, $34^{0/7}$ to $36^{6/7}$ weeks' gestation and with rescue therapy (p. 803). These issues were summarized by Battarbee (2020) in a recent review.

MANAGEMENT OF PRETERM LABOR WITH INTACT MEMBRANES

Women with signs and symptoms of preterm labor with intact membranes are managed similarly to those with PPROM. If possible, delivery before 34 weeks' gestation is delayed. Drugs used to abate or suppress preterm uterine contractions are subsequently discussed.

Amniocentesis to Detect Infection

One of every 10 women with preterm labor and intact membranes will have intraamnionic infection that is largely subclinical (Yoon, 2019). Because of this, several tests have been used to diagnose intraamnionic infection (Andrews, 1995; Romero, 1993; Yoon, 1996). Although such infection can be identified with a positive test result, routine amniocentesis offers little value.

Corticosteroid Therapy

Glucocorticosteroids were found to accelerate lung maturation in preterm sheep fetuses, and Liggins and Howie (1972) evaluated them to treat women with preterm labor. Corticosteroid therapy was effective in lowering the incidence of respiratory distress syndrome (RDS) and neonatal mortality rates if birth was delayed for at least 24 hours after *initiation* of betamethasone. Infants exposed to corticosteroids in these early studies have now been followed into adulthood with no ill effects detected.

In 1995, a National Institutes of Health (NIH) Consensus Development Conference panel recommended corticosteroids for fetal lung maturation in threatened preterm birth. A subsequent NIH Conference (2000) summarized that data were insufficient to assess corticosteroid effectiveness in pregnancies complicated by hypertension, diabetes, multifetal gestation, fetal-growth restriction, or fetal hydrops. It was concluded, however, that administering corticosteroids to these women is reasonable.

One metaanalysis of 30 studies totaling 7774 women and 8158 infants quantified the benefit of a single course of corticosteroids (Roberts, 2017). Treatment was associated with lower rates of perinatal death, neonatal death, RDS, intraventricular hemorrhage, necrotizing enterocolitis, mechanical ventilation, and systemic infection in the first 48 hours of life. No obvious benefits were gained for chronic lung disease, death in childhood, or neurodevelopmental delay in childhood. Therapy was not associated with chorioamnionitis.

Parenthetically, corticosteroids given prophylactically to women at risk of preterm birth in low- and middle-income countries actually *increased* perinatal mortality rates (Althabe, 2015). Because of this unexpected finding, a multicountry randomized trial comparing dexamethasone to placebo and involving pregnant women between $26^{0/7}$ and $33^{6/7}$ weeks' gestation was recently completed (WHO ACTION Trials Collaborators, 2020). The trial was stopped early due to benefits of dexamethasone, which resulted in a significantly lower risk of stillbirth or neonatal death. The discrepancy between the two reports was attributed to inaccuracies in gestational age assessment (Rohwer, 2020).

A single course of corticosteroids is currently recommended for women between 24 and 34 weeks' gestation who are at risk for delivery within 7 days (American College of Obstetricians and Gynecologists (2020a). This recommendation for premature twins has been challenged (Viteri, 2016). For pregnancies at 23 weeks and at risk of delivery within 7 days, a single course of corticosteroids may be considered (p. 785). Administration of corticosteroids during the periviable period is linked to parental decisions regarding resuscitation and should be considered in that context (American College of Obstetricians and Gynecologists, 2019d).

Agent Selection

Betamethasone and dexamethasone are glucocorticoids that appear equivalent in stimulating fetal lung maturation (Murphy, 2007). Reduced rates of major preterm neonatal morbidities and increased rates of survival without neurosensory disability at age 2 years do not differ between them (Crowther, 2019; Elimian, 2007). A treatment course may be two 12-mg doses of betamethasone, and each dose is given intramuscularly 24 hours apart. With dexamethasone, 6-mg doses are given intramuscularly every 12 hours for four doses. Because treatment for less than 24 hours may be beneficial and reduce neonatal morbidity and mortality rates, a first dose of antenatal corticosteroids is administered regardless of the ability to complete additional doses before delivery (American College of Obstetricians and Gynecologists, 2020a).

Late-preterm Delivery

Antenatal betamethasone has been compared against placebo for neonates that are likely to deliver in the late-preterm period (Gyamfi-Bannerman, 2016). Although only 60 percent of 2831 women received both injections, the rate of respiratory complications measured as a composite outcome was significantly lower with corticosteroid use compared with placebo—11.6 versus 14.4 percent. Because of these findings, *consideration* for administration of a single course of betamethasone for women between $34^{0/7}$ and $36^{6/7}$ weeks is advocated by both the American College of Obstetricians and Gynecologists (2020a) and the Society for Maternal-Fetal Medicine (2016a).

Adoption of this practice has not been universal because of both short- and long-term neonatal safety concerns (Crowther, 2016; Kamath-Rayne, 2016). Specifically, in the newborns receiving betamethasone, rates of hypoglycemia were significantly greater (Gyamfi-Bannerman, 2016). Neonatal hypoglycemia is particularly worrisome for possible adverse long-term consequences that include developmental delay (Kerstjens, 2012). Another caveat is that the largest effects of betamethasone included a reduction in transient tachypnea of the newborn

(TTN), which is a self-limited condition with little clinical significance (Kamath-Rayne, 2016). Specifically, the rates of TTN were 6.7 and 9.9 percent in those given betamethasone and placebo, respectively. These rates are three- to fourfold higher than those reported by the Consortium on Safe Labor (2010). The latter was a retrospective, observational study from 19 hospitals across the United States that included 233,844 deliveries. Because of these issues, we do not provide corticosteroids beyond 34 weeks at Parkland Hospital at this time.

Repeated Courses

A single dose of intramuscular corticosteroids has been compared with repeated courses for lung maturation in two major randomized trials. Both found that repeated courses reduced neonatal respiratory morbidity rates, but the long-term consequences were much different. In one study, all women were given a primary course of betamethasone. If the preterm delivery risk persisted, they were assigned to serial weekly doses of betamethasone or placebo. These investigators found no adverse effects in the infants followed to age 2 years (Crowther, 2007).

In the second study, 495 women were randomly assigned to receive a single corticosteroid course that contained two doses or assigned to repeated courses that were given weekly (Wapner, 2007). In infants exposed to repeated courses, a nonsignificant rise in the cerebral palsy rate was identified. Still, exposure to the doubled betamethasone dose was worrisome because some experimental evidence supports the view that adverse effects are dose dependent (Bruschettini, 2006). We agree with Stiles (2007) who summarized these two studies as "early gain, long-term questions." At Parkland Hospital, our practice is to follow the recommendations of the American College of Obstetricians and Gynecologists (2020a) for single-course therapy.

Rescue Therapy

This refers to administration of a second corticosteroid dose when delivery becomes imminent and more than 7 days have elapsed since the initial dose. In one randomized trial, 326 women received placebo or a single 12-mg dose of betamethasone (Peltoniemi, 2007). Paradoxically, the rescue dose of betamethasone increased the risk of RDS. In another randomized study of 437 women with gestations <33 weeks, Garite and associates (2009) reported significantly lower rates of respiratory complications and neonatal composite morbidity with rescue corticosteroids versus placebo. Rates of perinatal mortality and other morbidities, however, did not differ. Another study found that treated infants had improved respiratory compliance (McEvoy, 2010). In a metaanalysis, Crowther and colleagues (2011) concluded that a single rescue course of corticosteroids should be considered in women whose prior course was administered at least 7 days previously and who were <34 weeks' gestation.

The American College of Obstetricians and Gynecologists (2020a) notes that a single rescue course of antenatal corticosteroids *should be considered* in women with fetuses <34 weeks' gestation whose prior course was administered at least 7 days previously. Effects of rescue therapy beyond 34 weeks are unknown. At Parkland Hospital, we currently do not provide additional courses of corticosteroids beyond the initial single-course therapy.

Magnesium Sulfate for Neuroprotection

Very-low-birthweight neonates whose mothers were treated with magnesium sulfate for preterm labor or preeclampsia were found to have a reduced incidence of cerebral palsy at 3 years (Grether, 2000; Nelson, 1995). Because of this, randomized trials were designed to investigate this hypothesis. In one trial, 1063 women at risk of delivery before 30 weeks' gestation were given magnesium sulfate or placebo (Crowther, 2003). Magnesium exposure improved some perinatal outcomes. Namely, rates of both neonatal death and cerebral palsy were lower in the magnesium-treated group. However, this study was not sufficiently powered. The multicenter French trial reported by Marret and associates (2008) had similar problems.

More convincing evidence for magnesium neuroprotection came from the randomized MFMU Network study—*Beneficial Effects of Antenatal Magnesium Sulfate—BEAM—study* (Rouse, 2008). In the study, 2241 women at imminent risk for preterm birth between 24 and 31 weeks' gestation were assigned to magnesium sulfate or placebo. Magnesium sulfate was given as a 6-g bolus over 20 to 30 minutes and was followed with a maintenance infusion of 2 g/hr. Magnesium sulfate was actually infusing at the time of delivery in approximately half of the treated women. Infusion continuation protocols vary by institution, including ours. In the BEAM study, after 12 hours with no signs of imminent delivery, the infusion was stopped and resumed if delivery again seemed imminent. If >6 hours had passed since discontinuation, another loading dose was given.

A 2-year assessment was available for 96 percent of the children in the BEAM trial (Table 45-10) (Rouse, 2008). The results can be interpreted differently depending on statistical methodologies employed. Some interpret these findings to mean that magnesium sulfate infusion prevents cerebral palsy regardless of the gestational age at which therapy is given. Those with a differing view conclude that this trial only supports use of magnesium sulfate for prevention of cerebral palsy potentially before 28 weeks.

Subsequently, Doyle and associates (2009) reviewed five randomized trials to assess neuroprotective effects. A total of 6145 infants were studied, and these reviewers concluded that magnesium sulfate exposure compared with no exposure significantly lowered risks for cerebral palsy. Rates of other neonatal morbidities did not differ significantly. It was calculated that treatment given to 63 women would prevent one case of cerebral palsy.

Controversy surrounding magnesium sulfate efficacy for neuroprotection prompted a debate at the 2011 annual meeting of the Society for Maternal-Fetal Medicine. Rouse (2011) spoke for the benefits of magnesium sulfate, whereas Sibai (2011) challenged that the reported benefits were falsely positive due to random statistical error in the metaanalysis by Doyle (2009). Another peculiarity is the apparent lack of dose-response for efficacy (McPherson, 2014).

Because none of the individual studies found a benefit from magnesium sulfate for fetal neuroprotection, the American College of Obstetricians and Gynecologists (2020d,g) concluded

TABLE 45-10. Magnesium Sulfate for the Prevention of Cerebral Palsy[a]

Perinatal Outcome[a]	Treatment		
	Magnesium Sulfate No. (%)	Placebo No. (%)	Relative Risk (95% CI)
Infants with 2-year follow-up	1041 (100)	1095 (100)	—
Fetal or infant death	99 (9.5)	93 (8.5)	1.12 (0.85–1.47)
Moderate or severe cerebral palsy:			
Overall	20/1041 (1.9)	3/1095 (3.4)	0.55 (0.32–0.95)
<28–31 weeks[b]	12/442 (2.7)	30/496 (6)	0.45 (0.23–0.87)
≥24–27 weeks[b]	8/599 (1.3)	8/599 (1.3)	1.00 (0.38–2.65)

[b]Weeks' gestation at randomization.
CI = confidence index.

that those electing prophylaxis should develop specific guidelines, and this includes those with PPROM. In a recent prospective observational study of infants born at $22^{0/7}$ to $26^{6/7}$ weeks' gestation, exposure to both corticosteroids and magnesium sulfate was associated with lower rates of neurodevelopmental impairment and death compared with corticosteroids alone (Gentle, 2020). At Parkland Hospital, for the periviable fetus, we individualize management as shown in Table 45-4.

Antimicrobial Treatment

Results have been disappointing in studies of antibiotics given to *arrest* preterm labor. From one Cochrane metaanalysis, antimicrobial prophylaxis given to women with intact membranes did not reduce preterm birth rates or affect other clinically important short-term outcomes (Flenady, 2013). However, rates of short- and longer-term harm were higher for children of mothers exposed to antibiotics.

In the ORACLE Collaborative Group study of 6295 women with spontaneous preterm labor, intact membranes, but without evidence of infection, women were randomly assigned to receive antimicrobial or placebo therapy (Kenyon, 2001). The primary outcomes of neonatal death, chronic lung disease, and major cerebral abnormality were similar in both groups. In a follow-up of the ORACLE II trial, fetal exposure to antimicrobials in this setting was associated with an increased cerebral palsy rate at age 7 years compared with that in children without fetal exposure (Kenyon, 2008b). Moreover, although preterm birth is associated with bacterial vaginosis, treatment with clindamycin in more recent randomized trials has failed to lower preterm birth rates (Bellad, 2018; Subtil, 2018). Importantly, antimicrobial use described here is distinct from that given for GBS prophylaxis (Chap. 67, p. 1195).

Bed Rest

This has been one of the most often prescribed interventions, yet one of the least supported by evidence (McCall, 2013). An earlier systematic review concluded that evidence neither supported nor refuted bed rest for preterm birth prevention (Sosa, 2004). Moreover, possible harms are thromboembolic events, deconditioning, and bone loss (Kovacevich, 2000; Promislow, 2004). Grobman and associates (2013) reported that women with activity restriction were nearly 2.5 times more likely to have a preterm birth before 34 weeks. This finding, however, may reflect ascertainment bias. That is, women with restricted activity may have been assigned to bed rest because they were viewed to have a greater risk for preterm delivery. The Society for Maternal-Fetal Medicine (2020a) and the American College of Obstetricians and Gynecologists (2020f) recommend against activity restriction to reduce preterm birth rates.

Cervical Pessaries

Silicone rings, such as the Arabin pessary, have been used to support the cervix in women with a sonographically short cervix. In one study, 385 women with a cervical length ≤25 mm were provided a silicone pessary or expectant management (Goya, 2012). Newborns spontaneously delivered before 34 weeks' gestation in 6 percent of women in the pessary group compared with 27 percent in the expectant management group. In another randomized trial, almost 100 women with a cervical length <25 mm at 20 to 24 weeks' gestation received either pessaries or expectant management (Hui, 2013). The pessary did not lower the rate of delivery <34 weeks. Others have reported similar findings (Nicolaides, 2016). Moreover, authors of a recent systematic review totaling 4687 women and 7167 infants found that current evidence does not support pessary use to prevent preterm birth or improve perinatal outcomes in singleton or twin gestations with a short cervix or in unselected twin gestations (Conde-Agudelo, 2020). The Society for Maternal-Fetal Medicine (2017) currently recommends pessary prophylaxis only within research protocols.

Emergency or Rescue Cerclage

Some evidence supports the concept that cervical incompetence and preterm labor lie along a spectrum leading to preterm delivery. Consequently, cerclage placement after preterm labor begins to manifest clinically has been studied. Importantly, for

women with labor and active cervical change, cerclage is contraindicated.

In one study, 23 women with cervical incompetence before 27 weeks' gestation were randomly assigned to bed rest, with or without an adjunctive emergency McDonald cerclage (Althuisius, 2003). Delivery delay was significantly greater in the cerclage group compared with those assigned to bed rest alone—54 versus 24 days, respectively. Terkildsen and coworkers (2003) studied 116 women who underwent second-trimester emergency cerclage. Nulliparity, membranes extending beyond the external cervical os, and cerclage before 22 weeks' gestation were associated with a significantly lower chance of significant pregnancy continuation. More recently, a multicenter randomized trial assessed women with twin pregnancies and asymptomatic cervical dilation of 1 to 5 cm between $16^{0/7}$ and $23^{6/7}$ weeks' gestation (Roman, 2020). From a total of 30 enrolled women, 17 women received physical examination-indicated cerclage, and 13 women received no cerclage. Of note, all women who underwent cerclage received indomethacin and antibiotics. In the cerclage group, the preterm birth rate was significantly decreased at all evaluated gestational ages, and specifically, cerclage lowered the birth rate for those <28 weeks by 50 percent. From these limited reports, for women facing a poor pregnancy prognosis due to cervical dilation at midgestation, emergency or rescue cerclage with appropriate counseling is reasonable. At this time, however, it is unclear if such interventions truly confer a benefit or merely increase the risk of membrane rupture and infection (Hawkins, 2017).

■ Tocolysis

Although several drugs have been used to prevent or inhibit preterm labor, none is completely effective. The American College of Obstetricians and Gynecologists (2020e) has concluded that tocolytic agents do not markedly prolong gestation but may delay delivery in some women for up to 48 hours. This may allow transport to an obstetrical center with higher-level neonatal care and permit time for a course of corticosteroid therapy. Although delivery may be delayed to administer corticosteroids, evidence does not support that tocolytic therapy has any direct favorable effect on neonatal outcomes or that any prolongation of pregnancy afforded by tocolytics alone translates into statistically significant neonatal benefit.

Beta-adrenergic agonists, magnesium sulfate, calcium-channel blockers, or indomethacin are the recommended tocolytic agents for short-term use. The gestational age range for tocolytic use is debatable (Mendez-Figueroa, 2020). But, because the perinatal outcomes in preterm neonates are generally good after 34 weeks' gestation, most do not recommend use of tocolytics after 33 weeks.

In many women, tocolytics stop contractions temporarily but rarely prevent preterm birth. Moreover, the American College of Obstetricians and Gynecologists (2020e) has concluded that maintenance therapy with tocolytics is ineffective for preventing preterm birth. No trial has ever convincingly shown reduced rates of any important adverse outcome by a tocolytic drug compared with placebo (Walker, 2016).

β-Adrenergic Receptor Agonists

Several compounds stimulate β-adrenergic receptors to reduce intracellular ionized calcium levels and prevent activation of myometrial contractile proteins (Chap. 21, p. 403). Of β-mimetic drugs in the United States, ritodrine and terbutaline have been used in obstetrics, but only ritodrine is FDA-approved for preterm labor.

Ritodrine was voluntarily withdrawn from the United States market in 2003, but a discussion of ritodrine is included here to present issues with β-mimetic drug use. In a randomized trial at Parkland Hospital, intravenous ritodrine delayed delivery for 24 hours but without other benefits (Leveno, 1986b). Additional studies confirmed a delivery delay up to 48 hours (Canadian Preterm Labor Investigators Group, 1992).

Importantly, β-agonist infusion resulted in serious and even fatal maternal side effects. Pulmonary edema is a special concern, and its cause is multifactorial. Risk factors include tocolytic therapy with β-agonist drugs, multifetal gestation, concurrent corticosteroid therapy, tocolysis for more than 24 hours, and intravenous infusion of large volumes of crystalloid. β-Agonist agents cause retention of sodium and water, and with time—usually 24 to 48 hours—these can cause volume overload (Hankins, 1988). The drugs have been implicated in increased capillary permeability, cardiac rhythm disturbances, and myocardial ischemia. For example, in an earlier study, tocolysis was the third most common cause of acute respiratory distress and death in pregnant women during a 14-year period in Mississippi (Perry, 1998).

Terbutaline is commonly used in the United States to forestall preterm labor. Like ritodrine, it may cause pulmonary edema (Angel, 1988). Low-dose terbutaline can be administered long-term by subcutaneous pump, but randomized trials fail to show benefit for such therapy (Guinn, 1998; Wenstrom, 1997). Oral terbutaline also is ineffective (How, 1995; Parilla, 1993). In one trial, 203 women with arrested preterm labor at 24 to 34 weeks' gestation were randomly assigned to receive 5-mg terbutaline tablets or placebo every 4 hours (Lewis, 1996). Of outcomes, delivery rates at 1 week, median days of pregnancy extension, mean gestational age at delivery, and incidence of preterm labor relapse were similar in both groups.

Because of serious maternal side effects, the FDA (2011) issued a warning regarding terbutaline use for preterm labor. The American College of Obstetricians and Gynecologists (2020e) recommends only short-term inpatient use of terbutaline as a tocolytic or as acute therapy for uterine tachysystole. Subcutaneous dosages of 0.25 mg are commonly used for the latter indication.

Magnesium Sulfate

Ionic magnesium in a sufficiently high concentration can alter myometrial contractility. It functions as a calcium antagonist, and when given in pharmacological doses, it may inhibit labor. Magnesium sulfate treatment has been associated with pulmonary edema (Samol, 2005). As discussed in Chapter 41 (p. 720), this has not been our experience at Parkland Hospital with treatment of tens of thousands of preeclamptic women with intramuscular or intravenous magnesium sulfate.

In one randomized trial, 54 women with preterm labor received magnesium sulfate, ritodrine, or placebo. Few differences in outcomes were identified (Cotton, 1984). Cox and coworkers (1990) randomly assigned 156 women to receive magnesium sulfate or infusions of normal saline. Magnesium sulfate–treated women and their neonates had identical outcomes compared with those given placebo. Because of these findings, this method of tocolysis was abandoned at Parkland Hospital. Similarly, Crowther and associates (2014) concluded that magnesium sulfate to treat preterm labor was ineffective and potentially harmful. Last, the FDA (2013) has warned against prolonged use of magnesium sulfate given to arrest preterm labor because of bone thinning and fractures in fetuses exposed for more than 5 to 7 days. This was attributed to low calcium levels in the fetus. Yule and associates (2020) demonstrated the influence of magnesium sulfate on maternal serum calcium levels.

Prostaglandin Inhibitors

These compounds are intimately involved in the contractions of normal labor (Chap. 21, p. 413). Antagonists act by inhibiting prostaglandin synthesis or by blocking their action on target organs.

Indomethacin, a nonselective cyclooxygenase inhibitor, was first used as a tocolytic in one study of 50 women (Zuckerman, 1974). Studies that followed reported the efficacy of indomethacin in halting contractions and delaying preterm birth (Muench, 2003; Niebyl, 1980). Morales and coworkers (1989, 1993a), however, compared indomethacin with either ritodrine or magnesium sulfate and found no difference in their efficacy to forestall preterm delivery. Berghella and associates (2006) reviewed four trials of indomethacin given to women with a sonographically determined short cervix and found such therapy to be ineffective to halt labor. But, as discussed earlier, its use with cerclage is gaining favor.

Most studies have limited indomethacin use to 24 to 48 hours because of concerns for oligohydramnios, which can develop with therapeutic doses. If amnionic fluid is monitored, oligohydramnios can be detected early, and it is reversible with drug discontinuation. There has also been considerable debate on the association of necrotizing enterocolitis or early ductus arteriosus closure and use of indomethacin (Doni, 2020; Hammers, 2015; Muench, 2001). Two metaanalyses of the effects of antenatal indomethacin on neonatal outcomes had conflicting findings (Amin, 2007; Loe, 2005). In one review of 20 studies, cyclooxygenase inhibitors, including indomethacin, provided no clear benefit compared with placebo or any other tocolytic agent (Reinebrant, 2015).

Calcium-channel Blockers

Myometrial activity is directly related to cytoplasmic free calcium, and reduced calcium concentrations inhibit contractions. Calcium-channel blockers inhibit, by various mechanisms, calcium entry through cell membrane channels.

From study results, calcium-channel blockers, especially nifedipine, are safer and more effective tocolytic agents than β-agonist drugs (King, 2003; Papatsonis, 1997). Comparing magnesium sulfate and nifedipine, one study of 192 women at 24 to 33 weeks' gestation found no substantial differences in efficacy or adverse effects (Lyell, 2007). Comparing nifedipine and atosiban in 145 women with preterm labor between 24 and 33 weeks, another randomized study showed that neither agent was superior to delay delivery. Neonatal morbidity rates were equivalent (Salim, 2012).

Flenady and coworkers (2014b) reviewed 38 trials of calcium-channel blockers for preterm labor and concluded that these agents have benefits compared with placebo. It is problematic, however, that this conclusion stemmed from a trial with unclear risk of selection bias and a three-arm study of 84 women that was not blinded (Ara, 2008; Zhang, 2002). More recently, Hawkins and associates (2021) performed a randomized, placebo-controlled trial of nifedipine for acute tocolysis of preterm labor at Parkland Hospital. Acute tocolysis with nifedipine did not affect preterm birth rates. However, the study results were obtained following an interim analysis demonstrating futility for study continuation.

Importantly, the combination of nifedipine and magnesium sulfate for tocolysis is potentially dangerous. Ben-Ami (1994) and Kurtzman (1993) and their coworkers reported that nifedipine enhances the neuromuscular blocking effects of magnesium, which can interfere with pulmonary and cardiac function. In one small study of 54 women with preterm labor who received either magnesium sulfate plus nifedipine or no tocolytic, neither benefit nor harm was found (How, 2006).

Other Agents

Atosiban is a nonapeptide oxytocin analogue and an oxytocin-receptor antagonist that is used in European countries to forestall labor. In randomized trials, atosiban failed to improve relevant neonatal outcomes and was linked with significant neonatal morbidity (Flenady, 2014a; Moutquin, 2000; Romero, 2000). The FDA has denied approval of atosiban for use in the United States because of these findings.

Nitric oxide donors are potent smooth-muscle relaxants that affect the vasculature, gut, and uterus. In randomized clinical trials, nitroglycerin administered orally, transdermally, or intravenously was ineffective or showed no superiority compared with other tocolytics. In addition, maternal hypotension is a common side effect (Bisits, 2004; Lees, 1999).

■ Labor and Delivery

Fetal heart rate and uterine contractions are monitored with preterm labor. We prefer continuous electronic monitoring. Fetal tachycardia, especially with ruptured membranes, suggests sepsis. Some evidence supports that intrapartum acidemia may intensify some of the neonatal complications usually attributed to preterm delivery. For example, Morgan and associates (2017) found that metabolic acidemia significantly raised the risks related to prematurity in neonates delivered <34 weeks' gestation. Low and colleagues (1995) observed that intrapartum acidosis—umbilical artery blood pH <7.0—had an important role in neonatal complications. GBS infections are common and dangerous in the preterm neonate, and antimicrobial prophylaxis should be provided (Chap. 67, p. 1195).

For delivery, perinatal outcome data do not support routine episiotomy or forceps delivery to protect the "fragile" preterm

fetal head. Staff proficient in resuscitative techniques commensurate with the gestational age and fully oriented to any specific problems should be present at delivery. The importance of specialized personnel and facilities for preterm newborn care is underscored by the improved survival rates of these neonates when delivered in tertiary-care centers. For community-based hospitals, multidisciplinary team-based simulation for preterm delivery can improve performance (Barbato, 2020).

Preterm newborns frequently have intracranial germinal matrix bleeding that can extend to more serious intraventricular hemorrhage. It was hypothesized that cesarean delivery to obviate trauma from labor and vaginal delivery might prevent these complications. This has not been validated by subsequent studies (Malloy, 1991). At Parkland Hospital, cesarean delivery is reserved for usual obstetrical indications.

CHAPTER 46

Postterm Pregnancy

The adjectives *postterm*, *prolonged*, *postdates*, and *postmature* are used interchangeably to describe pregnancies that have exceeded a duration considered to be the upper limit of normal. We eschew use of the term *postdates* because the real issue in many postterm pregnancies is uncertainty in the estimated date of delivery (EDD). *Postmature* is reserved for the uncommon clinical fetal syndrome in which the newborn has recognizable features indicating a pathologically prolonged pregnancy. Thus, *postterm* or *prolonged pregnancy* is our preferred term for an extended pregnancy.

The definition of postterm pregnancy is one that exceeds $42^{0/7}$ weeks or is ≥294 days from the first day of the last menstrual period (LMP). Importantly, this is 42 "completed weeks." Pregnancies between $41^{1/7}$ and $41^{6/7}$ weeks, although in the 42nd week, do not complete 42 weeks until the seventh day has elapsed. These are considered *late term* (American College of Obstetricians and Gynecologists, 2019e, 2020b).

ESTIMATED GESTATIONAL AGE

The current definition of postterm pregnancy assumes that ovulation occurs 2 weeks after the LMP. Thus, some pregnancies may not actually be postterm because of error in menstrual date recall or delayed ovulation. Even with exactly recalled menstrual dates, there still is imprecision, and first-trimester sonography is the most accurate method to establish or confirm gestational age (American College of Obstetricians and Gynecologists, 2019b, 2020b). Several studies support this (Bennett, 2004; Joseph, 2007). If available, gestational ages calculated from the LMP and from the first accurate ultrasound are reconciled as shown in Table 14-1 (p. 248), and the EDD is recorded (American College of Obstetricians and Gynecologists, 2019c).

INCIDENCE

Of the 3.75 million neonates born in the United States during 2019, 0.3 percent were delivered at ≥42 weeks (Martin, 2021). This rate has declined because of improved pregnancy dating accuracy and earlier intervention. To identify predisposing factors for postterm pregnancy, one analysis of the Danish Birth Cohort found only prepregnancy body mass index ≥25 and nulliparity to be significantly associated (Olesen, 2006). Others reported similar associations (Arrowsmith, 2011; Mission, 2015). Nulliparas with a long midpregnancy cervical length (third or fourth quartile) are twice as likely to deliver after 42 weeks (van der Ven, 2016). Last, the risk for adverse pregnancy outcomes in postterm pregnancies increases with advancing maternal age (Kortekaas, 2020).

The tendency for some mothers to have repeated postterm births suggests that some prolonged pregnancies are biologically determined. In one study, if a mother and daughter had a prolonged pregnancy, the risk for the daughter to have a subsequent postterm pregnancy was significantly increased

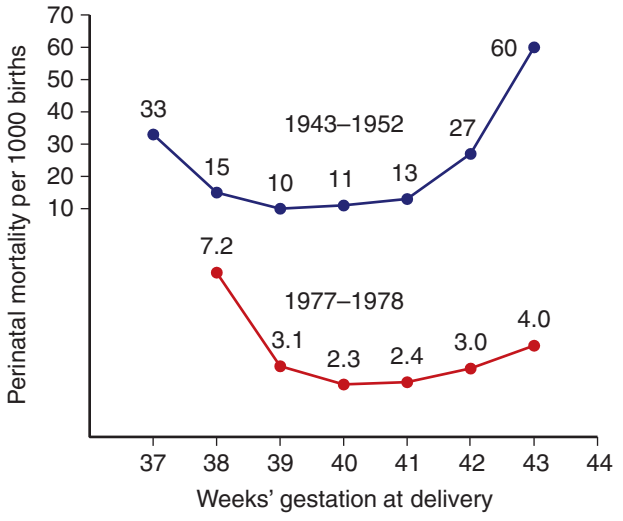

FIGURE 46-1 Perinatal mortality rates in late pregnancy according to gestational age of all births in Sweden during 1943–1952 compared with those during 1977–1978. The partially compressed scale is used for convenience in depiction. (Adapted from Bakketeig, 1991; Lindell, 1956.)

(Oberg, 2013). Maternal, not paternal, genes influence prolonged pregnancy (Laursen, 2004). For example, genes from one locus of chromosome 2q13 are associated with gestational duration (Liu, 2019). As discussed in Chapter 5 (p. 102), rare fetal-placental factors that predispose to postterm pregnancy include anencephaly, adrenal hypoplasia, and X-linked placental sulfatase deficiency (Ayyavoo, 2014; MacDonald, 1965).

PERINATAL MORTALITY AND MORBIDITY

Rates of stillbirth, neonatal death, and infant morbidity all rise after the EDD. Data from times before widespread intervention for postterm pregnancies are most illustrative. In two large Swedish studies, the perinatal mortality rate reached a nadir at 39 to 40 weeks' gestation and rose thereafter (Fig. 46-1). This trend is also reported for the United States (MacDorman, 2009). The major causes of morbidity in these studies include gestational hypertension, prolonged labor with cephalopelvic disproportion, birth injuries, and hypoxic-ischemic encephalopathy (Table 46-1). Similar outcomes were reported in 78,022 women with postterm pregnancies delivered before routine labor induction was adopted in Denmark (Olesen, 2003). A slight increase in cerebral palsy rates and two-point lower intelligence quotient (IQ) scores have been reported in postterm births (Moster, 2010; Williams, 2020; Yang, 2010). Conversely, data do not associate autism with postterm birth (Gardener, 2011).

Alexander and colleagues (2000a) reviewed 56,317 singleton pregnancies delivered at ≥40 weeks between 1988 and 1998 at Parkland Hospital. Labor was induced in 35 percent of pregnancies completing 42 weeks. The rate of cesarean delivery for dystocia or fetal distress was significantly greater at 42 weeks compared with earlier gestations. More newborns of postterm pregnancies were admitted to intensive care units. Notably, the incidence of neonatal seizures and deaths was doubled at 42 weeks.

TABLE 46-1. Adverse Maternal and Perinatal Outcomes Associated with Postterm Pregnancy

Maternal	Perinatal
Fetal macrosomia	Stillbirth
Oligohydramnios	Postmaturity syndrome
Preeclampsia	NICU admission
Cesarean delivery	Meconium aspiration syndrome
Labor dystocia	Neonatal convulsions
Fetal jeopardy	Hypoxic-ischemic encephalopathy
Shoulder dystocia	Birth injuries
Postpartum hemorrhage	Infection
Forceps delivery	Childhood obesity
Perineal lacerations	

NICU = neonatal intensive care unit.
From Amark, 2021; Kortekaas, 2020; Lindquist, 2021; MacDorman, 2009; Maoz, 2019; Middleton, 2018; Olesen, 2003.

Smith (2001) has challenged analyses such as these because the population at risk for perinatal mortality in a given week consists of all ongoing pregnancies rather than just the births in a given week. He calculated perinatal mortality rates using only births in a given week of gestation from 37 to 43 completed weeks compared with the cumulative probability—the *perinatal index*—of death when all ongoing pregnancies are included in the denominator. Using this computation, delivery at 38 weeks' gestation had the lowest risk for perinatal death. In current practice, perinatal death is balanced against morbidity associated with immaturity. This shapes the rationale for delaying delivery until 39 weeks' gestation unless a comorbidity warrants earlier intervention (American College of Obstetricians and Gynecologists, 2019d).

PATHOPHYSIOLOGY

Postmaturity Syndrome

The postmature newborn is unique, and features include wrinkled, patchy, peeling skin; a long, thin body that suggests wasting; and advanced maturity in that the neonate is open-eyed, unusually alert, and appears old and worried (Fig. 46-2). Skin wrinkling can be prominent on the palms and soles, and nails are typically long. Most postmature neonates are not technically growth restricted because their birthweight seldom falls below the 10th percentile for gestational age (Chap. 47, p. 825). However, severe growth restriction—which logically must have preceded completion of 42 weeks—may be present.

The incidence of postmaturity syndrome in newborns at 41, 42, or 43 weeks, respectively, has not been conclusively determined, but the syndrome complicates 10 to 20 percent of pregnancies at 42 completed weeks (American College of Obstetricians and Gynecologists, 2020b). Associated oligohydramnios substantially raises the likelihood of postmaturity. Trimmer and associates (1990) reported that 88 percent of fetuses were postmature if there was oligohydramnios, defined by a sonographic maximal vertical amnionic fluid pocket that measured ≤1 cm at 42 weeks.

FIGURE 46-2 Postmaturity syndrome. Neonate delivered at 43 weeks' gestation with thick, viscous meconium coating the desquamating skin. Note the long, thin appearance and wrinkling of the hands.

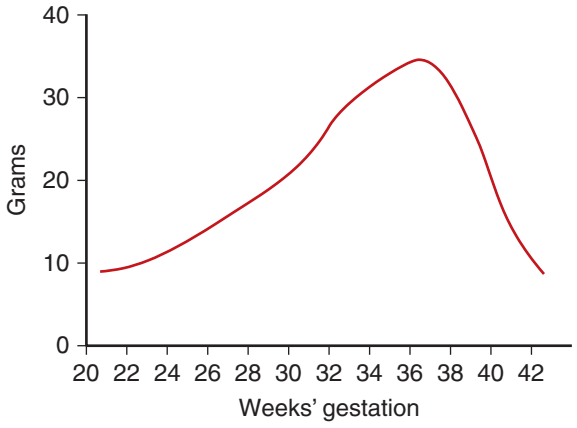

FIGURE 46-3 Mean daily fetal growth during previous week of gestation. (Redrawn from Hendricks CH: Patterns of fetal and placental growth: the second half of pregnancy. Obstet Gynecol 24:357, 1964.)

Placental Dysfunction

Many believe that postterm pregnancy is an abnormal state. Redman and Staff (2015) suggest that limited placental capacity, characterized by dysfunctional syncytiotrophoblast, explains the greater risks of the postmaturity syndrome. A murine model of stillborn fetuses supports this theory (Rahman, 2017).

Clifford (1954) proposed that the associated skin changes follow loss of the protective effects of vernix caseosa. He also attributed the postmaturity syndrome to placental senescence, although he did not find placental degeneration histologically. Still, the concept that postmaturity stems from placental insufficiency has persisted despite an absence of morphological or significant quantitative findings (Larsen, 1995; Redman, 2015; Rushton, 1991). However, the rate of placental apoptosis—programmed cell death—is significantly greater at 41 to 42 completed weeks compared with that at 36 to 39 weeks (Smith, 1999). Several proapoptotic genes such as *kisspeptin* are upregulated in postterm placental explants compared with the same genes in term ones (Torricelli, 2012). The clinical significance of such apoptosis is unclear.

Jazayeri and coworkers (1998) investigated cord blood erythropoietin levels in 124 appropriately grown newborns delivered from 37 to 43 weeks. The only known stimulator of erythropoietin is decreased partial oxygen pressure. Thus, they sought to assess whether fetal oxygenation was compromised due to placental aging in postterm pregnancies. All women had an uncomplicated labor and delivery. Cord blood erythropoietin levels were significantly elevated in pregnancies reaching 41 weeks or more. Although Apgar scores and acid-base studies were normal, these researchers concluded that fetal oxygenation was decreased in some postterm gestations.

However, the postterm fetus typically continues to gain weight and thus be unusually large at birth. This suggests that placental function is not severely compromised. Indeed, continued fetal growth is the norm—albeit at a slower rate beginning at 37 completed weeks (Fig. 46-3). Nahum and associates (1995) confirmed that fetal growth continues until at least 42 weeks. However, umbilical blood flow does not increase concomitantly (Link, 2007).

Fetal Distress and Oligohydramnios

The principal reasons for increased risks to postterm fetuses were described by Leveno and colleagues (1984). Both antepartum fetal jeopardy and intrapartum nonreassuring fetal status were found to be the consequence of cord compression associated with oligohydramnios. In their analysis of 727 postterm pregnancies, intrapartum nonreassuring fetal status detected with electronic monitoring was not associated with late decelerations characteristic of uteroplacental insufficiency. Instead, one or more prolonged decelerations such as shown in Figure 46-4 preceded three fourths of emergency cesarean deliveries for nonreassuring fetal heart rate tracings. In all but two cases, there were also variable decelerations. Another common fetal heart rate pattern, although not ominous by itself, was the saltatory baseline. As described in Chapter 24 (p. 453), these findings are consistent with cord occlusion as the proximate cause of the nonreassuring tracings. Other correlates included oligohydramnios and viscous meconium. Schaffer and coworkers (2005) implicated a nuchal cord in abnormal intrapartum fetal heart rate patterns, meconium, and compromised newborn condition in prolonged pregnancies.

Normally, the volume of amnionic fluid continues to decline after 38 weeks, and logically oligohydramnios may become problematic. Moreover, meconium release into an already reduced amnionic fluid volume results in thick, viscous fluid that may cause *meconium aspiration syndrome* (Chap. 33, p. 600). The risk for this increases to 5 percent at 42 weeks (Ward, 2020).

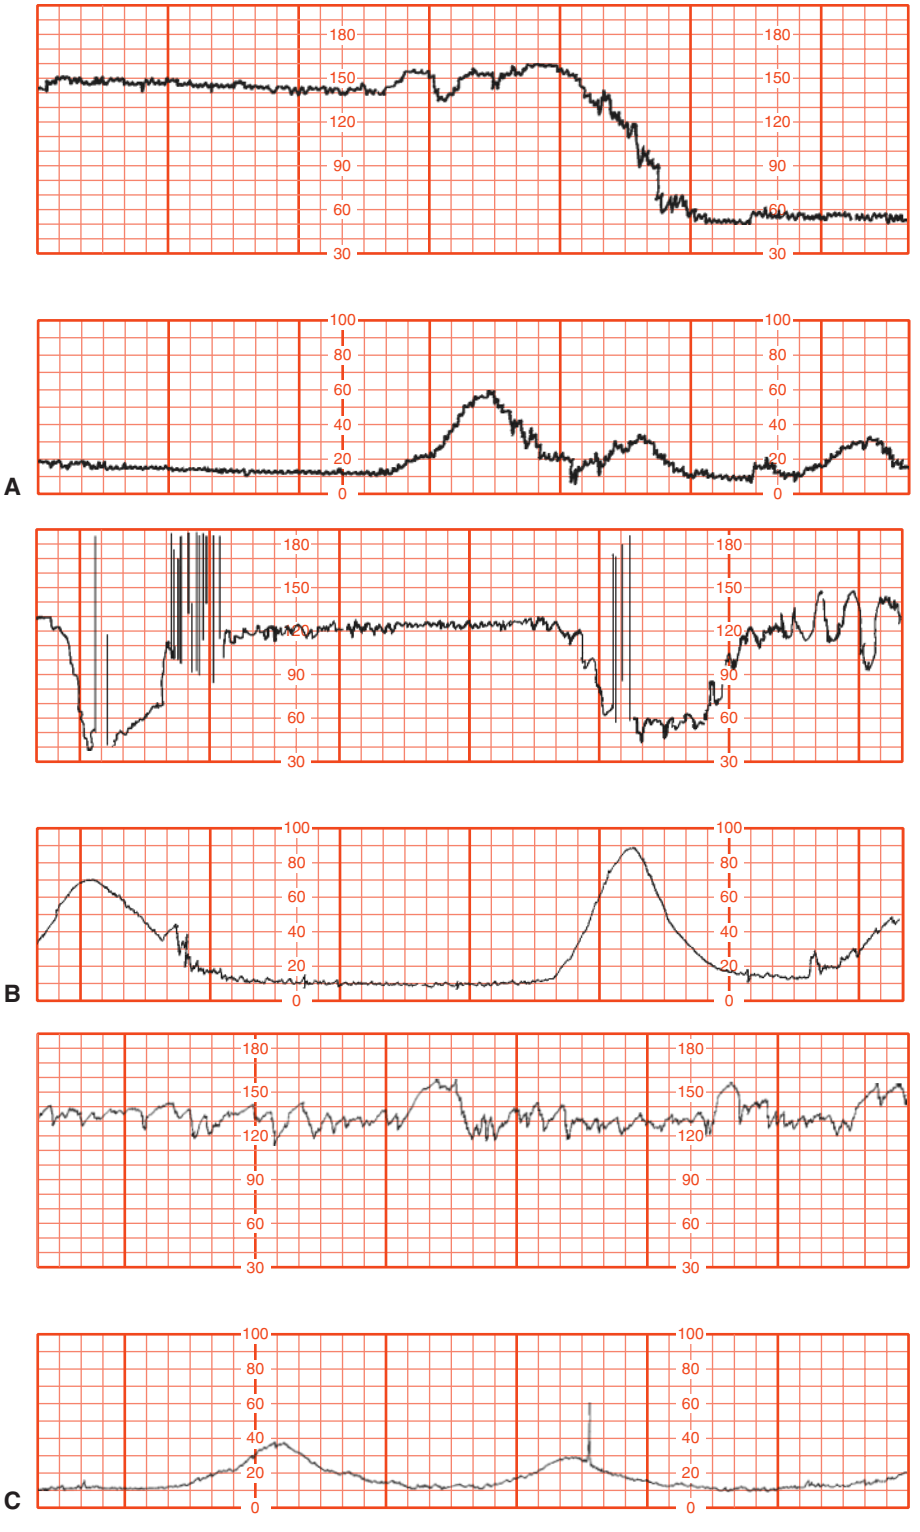

FIGURE 46-4 A. Prolonged fetal heart rate deceleration before emergency cesarean delivery in a postterm pregnancy with oligohydramnios. **B.** Variable decelerations in a postterm pregnancy with oligohydramnios. **C.** Saltatory baseline fetal heart rate showing oscillations exceeding 20 bpm and associated with oligohydramnios in a postterm pregnancy. (Reproduced with permission from Leveno KJ, Quirk JG, Cunningham FG, et al: Prolonged pregnancy, I. Observations concerning the causes of fetal distress, Am J Obstet Gynecol. 1984 Nov 1;150(5 Pt 1):465–473.)

Fetal-growth Restriction

In the late 1990s, the clinical significance of fetal-growth restriction in the otherwise uncomplicated pregnancy became more fully appreciated. Data from the National Swedish Medical Birth Registry showed that stillbirths were more common among growth-restricted newborns who were delivered after 42 weeks (Clausson, 1999; Divon, 1998). Indeed, a third of postterm stillborn neonates were growth restricted. During this time in Sweden, labor induction and antenatal fetal testing usually commenced at 42 weeks. In a study from Parkland Hospital, Alexander and colleagues (2000d) analyzed outcomes for 355 neonates from gestations ≥42 weeks and with birthweights <3rd percentile. These outcomes were compared with those of 14,520 similarly aged newborns above the 3rd percentile. Morbidity and mortality rates were significantly higher in the growth-restricted neonates. Moreover, a fourth of all stillbirths associated with prolonged pregnancy were in this comparatively small number of growth-restricted fetuses.

COMPLICATIONS

Oligohydramnios

Recognized postterm complications include oligohydramnios and fetal macrosomia. In 38 postterm pregnancies, Trimmer and colleagues (1990) sonographically measured hourly fetal urine production using sequential bladder volume measurements. Diminished urine production was found to be associated with oligohydramnios. Using Doppler waveforms, Oz and associates (2002) concluded that fetal renal blood flow is reduced in postterm pregnancies complicated by oligohydramnios. The lack of increasing umbilical blood flow postterm may be a possible cause (Link, 2007).

Diminished amnionic fluid volume at any gestational age signifies increased fetal risk. Unfortunately, an exact method to define this decreased volume is lacking. Currently, sonographic measurement of the deepest vertical pocket or calculation of the amnionic

fluid index (AFI) are options (Chap. 14, p. 257). One study of postterm pregnancies attempted to determine which amnionic fluid volume criteria best predicted normal and abnormal outcomes (Fischer, 1993). The smaller the amnionic fluid pocket, the greater the likelihood of clinically significant oligohydramnios. However, normal amnionic fluid volume did not preclude abnormal outcomes. One randomized trial assigned 500 women with postterm pregnancies to assessment using either AFI or the deepest vertical pocket (Alfirevic, 1997). The authors concluded that the AFI overestimated the number of abnormal outcomes in postterm pregnancies.

Regardless of the criteria used to diagnose oligohydramnios in postterm pregnancies, most investigators have found a higher incidence of some measure of "fetal compromise" during labor. Thus, oligohydramnios by most definitions is a clinically meaningful finding. Conversely, reassurance of continued fetal well-being in the presence of "normal" amnionic fluid volume is tenuous. This may be related to how quickly pathological oligohydramnios can develop.

Macrosomia

The velocity of fetal weight gain peaks at approximately 37 weeks (see Fig. 46-3). Although growth velocity slows at that time, most fetuses continue to gain weight. According to Duryea and associates (2014), the 95th percentile at 42 weeks is 4475 g. Even so, in one study, brachial plexus injury was not related to postterm gestation (Walsh, 2011).

Intuitively, it seems that both maternal and fetal morbidity associated with macrosomia would be mitigated with timely induction to preempt further growth. This, however, does not appear to be the case. The American College of Obstetricians and Gynecologists (2020a) concludes that current evidence does not support such a practice in women at term with suspected fetal macrosomia. Moreover, the College notes that in the absence of diabetes, vaginal delivery is not contraindicated for women with an estimated fetal weight up to 5000 g (Chap. 27, p. 501). Obvious problems with all such recommendations are substantive variations in fetal weight estimation.

ANTEPARTUM MANAGEMENT

After completing 42 weeks, labor induction is recommended to help avoid the just-described morbidity and mortality. For late-term gestations, some intervention is indicated, but the method and timing are not unanimous. The decision focuses on whether labor induction is warranted or if expectant management with fetal surveillance is best. In a survey done more than 15 years ago, 73 percent of members of the American College of Obstetricians and Gynecologists reported routinely induced women at 41 weeks (Cleary-Goldman, 2006). Most of the remainder performed twice-weekly fetal antepartum testing until 42 completed weeks.

Induction Factors

A cervix that is soft, dilated, and effaced improves labor induction success. However, investigators have used differing criteria in studies of prolonged pregnancy. Harris and coworkers (1983) defined an unfavorable cervix by a Bishop score <7 and reported this in 92 percent of women at 42 weeks (Chap. 26, p. 488). Others found that 40 percent of women with a 41-week gestation had an "undilated cervix" (Hannah, 1992). In a study of 800 women undergoing induction for postterm pregnancy at Parkland Hospital, women without cervical dilation had a twofold higher cesarean delivery rate for "dystocia" (Alexander, 2000b). Instead, a cervical length ≤3 cm measured with transvaginal sonography predicted successful induction (Yang, 2004). In a similar study, cervical length ≤25 mm positively predicted spontaneous labor or successful induction (Vankayalapati, 2008).

Several investigators have evaluated prostaglandin E_2 (PGE_2) and E_1 (PGE_1) for induction in women with an unfavorable cervix and postterm pregnancy. A study by the Maternal–Fetal Medicine Units Network (1994) found that PGE_2 gel was not more effective than placebo. Alexander and associates (2000c) treated 393 women with a postterm pregnancy with PGE_2, regardless of cervical "favorability," and reported that almost half of the 84 women with cervical dilation of 2 to 4 cm entered labor with PGE_2 use alone. Prostaglandins and other agents used for cervical ripening are discussed in Chapter 26 (p. 488).

Sweeping or stripping of the membranes to induce labor and thereby prevent postterm pregnancy has been evaluated. A metaanalysis of 44 studies found that membrane stripping slightly increased spontaneous labor and lowered induction rates (Finucane, 2020). However, this practice did not lower the cesarean delivery rate. Other trials have found that sweeping membranes did not reduce the need to induce labor (Hill, 2008; Kashanian 2006; Wong, 2002). Drawbacks of membrane stripping included pain, vaginal bleeding, and irregular contractions without labor.

The station of the fetal head within the pelvis is another predictor of successful postterm pregnancy induction. Shin and colleagues (2004) studied 484 nulliparas who underwent induction after 41 weeks' gestation. The cesarean delivery rate was directly related to station. The rate was 6 percent if the vertex before induction was at –1 station; 20 percent at –2 station; 43 percent at –3 station; and 77 percent at –4 station.

Induction versus Fetal Testing

The less than optimal benefits from induction with an unfavorable cervix lead some clinicians to prefer fetal antepartum testing beginning at 41 completed weeks. In a Canadian study, 3407 women were randomly assigned at ≥41 weeks to induction or to fetal testing (Hannah, 1992). Labor induction resulted in a small but significant reduction in the cesarean delivery rate compared with fetal testing—21 versus 24 percent, respectively. There were only two stillbirths in the fetal testing group.

The Maternal–Fetal Medicine Network then performed a randomized trial of induction versus fetal testing beginning at 41 weeks' gestation (Gardner, 1996). Fetal surveillance included nonstress testing and sonographic estimation of amnionic fluid volume performed twice weekly in 175 women. Perinatal outcomes were compared with those of 265 women also at 41 weeks but randomly assigned to induction with or without

TABLE 46-2. Selected Maternal and Perinatal Outcomes from SWEPIS Trial

Outcome	Induction (n = 1381)	Expectant (n = 1379)	*p* value
Maternal			
Gestational age (days)	289 ± 1.3	292 ± 2.7	—
Labor (hours)	7.1 ± 5.4	8.3 ± 5.9	<0.001
Cesarean delivery	10.4%	10.7%	0.79
Operative vaginal delivery	6.4%	6.6%	0.87
Perinatal			
Primary composite	2.4%	2.2%	0.9
Perinatal mortality	0	6/1000	0.03
Meconium aspiration	0.1%	0.2%	1.00
Macrosomia (>4500 g)	4.9%	8.3%	<0.001
NICU stay (days)	3.4 ± 3	4.6 ± 5.6	NS

g = grams; NICU = neonatal intensive care unit; NS = not significant; SWEPIS = SWEdish Post-term Induction Study.

cervical ripening. There were no perinatal deaths, and the cesarean delivery rate did not differ between groups. The results of this study support the validity of either management scheme.

In another study of women reaching 41 completed weeks' gestation, those who entered spontaneous labor prior to $42^{0/7}$ weeks had a lower cesarean delivery rate than those who did not spontaneously labor but who underwent induction after $42^{0/7}$ weeks (Alexander, 2001). Cesarean delivery rates were significantly increased—19 versus 14 percent—in the induced group because of failure to progress.

A study from Denmark is also instructive (Zizzo, 2017). In 2011, the Danish national guidelines were changed from labor induction at $42^{0/7}$ weeks with no fetal surveillance to labor induction at $41^{2/7}$ to $41^{6/7}$ weeks with fetal surveillance beginning at $41^{0/7}$ weeks. They compared two 3-year epochs—one before and one after 2011. The rate of pregnancies that progressed past $42^{0/7}$ weeks decreased from 2.85 to 0.62 percent. Concurrently, as expected, the induction rate rose significantly, and this was accompanied by a drop in the perinatal mortality rate—22 to 13 per 1000 births. The cesarean delivery rate was not changed. A similar before-and-after observational study reported that induction at ≥42 weeks' gestation was associated with a significantly lower cesarean delivery rate—15 versus 19.4 percent (Bleicher, 2017).

To further address the question, the SWEdish Post-term Induction Study—SWEPIS—was a randomized trial that included 2760 low-risk pregnancies at 41 weeks' gestation. The trial compared outcomes with induction of labor at 41 weeks against expectant management and induction at 42 weeks. As shown in Table 46-2, maternal and perinatal outcomes were not different with the exception of perinatal mortality and macrosomia (Wennerholm, 2019). The study was stopped early because of a significantly higher perinatal mortality rate in the expectantly management group. The investigators concluded that these results should be interpreted with caution because the primary composite outcomes were not significantly different.

Management Strategies

At this time, evidence is insufficient to mandate a management strategy between 40 and 42 completed weeks. Thus, induction of labor or initiation of fetal surveillance at 41 weeks' gestation is a reasonable option. The American College of Obstetricians and Gynecologists and the Society for Maternal-Fetal Medicine (2021) suggest that fetal surveillance should be done once or twice weekly beginning at 41 0/7 weeks. After completing 42 weeks, labor induction is recommended. A management algorithm by the American College of Obstetricians and Gynecologists (2020b) is summarized in Figure 46-5. In light of the recent studies that show an increased stillbirth rate associated with expectant management at 41 weeks, it is likely that routine induction will eventually become preferable in most circumstances.

When gestational age is uncertain, the American College of Obstetricians and Gynecologists (2019b) recommends delivery at 41 weeks' gestation using the best clinical estimate of gestational age. The College also recommends against amniocentesis for fetal lung maturity.

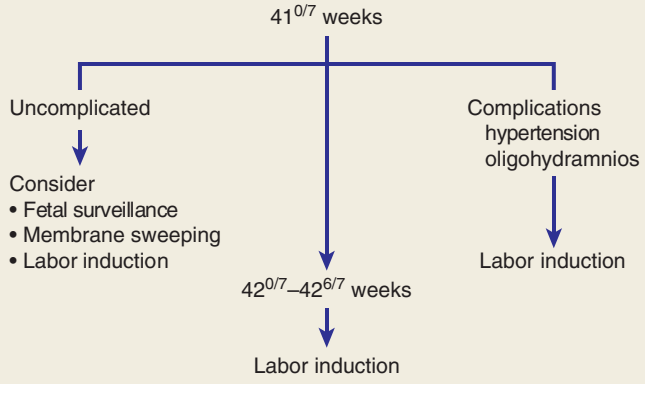

FIGURE 46-5 Algorithm for management of postterm pregnancy.

INTRAPARTUM MANAGEMENT

Labor is a particularly dangerous time for the postterm fetus. Thus, women whose pregnancies are known or suspected to be postterm ideally come to the hospital as soon as they suspect labor. While being evaluated for active labor, fetal heart rate and uterine contractions are monitored electronically for variations consistent with fetal compromise (Chap. 24, p. 457).

During labor, the decision to perform amniotomy is problematic. Further reduction in fluid volume following amniotomy can enhance the possibility of cord compression. Conversely, after membrane rupture, a scalp electrode and an intrauterine pressure catheter can be placed. These usually provide more precise data concerning fetal heart rate and uterine contractions. Amniotomy also aids identification of thick meconium.

Thick meconium in the amnionic fluid is particularly worrisome. The viscosity probably signifies the lack of liquid and thus oligohydramnios. Aspiration of thick meconium may cause severe pulmonary dysfunction and neonatal death (Chap. 33, p. 600). According to the American College of Obstetricians and Gynecologists (2019a), amnioinfusion does not prevent meconium aspiration syndrome. However, it remains a reasonable treatment approach for repetitive variable decelerations (Chap, 24, p. 459). Suctioning the pharynx once the head is delivered is not recommended (American College of Obstetricians and Gynecologists, 2019a; Wyckoff, 2020). If the depressed newborn has meconium-stained fluid, intubation is performed.

The likelihood of a successful vaginal delivery is reduced appreciably for the nullipara who is in early labor with thick, meconium-stained amnionic fluid. Thus, if a woman is remote from delivery, strong consideration should be given to prompt cesarean delivery, especially when cephalopelvic disproportion is suspected or either hypotonic or hypertonic dysfunctional labor is evident. Some practitioners choose to avoid oxytocin use in these cases.

CHAPTER 47

Fetal-Growth Disorders

Disorders of fetal growth occur at both ends of the spectrum, either fetal-growth restriction or macrosomia. Each poses concern because of associated morbidities and potential mortality. However, in both categories most of these newborns are ultimately deemed normal and healthy but merely constitutionally small or large. The clinical challenge thus lies in the evaluation and management of suspected fetal-growth disorders.

NORMAL FETAL GROWTH

Fetal growth may be divided into three phases. The initial phase of hyperplasia occurs in the first 16 weeks and is characterized by a rapid rise in cell number. The second phase, which extends up to 32 weeks' gestation, includes both cellular hyperplasia and hypertrophy. After 32 weeks, fetal mass accrues by cellular hypertrophy, and it is during this phase that most fetal fat and glycogen accumulate. The corresponding fetal-growth rates during these three phases approximate 5 g/d at 15 weeks' gestation, 15 g/d at 24 weeks', and 30 g/d at 34 weeks' (Grantz, 2018; Williams, 1982).

In the National Institute of Child Health and Human Development Fetal Growth Studies, serial sonographic evaluations were performed in 1733 nonobese, low-risk pregnancies at 12 sites across the United States (Grantz, 2018). As shown in Figure 47-1, growth velocity peaked at 35 weeks' gestation (Grantz, 2018).

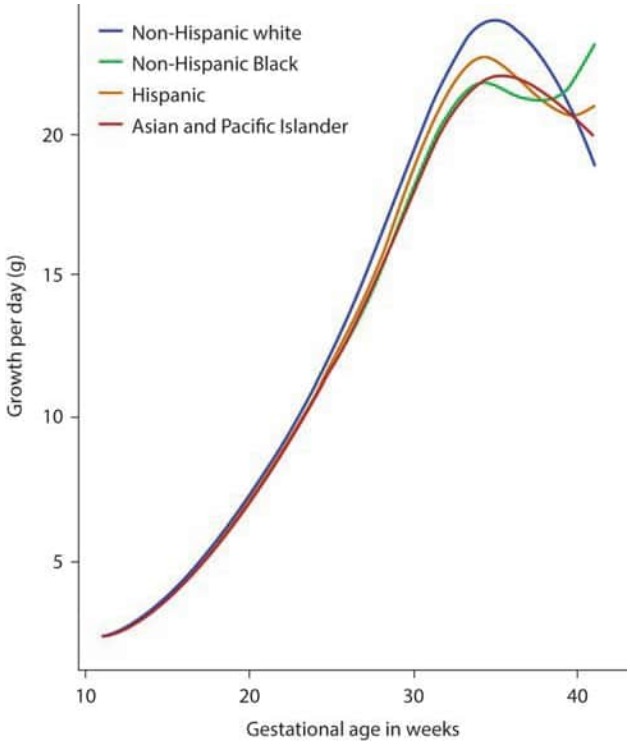

FIGURE 47-1 Fetal weight gain in grams per day by race/ethnicity throughout gestation.

The investigators demonstrated that fetal growth varies considerably and that it is *not* highly correlated with fetal birthweight percentile. Some fetuses with initial estimated weights below the 5th percentile maintained their growth velocity and ultimately weighed more at birth than other fetuses whose weight percentiles were initially higher but whose growth was slower. Such findings support our understanding that large and small fetal weight percentiles reflect constitutional size in some but indicate disordered growth in others. They further highlight the importance of serial sonography when abnormal growth is a concern.

Normal Birthweight

Accurate gestational age assessment is critical for determining whether birthweight is normal. Current normative data are based on birthweights from pregnancies in which gestational age is established using an *obstetrical estimate* that includes sonography and discussed in Chapter 14 (p. 248) (American College of Obstetricians and Gynecologists, 2019b). The birthweight percentiles shown in Table 47-1 were derived using data from more than 3 million liveborn singletons delivered across the United States in 2011 (Duryea, 2014). As shown in Figure 47-2, use of a birthweight percentile curve in which gestational age is based on a last menstrual period alone yields significantly larger weights for a given gestational age, particularly in the preterm period. The accuracy of a birthweight reference thus has potential to affect the prevalence of neonates diagnosed as small or large for gestational age.

The curve by Duryea and associates (2014) is most accurately termed a *population reference*, rather than a *standard*. A population reference incorporates pregnancies of varying risks, along with the resulting outcomes, both normal and abnormal. In contrast, a standard incorporates normal pregnancies with normal outcomes. Because population references include preterm births, which are more likely to be growth restricted, it has been argued that the associated birthweight data overestimate impaired fetal growth (Mayer, 2013; Zhang, 2010).

TABLE 47-1. 2011 Gestational Age Birthweight (g) Percentiles for 3,252,011 Singleton Live Births in the United States

	Percentile				
Age (wk)	5th	10th	50th	90th	95th

FIGURE 47-2 Fetal-growth curves for births in the United States in 2011. Curves vary depending on whether gestational age was calculated from the last menstrual period or from an improved obstetrical estimate, derived in part using sonography. (Modified with permission from Duryea EL, Hawkins JS, McIntire DD, et al: A revised birth weight reference for the United States. Obstet Gynecol. 2014 Jul;124(1):16–22.)

Physiology of Fetal Growth

Fetal development is believed to be determined by maternal provision of substrate and its placental transfer, whereas fetal growth potential is governed by the genome. The precise cellular and molecular mechanisms leading to normal fetal growth are incompletely understood. Considerable evidence supports the role of insulin and insulin-like growth factors in fetal growth and weight gain regulation (Luo, 2012). These growth factors are produced by virtually all organs and are potent stimulators of cell division and differentiation. Other hormones implicated in fetal growth include leptin and other adipokines, which are derived from adipose tissue. Fetal leptin concentrations rise during gestation, and they correlate both with birthweight and with neonatal fat mass (Briffa, 2015; Ökdemir, 2018; Simpson, 2017).

Both excessive and diminished maternal glucose availability also have the potential to affect fetal growth (Chap. 7, p. 135). That said, growth-restricted neonates do not typically show pathologically low glucose concentrations in cord blood (Pardi, 2006). Fetal-growth restriction in response to glucose deprivation generally results only after long-term severe maternal caloric deprivation (Lechtig, 1975). Conversely, hyperglycemia more consistently results in excessive growth. The Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) Study Cooperative Research Group (2008) found that elevated cord C-peptide levels, which reflect fetal hyperinsulinemia, are associated with greater birthweight. This relationship was noted even in women with maternal glucose levels below the threshold for diabetes.

Excessive transfer of lipids has similarly been implicated in fetal overgrowth (Delhaes, 2018). Free or nonesterified fatty acids in maternal plasma may be transferred to the fetus via facilitated diffusion or after liberation of fatty acids from triglycerides by trophoblastic lipases (Gil-Sánchez, 2012). Independent of prepregnancy body mass index (BMI), higher maternal free fatty acid levels during the latter half of pregnancy correlate with birthweight (Crume, 2015). Greater intake of certain fatty acids, particularly omega-3, is associated with greater birthweight (Calabuig-Navarro, 2016).

Placental fatty acid metabolism and transfer may be dysregulated in fetal-growth restriction and in maternal conditions associated with fetal overgrowth. For example, levels of endothelial lipase are reduced with deficient fetal growth, and this enzyme is overexpressed in placentas of women with diabetes (Gauster, 2007, 2011). Others have reported that diabetes and obesity are associated with altered placental lipid-transport gene expression (Segura, 2017). Obesity is also linked with greater expression of fatty acid binding/transport proteins within the trophoblast (Myatt, 2016). These alterations lead to an abnormal accumulation of lipids that can result in pathological placental inflammation and dysfunction (Calabuig-Navarro, 2016; Myatt, 2016; Yang, 2016).

FETAL-GROWTH RESTRICTION

Fundamental to understanding fetal-growth restriction (FGR) is an appreciation of the strengths and limitations of its defining criteria. A diagnosis based on *estimated fetal weight* alone does not indicate disease but rather a fetus that is in an at-risk category. Benefits of definitions such as the one used by the American College of Obstetricians and Gynecologists are ease of application and promotion of consistency across care settings. However, if applied to an otherwise low-risk population, a 10th-percentile threshold will label nearly 10 percent of fetuses as growth restricted, although most are merely *constitutionally small* rather than compromised. Moreover, a threshold will fail to identify at-risk fetuses with a weight above that threshold but who have not reached their growth potential. Thus, the definition is intended to strike a balance between false-positive and false-negative diagnoses.

Definition

Various criteria and thresholds have been used to define FGR. These have included estimated fetal weights (EFW) below the 3rd, 5th, or 10th percentiles; similar abdominal circumference (AC) percentiles; a specified decline in the EFW percentile or AC percentile over serial assessments; and various abnormal Doppler findings (Lees, 2020). All definitions are based solely on prenatal sonography and rely on accurate gestational age assessment.

Currently, the American College of Obstetricians and Gynecologists (2021a) and the Society for Maternal-Fetal Medicine (2020) recommend defining FGR as either an EFW <10th percentile for gestational age or an AC <10th percentile for gestational age. Use of the AC threshold may correctly identify one additional small-for-gestational age (SGA) newborn for every 14 sonograms performed in the last month of pregnancy (Blue, 2018). Importantly, management recommendations are further stratified based on lower percentile thresholds and findings such as oligohydramnios or abnormal umbilical artery Doppler velocimetry, as discussed subsequently (p. 829).

To more precisely identify growth-restricted fetuses, investigators have derived customized growth charts that incorporate variables such as maternal height and weight, race or ethnicity, parity, and fetal sex. However, customized growth curves do not improve outcomes and thus are not recommended (American College of Obstetricians and Gynecologists, 2021a; Chiossi, 2017; Costantine, 2013; Grobman, 2013; Zhang, 2011).

FGR should be differentiated from SGA, which is a postnatal designation based on birthweight percentile. When considering FGR *detection*, investigators study the proportion of SGA neonates identified as FGR during prenatal sonography. However, FGR often does not equate to SGA because of the inherent error of sonographic measurement. One population-based study of routine third-trimester sonography found that 50 percent of those with suspected FGR had birthweights above the 10th percentile (Monier, 2015). Those with false-positive diagnoses of FGR were delivered 2 weeks earlier in gestation, which raises concerns about potential iatrogenic sequelae of routine screening.

Importantly, as many as 70 percent of SGA newborns are not pathologically growth restricted. Indeed, such children have normal outcomes and are thought to be appropriately grown when maternal ethnic group, parity, weight, and height are considered (Unterscheider, 2015). In a Swedish study of 130,000 term births, the maternal and paternal birthweights were estimated to account for 6 and 3 percent of variance in birthweight, respectively (Mattsson, 2013). Additionally, as shown in Figure 47-3, most adverse outcomes occur in newborns smaller

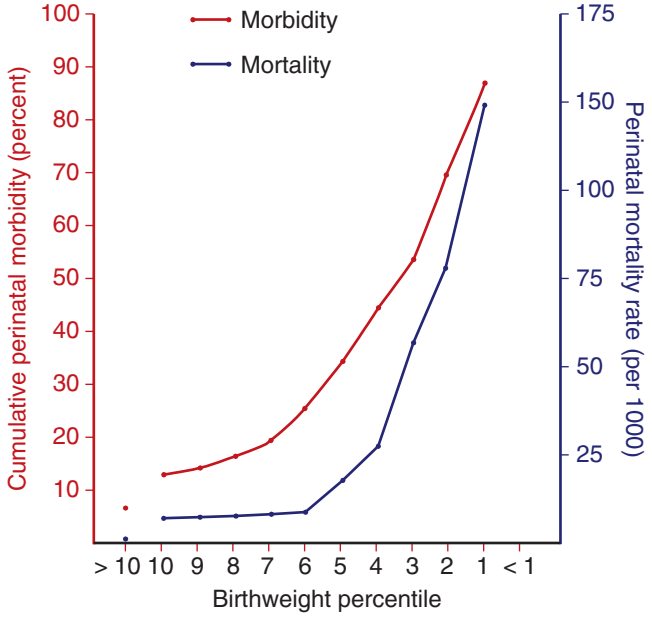

FIGURE 47-3 Relationship between birthweight percentile and perinatal mortality and morbidity rates in 1560 small-for-gestational-age fetuses. A progressive increase in both mortality and morbidity rates is observed as birthweight percentile decreases.

than the 3rd percentile (Manning, 1995). In a review of more than 80,000 singleton term births from Parkland Hospital, McIntire and colleagues (1999) found that neonatal mortality and most neonatal morbidity rates rose only at birthweights at or below the 3rd percentile.

Small-but-normal neonates do not show evidence of the postnatal metabolic derangements commonly associated with deficient fetal growth. Moreover, these intrinsically small newborns remain significantly smaller during surveillance to 2 years compared with appropriate-for-gestational-age sized neonates. However, they do not show differences in measures of metabolic risk that included glucose and insulin levels (Milovanovic, 2012). As discussed later, true SGA newborns carry short- and long-term metabolic risks.

Detection

Identification of truly impaired fetal growth remains a challenge. Ideally, it involves detecting fetuses who meet the aforementioned definition and also discerning those at risk for compromise. There are three main tenets:

1. The diagnosis relies on accurate gestational age assessment, optimally confirmed with sonography in the first or early second trimester (Table 14-1, p. 248). If gestational age is uncertain and the diagnosis is suspected, serial sonography is considered.
2. In low-risk pregnancies, the diagnosis is suspected based on clinical abdominal examination after 24 weeks' gestation in which the fundal height lags by ≥3 cm. Sonography is then performed.
3. If the pregnancy is at risk for FGR, based on factors reviewed in the next section, sonography is considered to assist with detection. This is performed at approximately 32 weeks' gestation. Care is individualized, and in some cases sonography may be needed every 4 weeks to assess fetal growth. One example of the latter is twin gestations, because fundal height cannot evaluate individual twin growth (Chap. 48, p. 851).

Uterine Fundal Height

At each prenatal visit after 20 weeks' gestation, fundal height is assessed to *screen* for fetal-growth impairment (Chap. 10, p. 182). The measurement in centimeters approximates the gestational age in weeks. The uterine size-date discrepancy may be unrelated to fetal size. However, if the measurement differs by ≥3 cm in the absence of an obvious explanation, sonography is generally performed.

Serial fundal height measurement is the only routine screening for FGR that is endorsed by the American College of Obstetricians and Gynecologists and Society for Maternal-Fetal Medicine (2021a). International consensus also indicates that carefully performed serial fundal height measurements are a simple, safe, inexpensive, and reasonably accurate method to screen for FGR (McCowan, 2018).

Limitations of fundal height screening are well documented. The overall sensitivity of fundal height to detect FGR ranges from 11 to 25 percent (Goetzinger, 2012; Grantz, 2021; Roex, 2012; Sparks, 2011). Detection rates are lower in obese women than in those with normal BMI (Goetzinger, 2012).

Sonographic Assessment

Studies of routine screening for FGR using third-trimester sonography have yielded variable results, and detection of SGA neonates ranges from <20 percent to >60 percent (Hammad, 2016; Monier, 2015; Sovio, 2015; Wanyonyi, 2021). One reason for poor detection is that sonography performed at any point in gestation will fail to detect pregnancies in which FGR develops *later*. Also, it will miss those needing delivery for FGR *before* the sonographic examination was performed. Compounding this is that EFW is an imperfect metric. Given that most SGA neonates are constitutionally small, it is not unexpected that the recurrence risk for FGR approximates 20 percent. Many of these cases are merely smaller mothers having smaller healthy children in successive pregnancies.

Routine third-trimester sonography to assess fetal growth is not recommended because it has not been demonstrated to improve outcomes (American College of Obstetricians and Gynecologists, 2021a). Indeed, a Cochrane database analysis of 13 trials with 34,980 women found that routine late-pregnancy ultrasound for a low-risk or an unselected population was not associated with maternal or fetal benefit (Bricker, 2015).

Pathophysiology

Fetal-growth restriction is one of the "major obstetrical syndromes" associated with defects in early placentation (Brosens, 2015). Mechanisms leading to abnormal trophoblastic invasion are likely multifactorial, and both vascular and immunological etiologies have been proposed. For example, *atrial natriuretic peptide converting enzyme*, also known as *corin*, plays a critical role in trophoblastic invasion and remodeling of the uterine spiral arteries (Cui, 2012). These processes are impaired in corin-deficient mice, which also develop evidence of preeclampsia. Moreover, mutations in the gene for corin are reported in women with preeclampsia (Chen, 2015).

Several immunological abnormalities are associated with FGR. This raises the prospect of maternal rejection of the "paternal semiallograft." Rudzinski and colleagues (2013) studied C4d, a component of complement that is associated with humoral rejection of transplanted tissues. They found this to be highly associated with chronic villitis—88 percent of cases versus only 5 percent of controls—and with reduced placental weight. In a study of 10,204 placentas, chronic villitis was associated with placental hypoperfusion, fetal acidemia, and FGR and its sequelae (Greer, 2012). Kim and coworkers (2015) extensively reviewed chronic inflammatory placental lesions and their association with fetal-growth restriction, preeclampsia, and preterm birth.

Risk Factors

Risk factors for impaired fetal growth may be divided into three overlapping categories or "compartments": those in the mother, the fetus, or the placenta. Some of these are depicted in Figure 47-4. Many causes of FGR are prospectively considered risk factors, because impaired fetal growth is not consistent in all affected women.

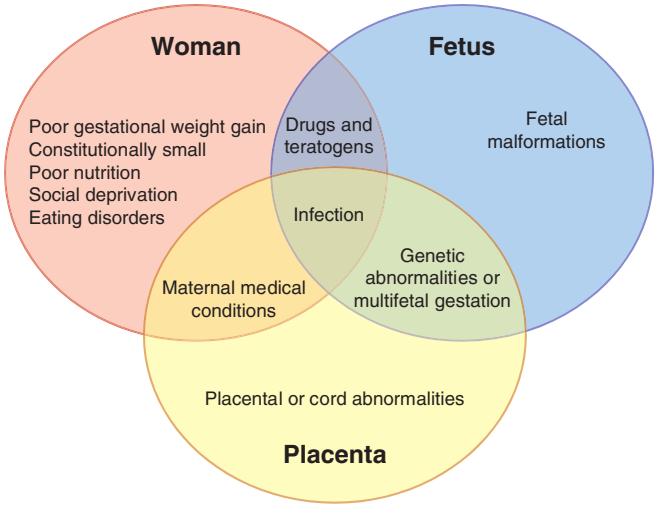

FIGURE 47-4 Risk factors and causes of impaired fetal growth centering on the mother, fetus, and placenta.

Gestational Weight Gain and Nutrition

Maternal weight gain during pregnancy is positively correlated with fetal size (Hutcheon, 2019). Among women with gestational diabetes, gestational weight gain is also associated with both neonatal birthweight and adiposity (Blackwell, 2016). In contrast, a gestational weight gain during the second and third trimesters that is less than that recommended by the Institute of Medicine is associated with increased risk of an SGA neonate in women of all weight categories except class II or III obesity (Durie, 2011) (Chap. 10, p. 183). The best-documented effect of famine on fetal growth was in the winter of 1944 in Holland. For 6 months, the German occupation army restricted dietary intake to 500 kcal/d for civilians, including pregnant women. As a result, the average birthweight declined by 250 g (Stein, 1975).

Undernourished women may benefit from micronutrient supplementation. In one study, almost 32,000 Indonesian women were randomly assigned to receive micronutrient supplementation or only iron and folate tablets (Prado, 2012). Offspring of those receiving the supplement had lower risks of early infant mortality and low birthweight and had improved childhood motor and cognitive abilities. A Cochrane review of 20 trials involving 141,849 women concluded that supplementation of micronutrients may lower the risk of low birthweight (Keats, 2019). The importance of antenatal vitamins and trace metals is discussed in Chapter 10 (p. 185).

Socioeconomic Factors

The effect of social deprivation on birthweight is interconnected with lifestyle factors such as smoking, alcohol or other substance abuse, and poor nutrition. With appropriate modifying interventions, women with psychosocial factors were significantly less likely to deliver a low-birthweight newborn and also had fewer preterm births and other pregnancy complications (Coker, 2012).

Food insecurity, late entry into prenatal care, and limited access to healthcare are all contributors to fetal-growth restriction (Bryant, 2010). Hall (2020) found that in a military population with equal access to healthcare, racial differences in late entry to prenatal care and FGR persist. An Australian study showed that the proportion of pregnancies affected by fetal-growth restriction increased as levels of social disadvantage rose (Langridge, 2011).

Vascular and Renal Disease

Especially when complicated by superimposed preeclampsia, chronic vascular disease commonly restricts fetal growth (Chap. 53, p. 948). Maternal vascular disease as evidenced by abnormal uterine artery Doppler velocimetry early in pregnancy is associated with higher rates of preeclampsia, SGA neonates, and delivery before 34 weeks (He, 2020; Poon, 2019). Using Washington state birth certificate data, Leary and colleagues (2012) found that maternal ischemic heart disease was associated with a 16-percent risk of having an SGA newborn.

Chronic renal insufficiency is frequently associated with underlying hypertension and vascular disease. Nephropathies are commonly accompanied by restricted fetal growth (Cunningham, 1990; Feng, 2015; Saliem, 2016). These relationships are considered further in Chapter 56 (p. 1004).

Pregestational Diabetes

Fetal-growth restriction in newborns of women with diabetes may be related to congenital malformations or may follow substrate deprivation from advanced maternal vascular disease (Chap. 60, p. 1072). The likelihood of restricted growth increases with worsening White classification, particularly nephropathy (Klemetti, 2016). That said, the prevalence of serious vascular disease associated with diabetes in pregnancy is low.

Chronic Hypoxia

Conditions associated with chronic hypoxia include asthma, maternal cyanotic heart disease, other chronic pulmonary disease, cigarette smoking, and living at high altitude. When exposed to a chronically hypoxic environment, some fetuses have significantly reduced birthweight. Smoking causes a dose-dependent reduction in fetal growth, resulting in an average birthweight 200 g below that of newborns of nonsmokers (D'Souza, 1981). For each 1000-meter rise in altitude, the birthweight declined 150 g in a study of more than 1.8 million births in Austria (Waldhoer, 2015).

Anemia

In most cases, maternal anemia does not impair fetal growth. Exceptions include sickle-cell disease and other inherited anemias (Desai, 2017; Thame, 2016). Importantly, curtailed maternal blood-volume expansion is linked to FGR (de Haas, 2017; Stott, 2017). This is further discussed in Chapter 4 (p. 59).

Antiphospholipid Syndrome

Adverse obstetrical outcomes including fetal-growth restriction have been associated with three types of antiphospholipid antibodies: *anticardiolipin antibodies, lupus anticoagulant*, and *anti-β2 glycoprotein-I antibodies*. Mechanistically, a "two-hit" hypothesis suggests that initial endothelial damage is then followed by intervillous placental thrombosis. More specifically, oxidative damage to certain membrane proteins is followed by antiphospholipid antibody binding, which leads to immune-complex formation and ultimately to thrombosis (Giannakopoulos, 2013). This syndrome is considered in detail in Chapters 55 (p. 979) and 62 (p. 1115). Women with more than one type of antiphospholipid

antibody are at higher risk for FGR compared with those with only one antibody (Saccone, 2017). Also, *anti-β_2 glycoprotein-I antibodies* may have a stronger association with FGR, particularly early-onset disease.

Placental, Cord, and Uterine Abnormalities

Several placental abnormalities are associated with poor fetal growth, which is presumed secondary to uteroplacental insufficiency. These are discussed further throughout Chapter 6 and include chronic placental abruption, extensive infarction, chorioangioma, velamentous cord insertion, and umbilical artery thrombosis. Abnormal placental implantation leading to endothelial dysfunction may also limit fetal growth (Brosens, 2015). This pathology is implicated in pregnancies complicated by preeclampsia (Chap. 40, p. 694). Last, some uterine malformations are linked to impaired fetal growth (Chap. 3, p. 43).

Multifetal Gestation

Pregnancy with two or more fetuses is more likely to be complicated by diminished growth of one or more fetuses compared with that of singletons (Fig. 47-5). Serial sonography is recommended for this reason. With the understanding that normal twin growth may be less than that of singletons, we use a chorionicity-specific twin nomogram to diagnose FGR at Parkland Hospital. Discordance in estimated fetal weight also is considered when evaluating twin growth (Chap. 48, p. 851).

Medications and Other Substances

Fortunately, most medications do not affect fetal growth. Selected medications and other substances that have been associated with FGR due to fetotoxicity are discussed in Chapter 8. Examples include cyclophosphamide and other antineoplastic drugs, significant lead exposure, and drugs such as cocaine and methamphetamine. Alcohol and tobacco each have potent effects on fetal growth. FGR is included among the diagnostic criteria for fetal alcohol syndrome, and cigarette smoking is associated with a two- to threefold increased risk of FGR (Werler, 1997).

Maternal and Fetal Infections

Viral, bacterial, protozoan, and spirochetal infections have been implicated in up to 5 percent of FGR cases and are discussed in Chapters 67 and 68. The best known of these are *rubella* and *cytomegalovirus infection*. Both promote calcifications in the fetus that are associated with cell death, and infection earlier in pregnancy correlates with worse outcomes. Toda and colleagues (2015) described a Vietnamese epidemic in which 39 percent of 292 term newborns with congenital rubella syndrome were low birthweight. In one study of 238 primary cytomegalovirus infections, no severe cases were observed when infection occurred after 14 weeks' gestation (Picone, 2013). These investigators later identified sonographic findings in 30 of 69 cases of congenital infection, and growth restriction was noted in 30 percent of these 30 cases (Picone, 2014).

Tuberculosis and *syphilis* also are associated with poor fetal growth. Both extrapulmonary and pulmonary tuberculosis are linked with low birthweight (Chap. 54, p. 965). Sobhy (2017) analyzed 13 studies that included a total of 3384 women with active tuberculosis. The odds ratio was 1.7 for low birthweight. The etiology is uncertain, however, the adverse effects on maternal health, compounded by effects of poor nutrition and poverty, are important (Jana, 2012). Congenital syphilis is more common, and paradoxically, the placenta is almost always larger and heavier than normal due to edema and perivascular inflammation (Chap. 68, p. 1208). Congenital syphilis is strongly linked with preterm birth and thus low-birthweight newborns (Sheffield, 2002).

Congenital infection with *toxoplasma gondii* is associated with FGR. Capobiango (2014) described 31 Brazilian pregnancies complicated by congenital toxoplasmosis. Only 13 percent were treated antepartum for toxoplasmosis, and low birthweight complicated nearly 40 percent of all the pregnancies. *Congenital malaria* may similarly cause low birthweight and poor fetal growth. Briand and colleagues (2016) emphasize the importance of prophylaxis early in pregnancy for women at risk.

Congenital Malformations

In a classic review of more than 13,000 fetuses with major malformations and chromosomal abnormalities, the rate of growth restriction was double the population prevalence (Khoury, 1988). The birth defect most strongly linked with FGR is gastroschisis. Nelson (2015) reviewed 111 fetuses with gastroschisis and found that a third had birthweights <10th percentile. Congenital cardiac abnormalities are also associated with a slight increase in FGR risk. In a recent review of 1789 singleton neonates with isolated congenital cardiac abnormalities, the prevalence of SGA was 13 percent, which was 3 percent higher than the general-population risk (Ghanchi, 2021). With few exceptions, the identification of growth restriction in the setting of a structural malformation further increases the risk for an underlying genetic syndrome. If not already performed, amniocentesis with chromosomal microarray analysis should be offered.

Genetic Abnormalities

Many genetic syndromes are strongly linked with prenatal-growth impairment or postnatal failure to thrive. Among live-born neonates with autosomal trisomies, trisomy 21 is associated with an SGA prevalence of 15 to 30 percent (Herrera, 2020; Khoury, 1988). With trisomies 13 and 18, the risk of SGA is significantly greater, 50 percent and >80 percent, respectively (Khoury, 1988). In trisomy 18, the combination of fetal abnormalities plus FGR and hydramnios is particularly common. The crown-rump length in fetuses with trisomy 18 and 13, unlike

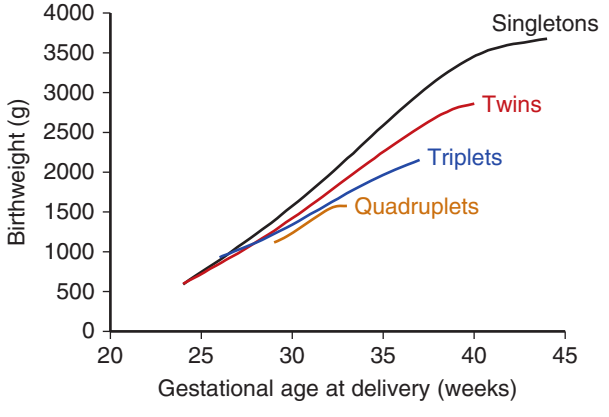

FIGURE 47-5 Birthweight and gestational age relationships in multifetal gestations without malformations delivered at Parkland Hospital.

that with trisomy 21, is also typically shorter than expected (Bahado-Singh, 1997; Schemmer, 1997). Poor fetal growth similarly complicates Turner syndrome, and the severity correlates with increasing haploinsufficiency of the short arm of the X chromosome (Fiot, 2016). In contrast, poor growth is not characteristic of an increased number of X chromosomes (Ottesen, 2010; Wigby, 2016). Discussed in Chapter 16 (p. 318), *confined placental mosaicism* is a recognized cause of FGR.

Management

If FGR is detected, efforts are made to assess the fetal condition and search for possible causes. The risk for stillbirth is increased, and early-onset growth restriction is especially problematic. General tenets of management include serial evaluation of fetal growth every 3 weeks and at least weekly evaluation of amnionic fluid and umbilical artery Doppler velocimetry. A fetus with slow but progressing EFW is more reassuring than one that has plateaued growth. This is supplemented with antepartum evaluation of fetal well-being, which is usually nonstress testing or biophysical profile (American College of Obstetricians and Gynecologists, 2021a) (Chap. 20, p. 387). Consideration is also given to performing a detailed fetal anatomic survey and amniocentesis to assess for underlying genetic abnormalities or infection—particularly with early-onset FGR. A management algorithm is shown in Figure 47-6.

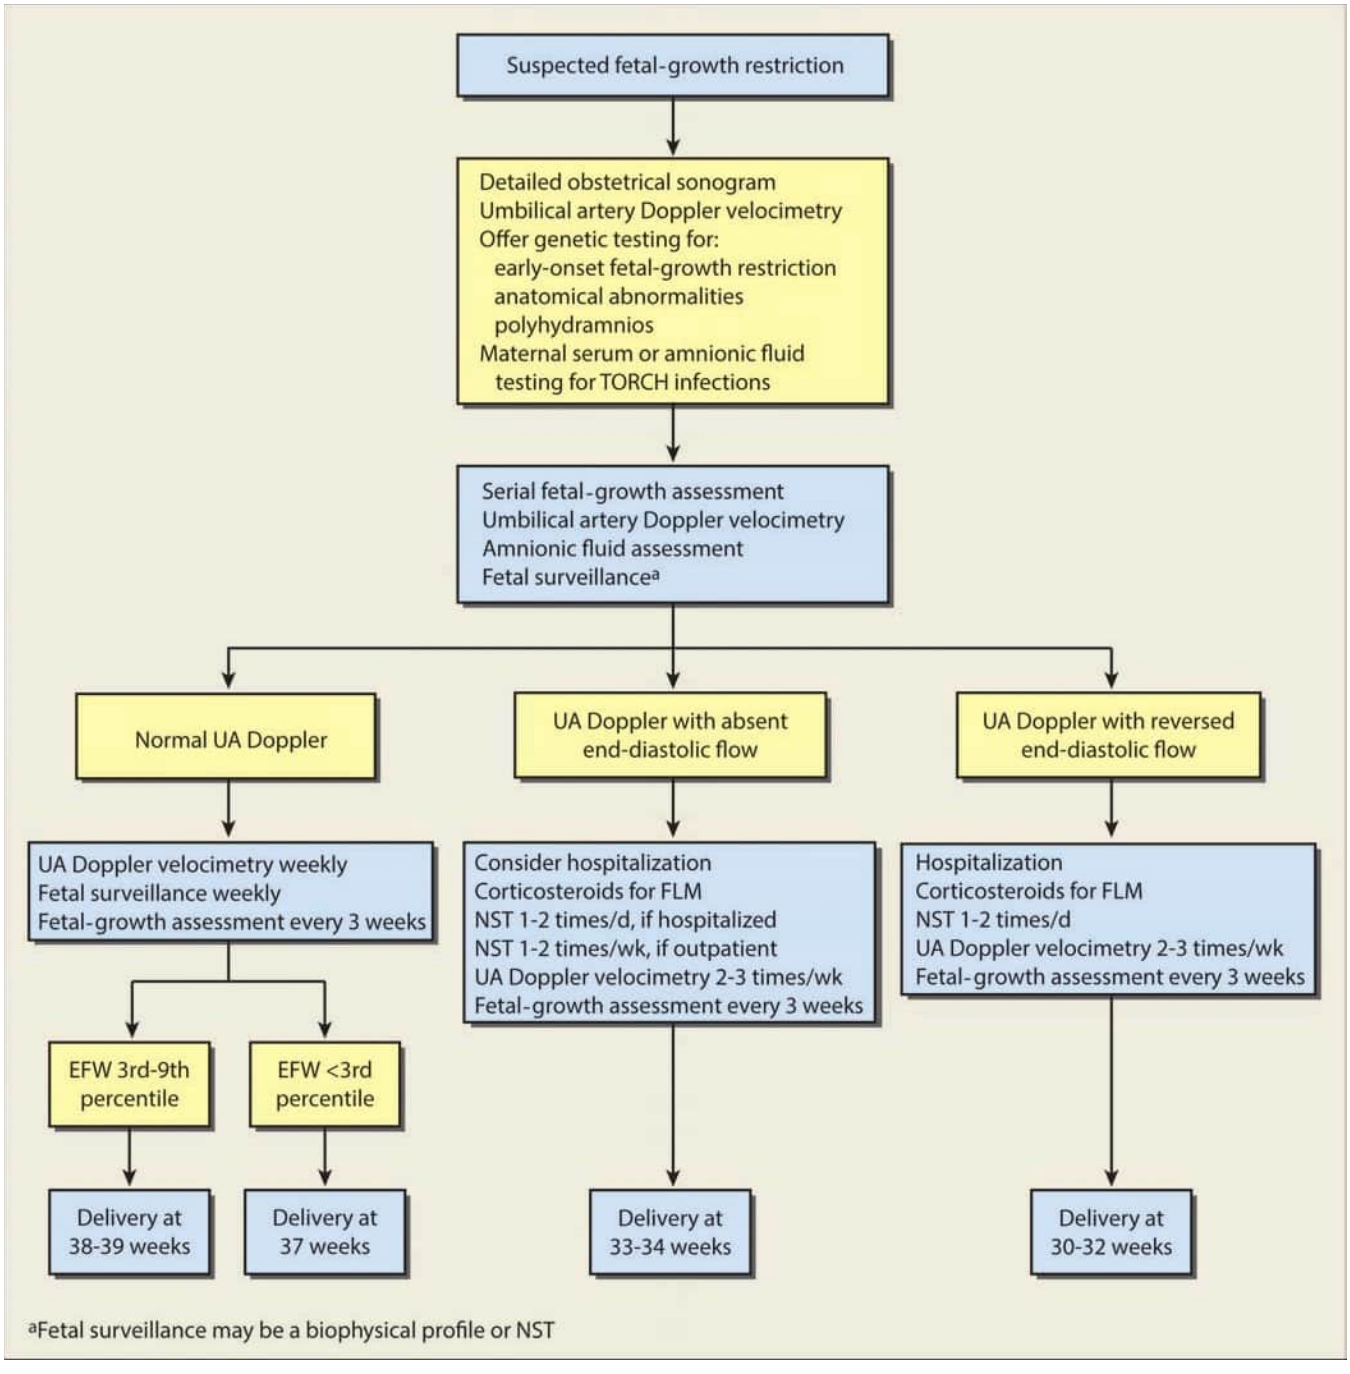

FIGURE 47-6 Algorithm for management of fetal-growth restriction. EFW = estimated fetal weight; FLM = fetal lung maturity; NST = nonstress test; TORCH = toxoplasmosis, other, rubella, cytomegalovirus, herpesvirus; UA = umbilical artery.

Delivery timing balances the risks of fetal death with the hazards of preterm birth. Several multicenter studies address these problems, but unfortunately, none has elucidated the optimal timing of delivery. For the preterm fetus, the only randomized trial of delivery timing is the Growth Restriction Intervention Trial (GRIT) (Thornton, 2004). This trial involved 548 women between 24 and 36 weeks' gestation. Women were randomly assigned to immediate delivery or to delayed delivery until the situation worsened. The primary outcome was perinatal death or disability after reaching age 2 years. Mortality rates did not differ through 2 years of age. Moreover, children aged 6 to 13 years did not show clinically significant differences between the two groups (Walker, 2011). The Disproportionate Intrauterine Growth Intervention Trial at Term (DIGITAT) study examined the delivery timing of growth-restricted fetuses who were 36 weeks' gestation or older. The 321 enrolled women were randomly assigned to labor induction or to expectant management. Composite neonatal morbidity rates did not differ, except that neonatal admissions were lower after 38 weeks' gestation in a secondary analysis (Boers, 2010, 2012). Secondary analyses of DIGITAT did not identify a clear subgroup that benefited from labor induction, and neurodevelopmental and behavioral outcomes at age 2 were similar in both groups (Tajik, 2014; Van Wyk, 2012).

Doppler Velocimetry

Umbilical artery Doppler flow studies are central to the evaluation and management of the fetus with growth restriction (Chap. 14, p. 262). Abnormalities represent the negative progression from fetal adaptation to failure. Specifically, initially increased impedance to flow in the umbilical artery may progress to absent end-diastolic flow and then reversed end-diastolic flow (Fig. 47-7). This negative progression correlates with hypoxia, acidosis, and fetal death. In one prospective series of 1116 fetuses with EFW <10th percentile, only 1 percent of those with normal umbilical artery Doppler studies had adverse outcomes compared with 12 percent of fetuses with Doppler abnormalities (O'Dwyer, 2014). The stillbirth risk in the setting of absent and reversed end-diastolic flow is 7 percent and 19 percent, respectively (Caradeux, 2018). Because of these findings, the American College of Obstetricians and Gynecologists (2021a,b) and Society for Maternal-Fetal Medicine (2020) recommend serial umbilical artery Doppler studies in the management of FGR.

Doppler abnormalities in other vessels may convey information regarding pathophysiology, but interrogation of these is not recommended for routine management of the pregnancy complicated by FGR (American college of Obstetricians and Gynecologists, 2021a; Society for Maternal-Fetal Medicine, 2020). Doppler abnormalities of the *ductus venosus* (Fig. 14-12, p. 264) reflect increased central venous pressure from decreased cardiac compliance and higher right ventricular end-diastolic pressure. Fetuses with abnormal ductus venosus Doppler flow have a 20-percent risk for stillbirth, and this increases to 46 percent in cases with a reversed A-wave (Caradeux, 2018). Second, pulsatile flow in the umbilical vein waveform (Fig. 14-12) indicates cardiac dysfunction. Last, cerebral vasodilation is the fetal adaptative response to hypoxemia in the setting of growth restriction. The cerebroplacental ratio (CPR)—defined as middle cerebral artery pulsatility index divided by umbilical artery pulsatility index—is a measure of this adaptation and may be abnormal in severe cases of FGR. An abnormal CPR <1 has been associated with greater risk for earlier delivery, lower birthweight, cesarean delivery, neonatal intensive care unit admission, and perinatal death (DeVore, 2015; Flood, 2014). However, a metaanalysis of 18,731 fetuses found the CPR was not predictive of adverse perinatal outcomes (Vollgraff, 2021).

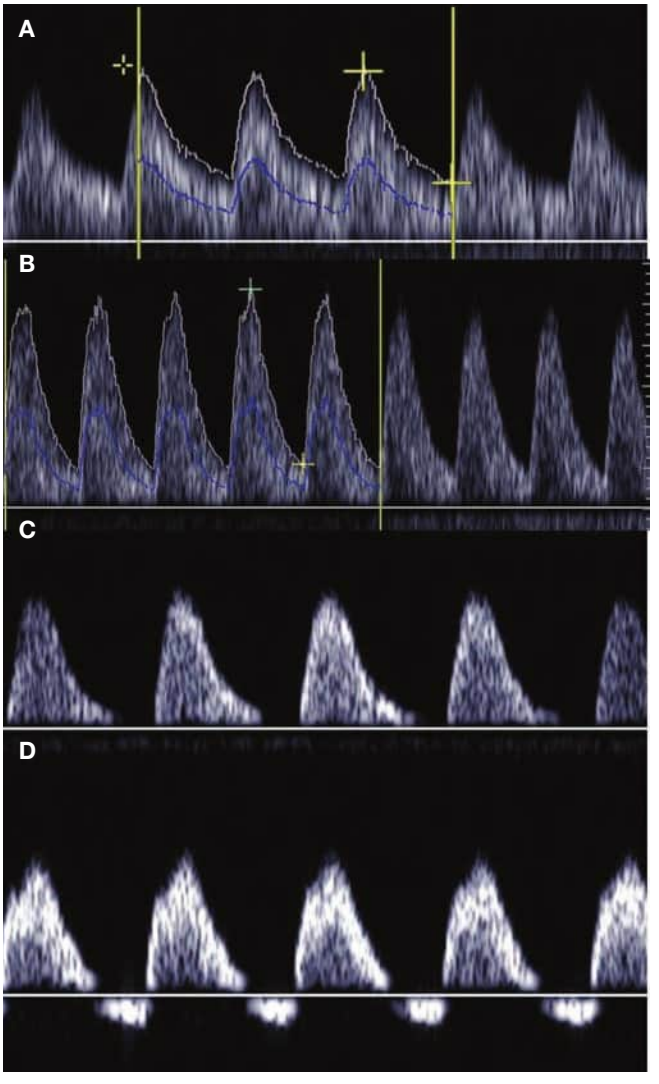

FIGURE 47-7 Doppler velocity waveforms. **A.** Normal waveform with normal S/D ratio. **B.** Increased impedance to flow with abnormally elevated S/D ratio. **C.** Absent end-diastolic flow. **D.** Reversed end-diastolic flow.

Management of the Near-term Fetus

Delivery of a suspected growth-restricted fetus with normal umbilical artery Doppler velocimetry, normal amnionic fluid volume, and reassuring fetal testing can likely be deferred until 37 to 38 weeks' gestation (see Fig. 47-6). Expectant management can be guided using antepartum evaluation of fetal well-being described in Chapter 20. If oligohydramnios is present, delivery between $36^{0/7}$ and $37^{6/7}$ weeks' gestation is recommended (American College of Obstetricians and Gynecologists, 2021c;

Society for Maternal-Fetal Medicine, 2020). With a normal fetal heart rate pattern, vaginal delivery is planned. Notably, some of these fetuses do not tolerate labor.

Management of the Fetus Remote from Term

If growth restriction is identified in a fetus before 34 weeks, and amnionic fluid volume and fetal surveillance findings are normal, observation is recommended. As long as interval fetal growth and fetal surveillance test results are normal, pregnancy is allowed to continue (see Fig. 47-6). Reassessment of fetal growth is typically made no sooner than 3 weeks later. Weekly outpatient assessment of umbilical artery Doppler velocimetry and amnionic fluid volume is combined with fetal well-being testing. If umbilical artery Doppler studies indicate absent or reversed end-diastolic flow, inpatient surveillance is undertaken. During hospitalization, more frequent sonographic evaluations and antenatal testing of fetal well-being and close proximity to labor and delivery are advantages.

With growth restriction remote from term, no specific treatment ameliorates the condition. Evidence does not support diminished activity or bed rest to accelerate growth or improve outcomes. Nutrient supplementation, attempts at plasma volume expansion, oxygen therapy, antihypertensive drugs, heparin, and aspirin are all ineffective (American College of Obstetricians and Gynecologists, 2021a).

Management decisions hinge on assessment of the relative risks of fetal death during expectant management versus the risks from preterm delivery. Reassuring results from fetal well-being tests may allow observation with continued maturation. However, long-term neurological outcome, which theoretically may suffer from additional weeks in an inhospitable intrauterine environment, is a concern (Baschat, 2014; Lees, 2015; Thornton, 2004). Baschat and associates (2009) showed that neurodevelopmental outcome at 2 years in growth-restricted fetuses was best predicted by birthweight and gestational age. Doppler abnormalities are generally not associated with poor childhood cognitive developmental scores among low-birthweight fetuses delivered in the third trimester (Llurba, 2013). These findings emphasize that adverse neurodevelopmental outcomes cannot always be predicted.

Intrapartum Management

When lagging fetal growth is the result of placental insufficiency due to poor maternal perfusion or reduction of functional placenta, the fetal condition may be aggravated by labor. Equally important, oligohydramnios raises the likelihood of cord compression during labor. For these and other reasons, the frequency of cesarean delivery is increased.

The risk of neonatal hypoxia or meconium aspiration is also greater. Thus, care for the newborn should be provided immediately by an attendant who can skillfully clear the airway and ventilate a neonate as needed (Chap. 32, p. 586). The severely growth-restricted newborn is particularly susceptible to hypothermia and may also develop other metabolic derangements such as hypoglycemia, polycythemia, and hyperviscosity. Risk is greatest at the lowest extremes of birthweight (Baschat, 2009, 2014; Llurba, 2013).

Outcomes

Lessons learned from SGA neonates inform concerns about FGR. More than 50 years ago, Battaglia and Lubchenco (1967) classified SGA neonates as those whose weights were below the 10th percentile for their gestational age. The mortality rate of SGA neonates born at 38 weeks was 1 percent compared with 0.2 percent in those with larger birthweights. More recent data also indicate that the overall stillbirth rate among SGA neonates approximates 1 percent, which is twice as high as the population prevalence (Getahun, 2007).

The risk for abnormal neurological development also is greater in SGA neonates. In an analysis of nearly 3000 newborns born before 27 weeks' gestation, those weighing <10th percentile had a nearly fourfold higher risk of neonatal death or neurodevelopmental impairment and a nearly threefold greater risk of cerebral palsy compared with non-SGA neonates (De Jesus, 2013). In another analysis of more than 91,000 otherwise uncomplicated pregnancies, newborns with birthweights <5th percentile had a higher risk of low 5-minute Apgar score, respiratory distress, necrotizing enterocolitis, and neonatal sepsis than appropriate-weight neonates. The risks of stillbirth and neonatal death were sixfold and fourfold higher, respectively (Mendez-Figueroa, 2016).

Newborns at the lowest birthweight percentiles are at greatest risk for adverse outcome. In one study of more than 44,561 neonates, only 14 percent of those weighing <1st percentile at birth survived to discharge (Griffin, 2015). Poor motor, cognitive, language and attention, and behavioral outcomes in growth-restricted newborns unfortunately persist into early childhood and adolescence (Baschat, 2014; Levine, 2015; Rogne, 2015).

Early-onset Growth Restriction

Perinatal morbidities are further increased in the 30 percent of FGR pregnancies diagnosed prior to 32 weeks' gestation (Savchev, 2014). Thus, this gestational age is used to demarcate early-onset from late-onset growth restriction (Society for Maternal-Fetal Medicine, 2020). Early-onset FGR is typically more severe and more commonly associated with placental dysfunction and maternal hypertension than late-onset growth restriction (Aviram, 2019; Dall'Asta, 2017). Pregnancies with early-onset FGR have greater rates of umbilical artery Doppler abnormalities compared with those with late onset. Similar to pregnancies complicated by preeclampsia, increased maternal serum levels of antiangiogenic factors that include soluble vascular endothelial growth factor receptor 1 (sVEGFR-1) and soluble fms-like tyrosine kinase 1 (sFlt-1) are reported in pregnancies complicated by early-onset growth restriction (Kingdom, 2018; Korzeniewski, 2016) (Chap. 40, p. 694).

Barker Hypothesis

Thirty years ago, Barker (1992) hypothesized that *adult* mortality and morbidity are related to fetal and infant health. This includes both under- and overgrowth. In the context of FGR, numerous reports describe a relationship between suboptimal fetal nutrition and a higher risk of subsequent adult hypertension, atherosclerosis, type 2 diabetes, and metabolic

derangement (Colella, 2018; Jornayvaz, 2016). The degree to which low birthweight mediates adult disease is controversial, as weight gain in early life also appears important (Breij, 2014; Kerkhof, 2012; McCloskey, 2016).

Evidence suggests that FGR may affect organ development, particularly that of the heart. Individuals with low birthweight demonstrate cardiac structural changes and dysfunction that persist through childhood, adolescence, and adulthood (Crispi, 2018). In one study, 80 infants who were born SGA before 34 weeks' gestation were compared at 6 months with 80 normally grown infants (Cruz-Lemini, 2016). The ventricle in SGA infants was more globular, resulting in systolic and diastolic dysfunction. In another study, echocardiography in 418 adolescents showed that low birthweight was associated with a thicker left ventricular posterior wall (Hietalampi, 2012). However, these findings have unclear long-term significance (Cohen, 2016).

Growth restriction is also associated with postnatal structural and functional renal changes. Luyckx and Brenner (2015) concluded that both low and high birthweight, maternal obesity, and gestational diabetes adversely affect in-utero development of the kidney and its health into adulthood. However, other variables that include childhood nutrition, acute kidney injury, excessive childhood weight gain, and obesity also worsen long-term renal function.

Prevention

Ideally, prevention begins before conception. Maternal medical conditions are treated, and medications are modified to help lower FGR risks. Smoking cessation is critical. Other risk factors are tailored to the maternal condition, such as antimalarial prophylaxis for women living in endemic areas and correction of nutritional deficiencies. Treatment of mild to moderate hypertension does not reduce the incidence of SGA newborns (Chap. 53, p. 950).

Currently, no pharmacologic therapies prevent growth restriction. Considerable study of low-dose aspirin therapy has not demonstrated consistent benefit in low-risk pregnancies. Daily aspirin therapy did not reduce the risk for SGA neonates in a randomized trial of 1700 women (Rolnik, 2017). Two large metaanalyses involving more than 20,000 women did find that low-dose aspirin was associated with a significantly lower risk of FGR, whether initiated prior to or after 16 weeks' gestation (Meher, 2017; Roberge, 2017). A Cochrane database analysis showed a small reduction in the risk of SGA neonates with maternal aspirin therapy (Duley, 2019). However, these studies included women at risk for preeclampsia, and the modest decrease in the risk for growth restriction was a secondary finding. Because evidence in women without risk factors for preeclampsia is lacking, aspirin therapy for the prevention of FGR is not recommended (American College of Obstetricians and Gynecologists, 2020a, 2021a; Society for Maternal-Fetal Medicine, 2020)

FETAL MACROSOMIA

Definition

The term *macrosomia* is used rather imprecisely to describe a fetus whose estimated weight exceeds a threshold—typically 4000 g, 4500 g, or even 5000 g (American College of Obstetricians and Gynecologists, 2019a). Although obstetricians generally agree that neonates weighing <4000 g are not excessively large, a similar consensus has not been reached for the definition of macrosomia.

TABLE 47-2. Birthweight Distribution of 354,509 Liveborn Infants at Parkland Hospital between 1988 and 2012

	Births		Maternal Diabetes	
Birthweight (g)	No.	%	No.	%
500–3999	322,074	90.9	13,365	86.2
4000–4249	19,106	5.4	1043	6.7
4250–4499	8391	2.4	573	3.7
4500–4649	3221	0.9	284	1.8
4750–4999	1146	0.3	134	0.7
5000–5249	385	0.1	57	0.4
5250–5499	127	0.04	31	0.2
5500 or more	59	0.02	14	0.09
Total	354,509		15,501	

Large for gestational age (LGA) denotes a fetus or newborn whose weight exceeds the 90th percentile for gestational age. Similar to SGA, the term LGA does not imply that growth is necessarily abnormal. Indeed, most such neonates are simply constitutionally larger than their peers. The 90th percentile for birthweight at 39 weeks' gestation approximates 3900 g (Duryea, 2014). Thus, most LGA neonates would not meet any of the common definitions of macrosomia.

In the United States in 2019, 6.4 percent of all newborns weighed 4000 to 4499 g; 0.9 percent weighed 4500 to 4999 g; and 0.1 percent were born weighing ≥5000 g (Martin, 2021). Similarly, during a 30-year period at Parkland Hospital, during which more than 350,000 singletons were born, only 1.4 percent of neonates weighed ≥4500 g (Table 47-2). We are of the view that the upper limit of fetal growth, above which growth can be deemed abnormal, is likely to be two standard deviations above the mean. This represents perhaps 3 percent of births. At 40 weeks, such a threshold would correspond to approximately 4500 g.

Detection

Because current methods fail to accurately estimate excessive fetal size, macrosomia cannot be definitively diagnosed until delivery (American College of Obstetricians and Gynecologists, 2019a). Inaccuracy in estimates of fetal weight, by either fundal height measurement or sonography, are often attributable to maternal obesity. In one study of 502 patients with sonographic estimated fetal weights >4000 g within 2 weeks of delivery, the risk of birthweight overestimation was >50 percent (Zafman, 2020). Of those who underwent cesarean delivery for suspected LGA, almost 30 percent delivered a neonate weighing <4000 g.

Pathophysiology

Particularly in women with diabetes and elevated cord blood levels of insulin-like growth factor 1, fetal macrosomia is asso-

Racial and ethnic factors

ciated with greater neonatal fat mass and morphological heart changes. Pedersen (1954) first proposed that hyperglycemia leads to fetal hyperinsulinemia and fetal overgrowth. This has been extended to organ dysmorphia, for example, increased interventricular septal thickness in neonates of mothers with gestational diabetes (Aman, 2011; Garcia-Flores, 2011). The cardiopulmonary vasculature also is adversely affected by diabetes in pregnancy. In 3277 cases of persistent pulmonary hypertension of the newborn, maternal obesity, diabetes, and both deficient and excessive fetal growth were independent risk factors (Steurer, 2017). Long-term metabolic consequences of fetal macrosomia in the setting of maternal obesity are discussed in Chapter 51 (p. 907).

Risk Factors

Some factors associated with fetal macrosomia are listed in Table 47-3. Many are interrelated. Advancing age usually correlates with multiparity and risk for diabetes, and obesity is similarly associated with diabetes. In one study, the birth prevalence of macrosomia exceeded 24 percent among obese women in China, and macrosomia rates were approximately 2.5-fold higher for prolonged pregnancy and gestational diabetes (Wang, 2017). As shown in Table 47-2, maternal diabetes is strongly associated with neonates weighing >4000 g. In a prospective study of 682 consecutive pregnancies complicated by diabetes, women with type 1 diabetes were significantly more likely than women with type 2 diabetes to have a neonate weighing above the 90th and 97.7th percentiles (Murphy, 2011). Higher third-trimester glucose concentration correlates with fetal macrosomia, and hemoglobin A_{1c} and fasting glucose values are independent predictors of macrosomia risk (Cyganek, 2017). Notably, maternal diabetes is associated with only a small percentage of the total number of LGA newborns.

Management

Several interventions have been proposed to interdict suspected or "impending" fetal overgrowth. Exercise in pregnancy is beneficial to the mother, does not increase the risk for growth impairment, and decreases macrosomia risk. One metaanalysis of 28 studies involving 5322 women concluded that exercise reduces the risk of an LGA newborn or birthweight >4000 g without raising the risk of an SGA neonate or birthweight <2500 g (Wiebe, 2015). Similarly, others have concluded that aerobic exercise increases the likelihood of a normal weight neonate (Di Mascio, 2016; Perales, 2016).

For women with diabetes, insulin therapy and glycemic control may lower the prevalence of neonatal macrosomia but have not consistently translated into reduced cesarean delivery rates. Fetal macrosomia, irrespective of the diagnosis of diabetes mellitus, is strongly associated with maternal obesity and excessive gestational weight gain (Durie, 2011; Durst, 2016; Harper, 2015). Currently recommended weight gains for pregnancy according to maternal BMI are described in Chapter 10 (p. 183).

"Prophylactic" Labor Induction

Some clinicians have induced labor when fetal macrosomia was suspected in nondiabetic women. The rationale for this approach was to obviate further fetal growth and, in theory, reduce the risk of delivery complications or cesarean delivery. In a systematic review of 11 studies of expectant management compared with labor induction for suspected macrosomia, labor induction significantly increased cesarean delivery rates without improving perinatal outcomes (Sanchez-Ramos, 2002). In contrast, Magro-Malosso and colleagues (2017) performed a metaanalysis of four randomized trials involving 1190 women and concluded that labor induction at ≥38 weeks' gestation for suspected macrosomia significantly reduces the frequency of fetal overgrowth and fractures. In one of these studies, 822 women with suspected LGA fetuses were randomly assigned either to early-term delivery or to expectant management (Boulvain, 2015). There was a higher rate of vaginal delivery that was marginally significant and a lower composite measure of morbidity. The authors cautioned that any benefits should be balanced with the risks of early-term labor induction and delivery. Namely, a review of early-term births indicates that elective delivery before 39 weeks' gestation does not improve maternal outcomes and is associated with worse neonatal outcomes (Tita, 2016). We agree with the American College of Obstetricians and Gynecologists (2019a, 2020b) that current evidence does not support a policy for early labor induction or delivery before 39 weeks' gestation.

Elective Cesarean Delivery

With the delivery of macrosomic neonates, shoulder dystocia and its attendant risks described in Chapter 27 (p. 501) are major concerns. That said, 9 percent of these injuries still follow cesarean delivery (Johnson, 2020). Therefore, planned cesarean delivery on the basis of suspected macrosomia to prevent brachial plexopathy is an unreasonable strategy in the *general population* (Chauhan, 2005). Ecker and coworkers (1997) analyzed 80 cases of brachial plexus injury in 77,616 consecutive newborns at Brigham and Women's Hospital. They concluded that an excessive number of otherwise unnecessary cesarean deliveries would be needed to prevent a single brachial plexus injury in neonates born to women without diabetes. Others echoed these sentiments in their analysis of nondiabetic mothers (Rouse, 1996; Van der Looven, 2020).

Conversely, planned cesarean delivery may be a reasonable strategy for *diabetic* women with an estimated fetal weight >4250 or >4500 g. Conway and Langer (1998) described a protocol of routine cesarean delivery for sonographic estimates of ≥4250 g in diabetic women. This management significantly lowered the shoulder dystocia rate from 2.4 to 1.1 percent.

TABLE 47-4. Maternal and Fetal Outcomes for 208,090 Pregnancies Delivered at Parkland Hospital from 1998 through 2012

Outcome[a]	<4000 g n = 187,119	4000–4499 g n = 17,750	4500–4999 g n = 2849	≥5000 g n = 372	*p* value

ICN = intensive care nursery.

In summary, we agree with the American College of Obstetricians and Gynecologists that elective delivery for the fetus that is suspected to be overgrown is inadvisable, particularly before 39 weeks' gestation. Last, we also conclude that elective cesarean delivery is not indicated when estimated fetal weight is <5000 g among women without diabetes and <4500 g among women with diabetes (American College of Obstetricians and Gynecologists, 2019a, 2020b).

Outcomes

The adverse consequences of excessive fetal growth are considerable. Neonates with a birthweight of at least 4000 g have cesarean delivery rates exceeding 50 percent. This is particularly true with maternal obesity or diabetes or with birthweights >5000 g (Cordero, 2015; Crosby, 2017; Hehir, 2015). Neonatal morbidity is higher in LGA neonates compared with those with lower birthweights. Macrosomic newborns have higher rates of shoulder dystocia, obstetrical brachial plexus injuries, and birth fractures (Beta, 2019; Chauhan, 2017). Rates of shoulder dystocia vary greatly and can reach nearly 30 percent for macrosomic neonates when maternal diabetes is comorbid (Cordero, 2015). In general obstetrical populations that include diabetic mothers, dystocia rates are at least 5 percent for neonates with birthweights ≥5000 g (Crosby, 2017; Hehir, 2015). The risk for stillbirth is greater with macrosomia, and this risk rises with increasing birth weight (Salihu, 2020). Rates of postpartum hemorrhage, perineal laceration, and maternal infection, which are related complications, also are higher in mothers delivering overgrown newborns. Table 47-4 shows maternal and neonatal outcomes by birthweight for neonates >4000 g delivered at Parkland Hospital.

CHAPTER 48

Multifetal Pregnancy

Multifetal pregnancies may result from two or more fertilization events, from a single fertilization followed by a splitting of the zygote, or both. In part because of infertility therapy, the twin birth rate in the United States was 3.2 percent in 2019. For higher-order multifetal births, the number peaked in 1998 at 0.2 percent of all births. Subsequent efforts in the reproductive endocrinology community to curb this rate have led to declines. Specifically, the rate of triplets or more declined by 55 percent from 1998 to 2019 (Martin, 2021).

Multifetal gestations remain problematic for both the mother and her fetuses. For the fetus, multifetal births accounted for 3 percent of all live births in 2013 but for 15 percent of all infant deaths. Specifically, the infant mortality rate for twins was more than four times the rate for singletons, and for triplets it was 12-fold higher (Matthews, 2015). Neonates from multifetal gestations also make up a disproportionate percentage of very-low-birthweight newborns in the United States (Martin, 2021). These two outcomes in singletons and twins from Parkland Hospital are shown in Table 48-1. Risks for congenital malformations and preterm birth are greater with multifetal gestation and discussed later.

The mother may also experience higher morbidity and mortality rates, and these rise with the number of fetuses (Society for Maternal-Fetal Medicine, 2019). In one study of more than 44,000 multifetal pregnancies, the risks for preeclampsia, postpartum hemorrhage, and maternal death were twofold higher than these rates in singleton gestations (Walker, 2004). Rates of placenta previa and placenta accreta spectrum are increased (Miller, 2021a). Moreover, compared with rates for singletons,

TABLE 48-1. Selected Outcomes in Singleton and Twin Pregnancies Delivered at Parkland Hospital from 1988 through 2021

Outcome	Singletons (No.)	Twins (No.)
Pregnancies	456,120	5366
Births[a,b]	456,120	10,732
Stillbirths	2532 (5.6)	258 (24.0)
Neonatal deaths	918 (2.1)	186 (18.2)
Perinatal deaths	3453 (7.6)	444 (41.4)
Very low birthweight (<1500 g)	4450 (10.0)	1109 (108.8)

[a]Birth data are represented as number (per 1000).
[b]Denominator for neonatal deaths and very low birthweight is liveborn infants.
Data from Dr. Don McIntire.

the peripartum hysterectomy rate was threefold greater for twins and 24-fold higher for triplets or quadruplets in one study (Francois, 2005).

MECHANISMS OF MULTIFETAL GESTATIONS

Dizygotic versus Monozygotic Twinning

Multifetal gestations are often described by *zygosity*, *amnionicity*, and *chorionicity*, which are the number of zygotes, amnions, and chorions, respectively. Twin fetuses most often result from fertilization of two separate ova, which yields *dizygotic* or *fraternal twins*. Less often, twins arise from a single fertilized ovum that then divides to create *monozygotic* or *identical twins*.

Dizygotic twins are not in a strict sense true twins because they result from the maturation and fertilization of two ova during a single ovulatory cycle. Genetically, these twins are like any other pair of siblings. Twins of opposite sex are almost always dizygotic. Rarely, somatic mutations or chromosome aberration in one monozygotic twin can yield differing gender karyotype or phenotype. For example, postzygotic loss of the Y chromosome in one 46,XY twin creates a phenotypically female twin with 45,X Turner syndrome.

Monozygotic twins, although they have the same genetic heritage, also are usually not identical. For example, the division of one fertilized zygote into two does not necessarily yield equal sharing of protoplasmic material. In addition, monozygotic twins may be discordant for genetic mutations because of a postzygotic mutation, or they may have the same genetic disease but with marked variability in its expression. In female fetuses, skewed lyonization can produce differential expression of X-linked traits or diseases. Last, sesquizygosity is a rare event of dispermic fertilization that leads to monozygotic twins. Some cases may have sex discordance (Gabbett, 2019).

Monozygotic Twinning

Mechanisms underlying monozygotic twinning are poorly understood. One association is assisted reproductive technology (ART) and in-vitro fertilization (IVF). The monozygotic twinning incidence is twofold greater in pregnancies conceived using blastocyst transfer compared with transfer of a later-stage embryo. The predisposition to splitting may stem from culture media effects (Busnelli, 2019).

The outcome of the monozygotic twinning process depends on when division occurs as depicted in Figure 48-1. If zygotes divide within the first 72 hours after fertilization, two embryos, two amnions, and two chorions develop, and a *monozygotic, dichorionic, diamnionic* twin gestation evolves. Two distinct placentas or a single, fused placenta may develop. If division occurs between days 4 through 8, a *monozygotic, monochorionic, diamnionic* twin pregnancy results. By 8 days, the chorion and the amnion have already differentiated, and division results in two embryos within a common amnionic sac, which is a *monozygotic, monochorionic, monoamnionic* twin gestation. Conjoined twins result if division initiates later.

Rarely, monochorionic twins may be dizygotic. Mechanisms are unclear. In one review of 31 cases, nearly 80 percent were conceived after ART procedures, and 90 percent were associated with chimerism (Peters, 2017).

Factors Affecting Twinning

Dizygotic twinning is much more common than monozygotic splitting of a single oocyte, and its incidence is positively influenced by infertility treatment and by maternal age, race, heredity, and size. By contrast, the frequency of monozygotic twin births is relatively constant worldwide—approximately one set per 250 births. This incidence is generally independent of most demographic factors, except ART.

Of *infertility therapies*, ovulation induction with clomiphene citrate or with follicle-stimulating hormone (FSH) plus human chorionic gonadotropin (hCG) remarkably enhances the likelihood of multiple concurrent ovulations. Moreover, with IVF, the greater the number of embryos that are transferred, the greater the risk of twins or more. In 2017, ART contributed to 1.9 percent of all newborns in the United States and to 14.7 percent of all neonates in multifetal gestations (Sunderam, 2020). The American Society for Reproductive Medicine (2017) revised their guidelines regarding the number of embryos or blastocysts transferred during IVF to reduce the incidence of multifetal pregnancies. For example, women younger than 35 years are encouraged to receive a single-embryo transfer, regardless of embryo stage. These practices have effectively lowered multifetal rates (Martin, 2021).

Advancing maternal age and *delayed childbearing* are other important risk factors (Adashi, 2018; Otta, 2016). One explanation is FSH levels, which rise with age and lead to greater ovarian stimulation (Beemsterboer, 2006). Higher levels of FSH have been linked with dizygotic twinning (Lambalk, 1998). Another explanation may be a higher use of ART in older women. *Paternal age* has also been linked to twinning, but its effect is felt to be small (Abel, 2012).

Different races and ethnic groups vary in their frequency of multifetal births. In the United States in 2019, the twin birth rate was 4.1 percent in black women, 3.3 percent in whites, and 2.5 in Hispanics (Martin, 2021). In one rural community in Nigeria, twinning occurred once in every 20 births (Knox, 1960). These marked differences in twinning frequency may stem from racial variations in FSH levels (Nylander, 1973).

Heredity is another factor, and maternal influence appears to supersede that of the father. In a study of 4000 genealogical records, women who themselves were a dizygotic twin gave birth to twins at a rate of one set per 58 births (White, 1964). Women who were not a twin, but whose husbands were a dizygotic twin, gave birth to twins at a rate of one set per 116 pregnancies. Genome-wide association studies have identified potentially contributory genes, and two are related to FSH (Mbarek, 2016). However, the contribution of these variants to the overall incidence of twinning is likely small (Hoekstra, 2008).

Maternal size is another risk factor. Nylander (1971) showed an increasing gradient in the twinning rate in taller, heavier women. These had a twinning rate 25 to 30 percent higher than short, nutritionally deprived women. Likewise, another study found an association between greater maternal weight

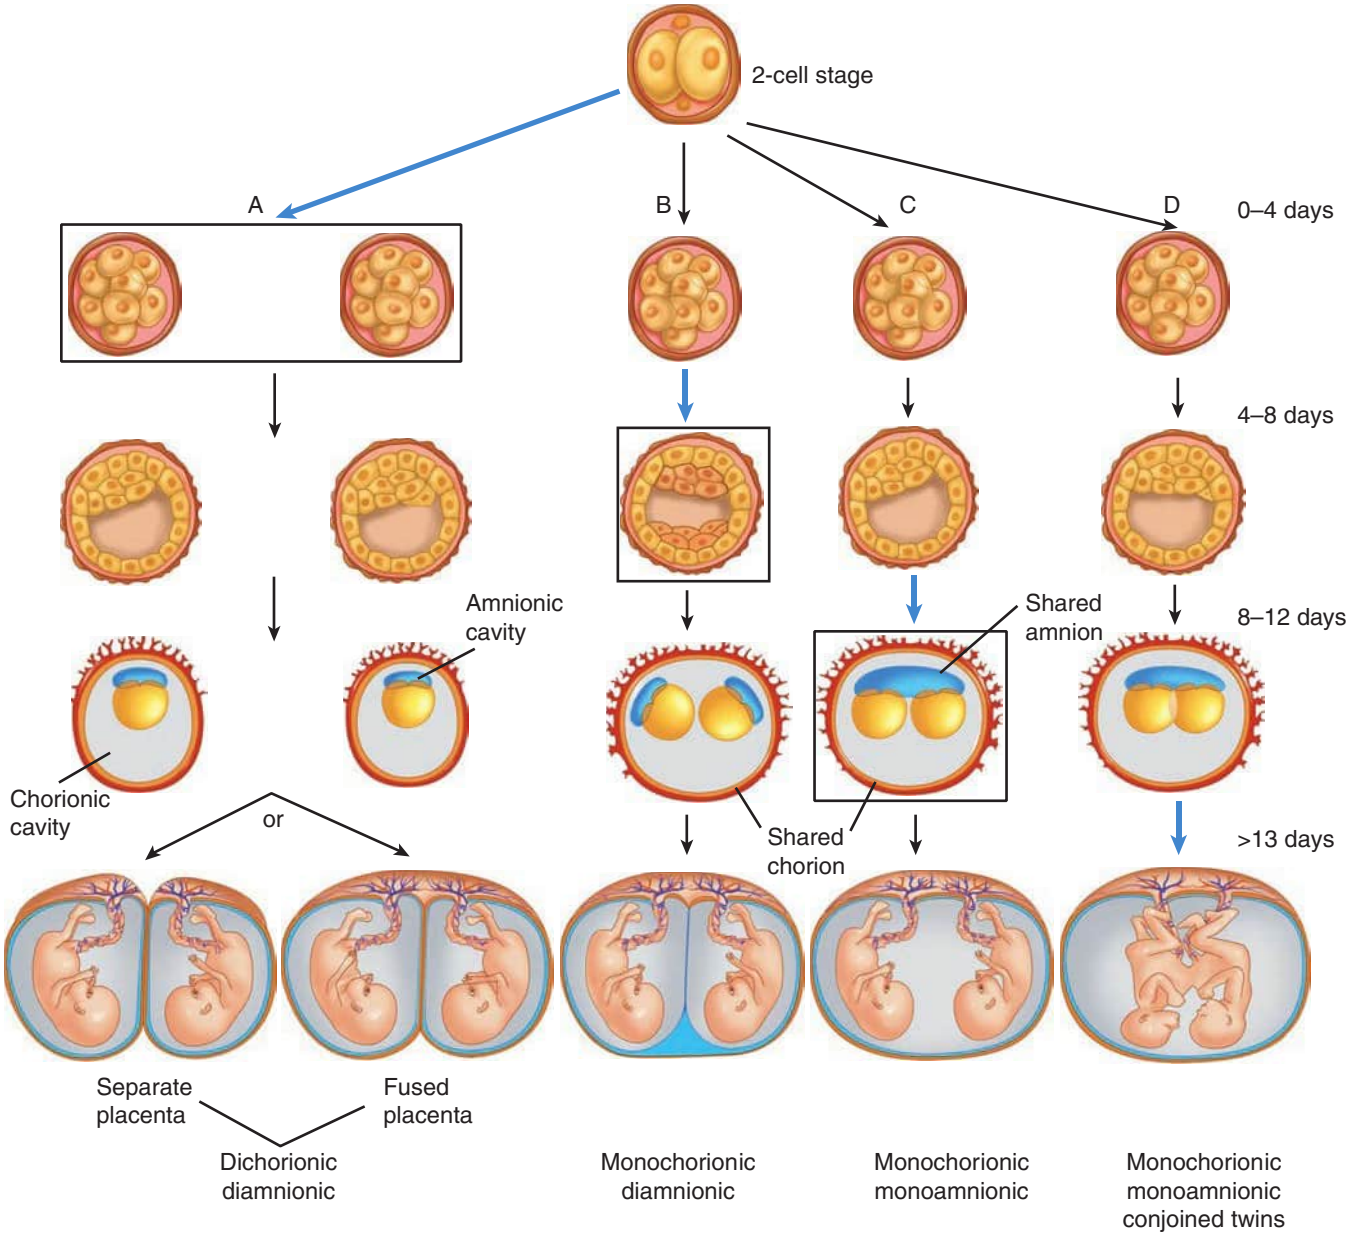

FIGURE 48-1 Mechanism of monozygotic twinning. Black boxing and blue arrows in columns A, B, and C indicate timing of division. **A.** At 0 to 4 days postfertilization, an early conceptus may divide into two. Division at this early stage creates two chorions and two amnions (dichorionic, diamnionic). Placentas may be separate or fused. **B.** Division between 4 to 8 days leads to formation of a blastocyst with two separate embryoblasts (inner cell masses). Each embryoblast will form its own amnion within a shared chorion (monochorionic, diamnionic). **C.** Between 8 and 12 days, the amnion and amnionic cavity form above the germinal disc. Embryonic division leads to two embryos with a shared amnion and shared chorion (monochorionic, monoamnionic). **D.** Differing theories explain conjoined twin development. One describes an incomplete splitting of one embryo into two. The other describes fusion of a portion of one embryo from a monozygotic pair onto the other.

and dizygotic twinning (Reddy, 2005). Evidence acquired during and after World War II suggests that twinning correlates more with nutrition than with body size. Widespread undernourishment in Europe during those years was associated with a marked fall in the dizygotic twinning rate (Bulmer, 1959).

■ Superfecundation and Superfetation

Superfecundation is fertilization of two ova within the same menstrual cycle but not at the same coitus nor necessarily by sperm from the same male. The latter leads to *heteropaternity* (Silver, 2021).

In *superfetation*, an interval as long as or longer than a menstrual cycle intervenes between fertilizations. Superfetation is not known to occur spontaneously and is likely due to ART (Lantieri, 2010). Pseudo-superfetation often results from markedly unequal growth of twins with the same gestational age.

DIAGNOSIS OF MULTIFETAL GESTATION

■ Clinical Evaluation

Early diagnosis can help with management of the associated risks posed by twins. Accurate fundal height measurement can

TABLE 48-2. Incidence of Some Complications Related to Twin Characteristics

Type of Twinning	Twins	Rates of Twin-Specific Complications in Percent			
		Fetal-Growth Restriction	Preterm Delivery[a]	Placental Vascular Anastomosis	Perinatal Mortality
Dizygotic	80	25	40	0	10–12
Monozygotic	20	40	50	—	15–18
Diamnionic/dichorionic	6–7	30	40	0	18–20
Diamnionic/monochorionic	13–14	50	60	100	30–40
Monoamnionic/monochorionic	<1	40	60–70	80–90	58–60
Conjoined	0.002 to 0.008	—	70–80	100	70–90

[a]Delivery before 37 weeks.

be an initial tool. With multiples, uterine size is typically larger during the second trimester than that expected for a singleton. In one study, fundal heights obtained between 20 and 30 weeks' gestation averaged 5 cm greater in twins than in singletons (Rouse, 1993).

Palpation of fetal parts to diagnose twins before the third trimester is difficult. Even then, obesity or hydramnios can hinder assessment. Palpating two fetal heads strongly supports the diagnosis. Moreover, a hand-held Doppler ultrasonic unit may isolate two fetal heartbeats if their rates are clearly distinct from each other and from the mother.

Overall, however, clinical criteria alone to diagnose multifetal gestations is unreliable. In the Routine Antenatal Diagnostic Imaging with Ultrasound (RADIUS) trial, for 37 percent of women who did not have a screening ultrasound examination, their twin pregnancy was not diagnosed until 26 weeks' gestation. In 13 percent of unscanned women, their multifetal gestation was identified only during their admission for delivery (LeFevre, 1993).

■ Sonography

Sonographic examination should detect practically all sets of twins. Further, it should aim to determine fetal number, estimated gestational age, chorionicity, and amnionicity. Importantly, the risk for many twin-specific complications varies in relation to these (Table 48-2) (Hack, 2008; Manning, 1995).

With sonography, separate gestational sacs, if present, can be identified early in twin pregnancy (Fig. 48-2). Subsequently, each fetal head should be seen in two perpendicular planes to avoid mistaking a fetal trunk for a second fetal head. Ideally, two fetal heads or two abdomens are seen in the same image plane to avoid scanning the same fetus twice and interpreting it as twins. Higher-order multifetal gestations are more challenging to evaluate. Even in the first trimester, identifying the actual number of fetuses and their position can be difficult. This determination is especially important if selective reduction is considered (p. 858).

In determining chorionicity, sonography's accuracy diminishes as gestational age advances. It has a 98-percent accuracy in the first trimester but may be incorrect in up to 10 percent of second-trimester examinations. Overall, chorionicity can be correctly determined with sonography before 24 weeks in approximately 95 percent of cases (Emery, 2015; Lee, 2006).

The sonographic features that are used to determine chorionicity vary according to gestational age. Early in the first trimester, the number of chorions equates to the number of

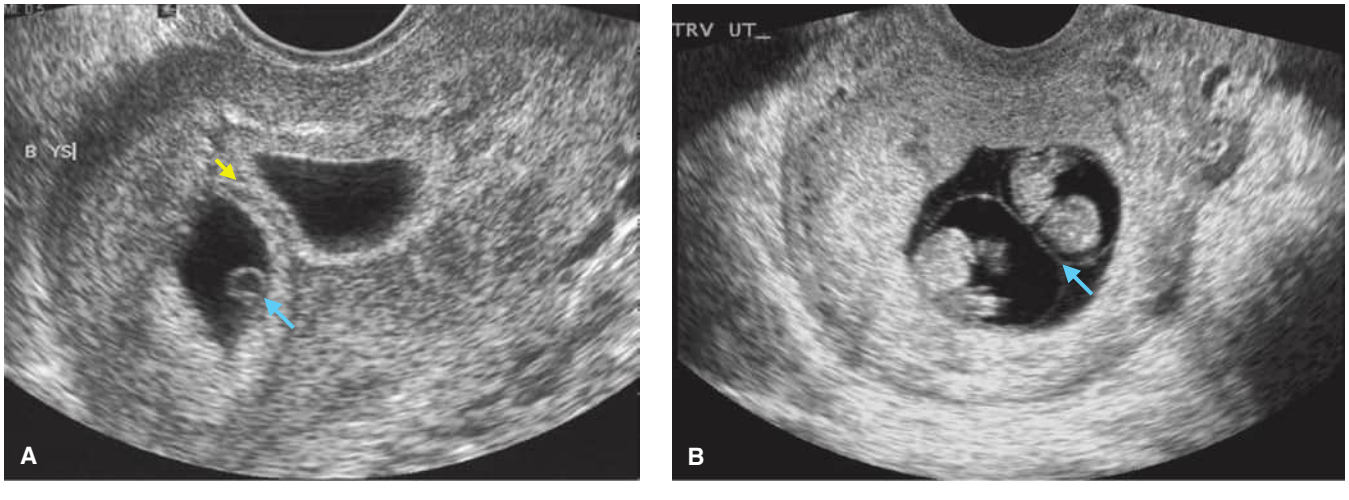

FIGURE 48-2 Sonograms of first-trimester twins. **A.** Dichorionic diamnionic twin pregnancy at 6 weeks' gestation. Note the thick dividing chorion (*yellow arrow*). One of the yolk sacs is indicated (*blue arrow*). **B.** Monochorionic diamnionic twin pregnancy at 8 weeks' gestation. Note the thin amnion encircling each embryo, resulting in a thin dividing membrane (*blue arrow*).

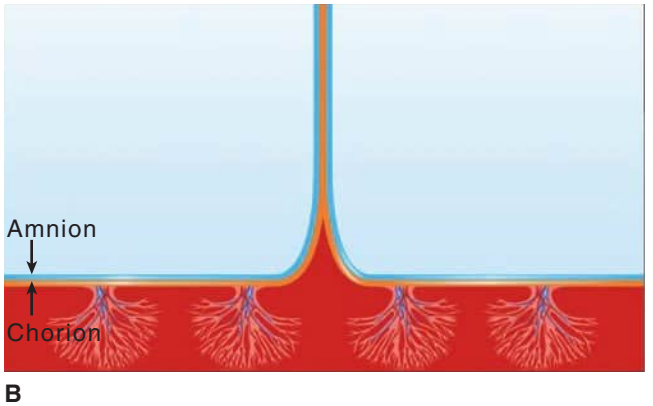
gestational sacs. A thick band of chorion that separates two gestational sacs signals a dichorionic pregnancy, whereas monochorionic twins have a single gestational sac. If the gestation is monochorionic diamnionic, it may be difficult to visualize the thin intervening amnion before 8 weeks' gestation. If the intervening membrane is difficult to visualize, the number of yolk sacs *usually* correlates with the number of amnions. However, the number of yolk sacs as a predictor of amnionicity may not always be accurate (Shen, 2006). Although uncommonly seen early, cord entanglement identifies a monoamnionic gestation.

At 10 to 14 weeks' gestation, sonographic assessment of chorionicity may be determined using four features. These are the number of placental masses, presence of an intervening membrane dividing the sacs, thickness of that membrane, and fetal gender (Emery, 2015; Khalil, 2016). First, two separate placentas suggest dichorionicity. The converse is not necessarily true, such as cases with a single fused placental mass. Second, identification of a thick dividing membrane—generally ≥2 mm—supports a presumed diagnosis of dichorionicity. In a dichorionic pregnancy, this visualized membrane is composed of four layers—two amnions and two chorions. Also, the *twin peak sign*—also called *lambda* or *delta sign*—is seen by examining the point of origin of the dividing membrane on the placental surface. The peak appears as a triangular projection of placental tissue extending a short distance between the layers of the dividing membrane (Fig. 48-3).

In contrast, monochorionic pregnancies have a dividing membrane that is so thin (generally <2 mm) that it may not be seen until the second trimester. The relationship between the membranes and placenta without apparent extension of placenta between the dividing membranes is called the *T sign* (Fig. 48-4). Evaluation of the dividing membrane can establish chorionicity in more than 99 percent of pregnancies in the first trimester (Maruotti, 2016; Miller, 2012). Lack of a dividing membrane signals a monochorionic monoamnionic gestation.

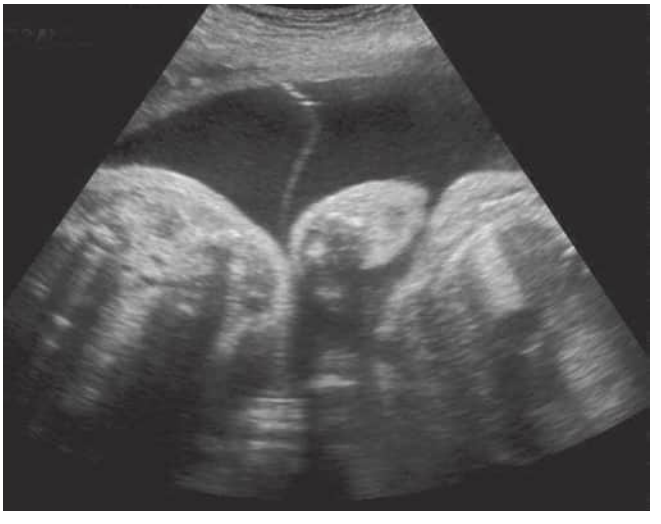
Last, twins with differing gender indicates a dichorionic (and dizygotic) gestation. Rare exceptions were described earlier (p. 839).

A

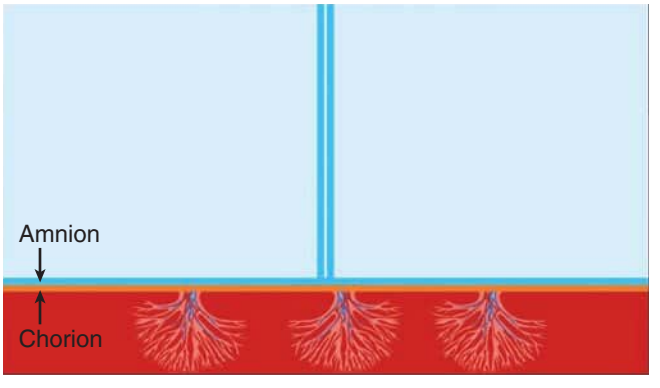


B

FIGURE 48-3 A. Sonographic image of the "twin-peak" sign, also termed the "lambda sign," in a 24-week gestation. At the top of this sonogram, tissue from the anterior placenta is seen extending downward between the amnion layers. This sign confirms dichorionic twinning. **B.** The "twin-peak" sign is seen at the bottom of this schematic diagram. The triangular portion of placenta insinuates between the amniochorion layers.



A



B

FIGURE 48-4 A. Sonographic image of the "T" sign in a monochorionic diamnionic gestation at 30 weeks. At the top of this sonogram, the two apposed amnion layers are seen as the thin line extending downward. **B.** Schematic diagram of the "T" sign. Twins are separated only by a membrane created by the juxtaposed amnion of each twin. A "T" is formed at the point at which amnions meet the placenta.

■ Other Diagnostic Aids

Magnetic resonance (MR) imaging may help delineate complications in monochorionic twins, including conjoined twins (Hu, 2006). Abdominal radiography can be used if fetal number in a higher-order multifetal gestation is uncertain. However, radiographs generally have limited utility and lead to an incorrect diagnosis if fetuses move during the exposure.

No biochemical test reliably identifies multifetal gestations. Serum levels of β-hCG and of maternal serum alpha-fetoprotein (MSAFP) are usually higher, but ranges may overlap with those of singletons.

■ Placental Examination

Careful visual examination of the placenta and membranes after delivery can establish zygosity and chorionicity in many cases. First, the placenta is gently delivered to preserve the attachment of the amnion and chorion. With one common amnionic sac or with juxtaposed amnions not separated by chorion, the fetuses are monozygotic (see Fig. 48-1). If adjacent amnions are separated by chorion, the fetuses could be either dizygotic or monozygotic, but dizygosity is more common (Fig. 48-5). If the neonates are of the same sex, blood typing of cord blood samples may be helpful. Different genders or blood types reflects dizygosity, although the same gender or blood type in each fetus does not confirm monozygosity. Postnatal zygosity genetic testing is available, and the benefits and ethics have been debated (Brown, 2015; Craig, 2015).

MATERNAL PHYSIOLOGICAL ADAPTATIONS

The physiological burdens of pregnancy and likelihood of serious maternal complications are typically greater with multifetal gestations than with singleton ones. In the first trimester and with its higher serum β-hCG levels, multifetal gestations often cause nausea and vomiting. In women carrying more than one fetus, blood volume expansion is greater and averages 50 to 60 percent compared with 40 to 50 percent in those with a singleton (Pritchard, 1965). This augmented hypervolemia teleologically offsets blood loss with vaginal delivery of twins, which is twice that with a single fetus. Although red cell mass also accrues, it does so proportionately less in twin pregnancies. Combined with greater iron and folate requirements, this predisposes to anemia.

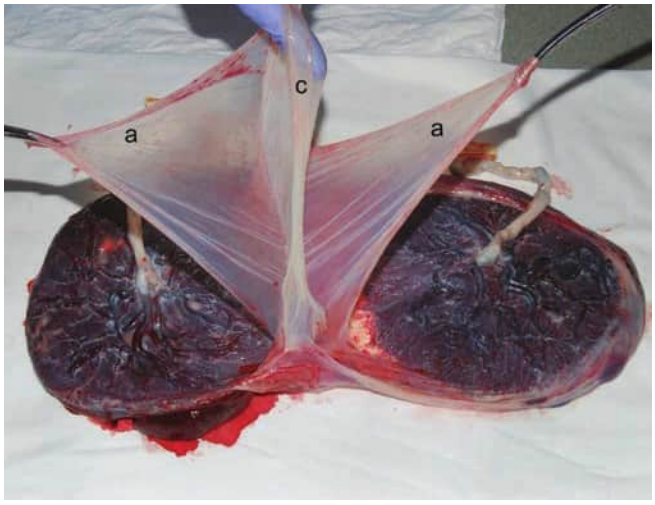


FIGURE 48-5 Dichorionic diamnionic twin placenta. The membrane partition that separated twin fetuses is elevated and consists of chorion (*c*) between two amnions (*a*).

Women carrying twins also have a typical pattern of blood pressure change. One study assessed serial blood pressures in more than 13,000 singleton and twin pregnancies (MacDonald-Wallis, 2012). As early as 8 weeks' gestation, the diastolic blood pressure in women with twins was lower than that with singleton pregnancies. It generally rose by a greater degree at term. An earlier study demonstrated that this later rise was at least 15 mm Hg in 95 percent of women with twins compared with only 54 percent of women with a singleton (Campbell, 1986).

Hypervolemia along with decreased vascular resistance has an impressive effect on cardiac function. In one study of 119 women with twins, cardiac output rose another 20 percent above that in women with a singleton (Kametas, 2003). Similarly, a study of serial maternal echocardiography examinations found a greater elevation in cardiac output in 20 women with uncomplicated twin pregnancies (Kuleva, 2011). Both studies found that the augmented cardiac output was predominantly due to greater stroke volume rather than higher heart rate. Vascular resistance was significantly lower in twin gestations throughout pregnancy compared with singleton ones. In a study of 30 uncomplicated twin pregnancies, this same group of investigators identified progressive diastolic dysfunction from the first to third trimester. The dysfunction subsequently normalized after delivery (Ghi, 2015).

Uterine growth in a multifetal gestation is substantively greater than in a singleton one. The uterus and its nonfetal contents may achieve a volume of 10 L or more and weigh in excess of 20 pounds. Especially with monozygotic twins, excessive amounts of amnionic fluid may rapidly accumulate. In these circumstances, maternal abdominal viscera and lungs can be appreciably compressed and displaced by the expanding uterus. As a result, the size and weight of the large uterus may preclude more than a sedentary existence for these women.

Rarely, maternal renal function can become seriously impaired, most likely as the consequence of obstructive uropathy (Jena, 1996). Hydramnios is a common associate, and therapeutic amniocentesis may provide relief for the mother, may improve obstructive uropathy, and possibly may lower rates of preterm labor or rupture of membranes. Unfortunately, hydramnios often develops remote from term and rapidly reaccumulates.

PREGNANCY COMPLICATIONS

Several complications, discussed next, complicate multifetal pregnancy. Others are preterm birth and discordant fetal growth, which are discussed in later sections.

■ Spontaneous Abortion and Vanishing Fetus

Among twins, monochorionic twins have significantly higher early fetal loss rates than dichorionic pairs (D'Antonio, 2013).

Twins achieved through ART may be at greater risk for abortion compared with those conceived spontaneously (Szymusik, 2012). However, among ART-conceived gestations, twins have lower miscarriage rates than singletons (Matias, 2007).

In some cases, only one fetus is spontaneously lost. As a result, the incidence of twins in the first trimester is much greater than the incidence of twins at birth. Estimates suggest that while 1 in 8 *pregnancies* begin multifetal, only 1 in 80 *births* are multifetal (Corsello, 2010). Sonography studies in the first trimester have shown that one twin dies and "vanishes" before the second trimester in 10 to 40 percent of all twin pregnancies (Brady, 2013; Harris, 2020). The incidence is higher following ART conception.

A vanishing fetus is more common in higher-order multiples. In one study of spontaneous reduction in 709 multifetal pregnancies before 12 weeks' gestation, one or more embryos died in 36 percent of twin pregnancies, in 53 percent of triplet pregnancies, and in 65 percent of quadruplet pregnancies (Dickey, 2002). Interestingly, in one study, ultimate pregnancy duration and birthweight were inversely related to initial gestational sac number regardless of the final number of fetuses at delivery (Seong, 2020). This effect was most pronounced in twins who started as quadruplets. Evidence for adverse immediate and long-term effects of twin spontaneous reduction on the remaining pregnancy is conflicting (Harris, 2020; McNamara, 2016).

Spontaneous reduction of a twin gestation may affect prenatal screening results. In one study of ART-conceived gestations, 56 twin pregnancies with a single early demise and 897 singleton gestations were compared (Gjerris, 2009). First-trimester serum marker concentrations did not differ between the groups if the embryonic loss was identified before 9 weeks' gestation. If diagnosed after 9 weeks, the marker levels were higher and less precise. With a vanishing twin, first-trimester maternal serum levels of the pregnancy-associated plasma protein A (PAPP-A) can be elevated. Second-trimester MSAFP and dimeric inhibin A levels also can be higher (Huang, 2015). Early loss of one twin may also affect noninvasive prenatal testing using cell-free DNA (cfDNA) (Chap. 17, p. 336). In one report, 15 percent of the false-positive results were attributed to this effect (Futch, 2013). The development of single-nucleotide polymorphism technology for cfDNA testing holds promise in better identifying these cases (Curnow, 2015). Thus, a spontaneously reduced abortus is ideally identified to help avoid confusion with results from aneuploidy and neural-tube defect screening.

Congenital Malformations

The incidence of these is appreciably higher in multifetal gestations compared with singleton ones. In one study, the congenital malformation rate was 406 per 10,000 twins compared with 238 per 10,000 singletons (Glinianaia, 2008). This rate in monochorionic twins was almost twice that of dichorionic twin gestations. One large study between 1998 and 2010 found that twins had a 73-percent greater risk of congenital heart disease than singletons. The occurrence risk and concordance were substantially higher among monochorionic twins (Best, 2015; Gijtenbeek, 2019).

From a 30-year European registry of multifetal births, structural anomaly rates rose steadily from 2.2 percent in 1987 to 3.3 percent in 2007 (Boyle, 2013). Yet, during this time, the proportion of dizygotic twins grew by 30 percent, whereas the proportion of monozygotic twins remained stable. This higher risk of congenital malformations in dizygotic twins over time correlated with increased availability of ART. An increase in birth defect rates related to ART has been reported (Wen, 2020). However, if data are adjusted for maternal age or duration of subfertility, the risk of congenital anomalies does not appear to be increased by ART (Zhu, 2006).

Low Birthweight

Multifetal gestations are more likely to be low birthweight than singleton pregnancies due to restricted fetal growth and preterm delivery. Birthweights in twins closely paralleled those of singletons until 28 to 30 weeks' gestation. Thereafter, twin birthweights progressively lagged (Fig. 48-6). Beginning at 35 to 36 weeks' gestation, twin birthweights clearly diverge from those of singletons. Thus, abnormal growth should be diagnosed only when fetal size is less than expected for *multifetal gestation*. Accordingly, twin and triplet growth curves have been developed (Kim, 2010; Odibo, 2013; Vora, 2006). To confirm suitable growth in dichorionic pairs, we perform sonography every 4 weeks, starting at 16 to 20 weeks. Monochorionic twins are imaged every 2 weeks for twin-twin transfusion syndrome (p. 848). To identify suspected fetal-growth restriction, we use the standards of birthweight for twin gestations stratified by placental chorionicity (Ananth, 1998).

Hypertension

Compared with mothers of singletons, those with multifetal gestations are more likely to develop a pregnancy-associated hypertensive disorder, and the incidence further rises with advancing fetal number (Day, 2005). In one analysis, 14 percent of parturients with twins developed a hypertensive disorder

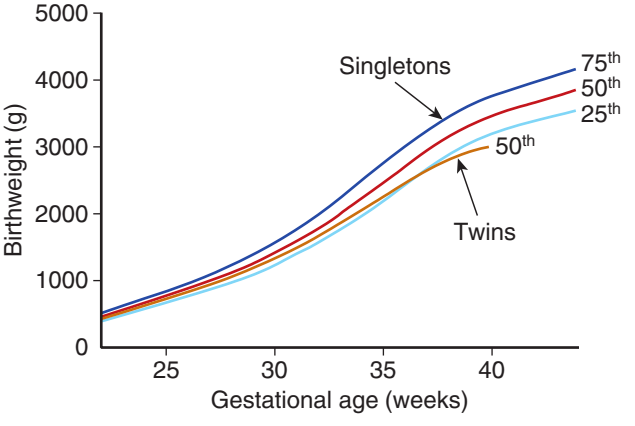

FIGURE 48-6 Birthweight percentiles (25th to 75th) for 357,205 singleton neonates compared with the 50th birthweight percentile for 3714 twins, Parkland Hospital 1988–2012. Infants with major malformations, pregnancies complicated by stillbirth, and twin gestations with >25 percent discordance also were excluded. (Data from Dr. Don McIntire.)

of pregnancy (Aviram, 2021). No specific zygosity confers a greater rate of these disorders (Lučovnik, 2016). However, with twins and gestational diabetes, the preeclampsia incidence is increased (Dave, 2021). Similar to singleton pregnancies with hypertensive disorders, fetal-growth restriction is a potential outcome (Proctor, 2019) (Chap. 40, p. 702).

Data suggest that rising fetal number and levels of antiangiogenic factor play roles in preeclampsia pathogenesis in multiples (Chap. 40, p. 694). Nonhypertensive women with twins compared with those with singletons have higher levels of the antiangiogenic factors *soluble fms-like tyrosine kinase 1 (sFlt-1)* and *soluble endoglin* and lower levels of proangiogenic *placental growth factor (PlGF)* (Faupel-Badger, 2015). In women with twins *and* preeclampsia in one study, both sFlt-1 levels and sFlt-1/PlGF ratios rose and PlGF concentrations declined compared with *normotensive* women with twins (Rana, 2012). Aspirin therapy is recommended to help prevent preeclampsia and is discussed with prenatal care (p. 853).

Long-term Infant Development

In cohort studies evaluating twin and singletons, academic performance is similar and is unaffected by ART-assisted conception (Christensen, 2006; Spangmose, 2017). For mono- or dichorionic pairs born preterm, neurodevelopment at 2 years was reported to be similar (Tosello, 2021).

However, among normal-birthweight neonates, the cerebral palsy (CP) risk is twofold higher among multifetal pregnancies compared with singletons. In term and preterm neonates from 12 large CP registries, the overall CP rate was 1.6 per 1000 singleton live births and 7 per 1000 live births from multifetal pregnancies (Perra, 2021). In this and another registry study, the higher CP rate in multifetal gestations was attributed mainly to prematurity (Sellier, 2021) (Chap. 34, p. 620). Fetal-growth restriction, congenital anomalies, twin-twin transfusion syndrome, and fetal demise of a co-twin are other potential contributors.

UNIQUE FETAL COMPLICATIONS

Several unique complications arise in multifetal pregnancies. These are described in twins but also can be found in higher-order multifetal gestations. Most fetal complications attributed to the twinning process itself are seen with monozygotic twins. Their pathogenesis is best understood after reviewing the possibilities shown in Figure 48-1.

Monoamnionic Twins

These twins make up less than 1 percent of all twin pregnancies and 4 percent of monochorionic pairs (Chitrit, 2021; Sebire, 2000). However, they have high rates of many significant complications.

Fetal loss rates in monoamnionic twins are substantial. Among fetuses alive before 16 weeks' gestation, less than half survive to the neonatal period. Fetal abnormalities and spontaneous miscarriage contribute to most losses (Prefumo, 2015). A high perinatal death rate is attributable to preterm birth, twin-twin transfusion syndrome, cord entanglement, birthweight discordance, and congenital anomalies (Buca, 2020; Saccone, 2020).

Congenital anomaly rates in monoamnionic twins reach 18 to 28 percent (Post, 2015). Concordance of anomalies is found in only approximately one quarter of cases. Because of the greater risk of cardiac anomalies, fetal echocardiography is indicated. Of note, monoamnionic twins are by definition monozygotic and thus presumed to be genetically identical, except in rare cases (Zwijnenburg, 2010). Interestingly, the risk for Down syndrome in each fetus of the monozygotic pair is similar to or lower than the risk in maternal age-matched singletons (Sparks, 2016).

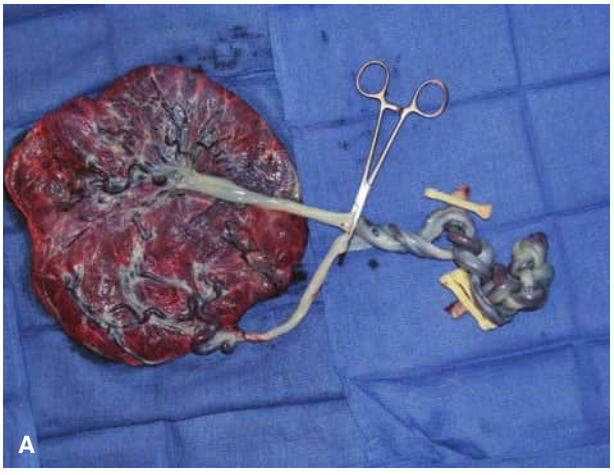
Twin-twin transfusion syndrome rates in monoamnionic twins are lower than in monochorionic diamnionic pregnancies (Murgano, 2020). This may be due to the near universal presence in monoamnionic twins of arterioarterial anastomoses, which are presumed to be protective (Hack, 2009). Nonetheless, twin-twin transfusion syndrome surveillance is recommended and described in that section.

Umbilical cord entanglement is a frequent event (Fig. 48-7). Although color-flow Doppler sonography can help diagnose entanglement, factors that lead to pathological umbilical vessel constriction are unknown. Fetal death from cord entanglement is thus unpredictable, and monitoring for this is relatively ineffective. Moreover, studies of inpatient or outpatient fetal surveillance of monoamnionic twin pregnancies show conflicting data. Heyborne and coworkers (2005) reported no stillbirths in 43 women admitted at 26 to 27 weeks' gestation for daily fetal surveillance. Conversely, 13 fetuses died in 44 women managed as outpatients. In the MONOMONO Working Group (2019) study of 195 women with these twins, the fetal death rate was 3.3 percent in 75 mothers admitted at 24 to 29 weeks' gestation compared with 10.8 percent in the 120 gravidas monitored outpatient. Notably, no fetal deaths occurred after 32 weeks' gestation in either group. Last, Van Mieghem and associates (2014) found the risk of "potentially preventable death" was not significantly different in women with inpatient (2.1 percent) or outpatient (4.7 percent) fetal surveillance.

In the United States, mothers with monoamnionic twins are often admitted at 24 to 28 weeks' gestation to begin 1 hour of daily fetal heart rate monitoring (American College of Obstetricians and Gynecologists, 2021b). Optimal surveillance is unclear and may include nonstress testing or biophysical profile assessment (Chap. 20, p. 386). Betamethasone, discussed later, is considered to promote pulmonary maturation (p. 855). If fetal testing remains reassuring and no other intervening indications arise, cesarean delivery is performed at $32^{0/7}$ to $34^{0/7}$ weeks' gestation. To help manage these many care items, the Society for Maternal-Fetal Medicine (2020) offers a prenatal checklist.

Unique and Aberrant Twinning

Several aberrations in monozygotic twinning result in a spectrum of fetal malformations. These are traditionally ascribed to incomplete splitting of an embryo into two separate twins. However, they theoretically may result from early secondary



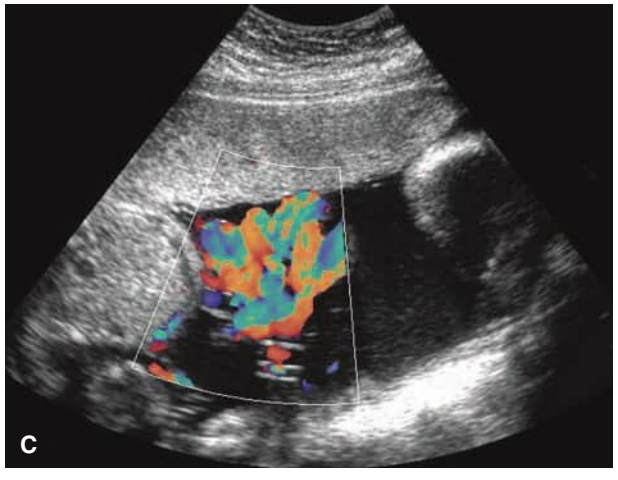


FIGURE 48-7 Monochorionic monoamnionic cord entanglement. **A.** Despite marked knotting of the cords, vigorous twins were delivered by cesarean. **B.** Preoperative sonogram of this pregnancy shows entwined cords. **C.** This finding is accentuated with application of color Doppler. (Reproduced with permission from Dr. Julie Lo.)

fusion of two separate embryos. These separated embryos are either symmetrical or asymmetrical. The spectrum of asymmetrical twinning includes external parasitic twins, fetus-in-fetu, and twin reversed-arterial-perfusion (TRAP) sequence, which is described later (p. 850).

Conjoined Twins

Joining of the twins may begin at either pole and produce characteristic forms depending on which body parts are joined or shared (Fig. 48-8) (Spencer, 2000). The frequency of conjoined twins has a prevalence of 1.5 in 100,000 births, and thoracopagus is the most common type (Mutchinick, 2011).

Conjoined twins can be identified using sonography in the first trimester (Chen, 2011). This provides an opportunity for parents to decide whether to continue the pregnancy. During sonographic interrogation, fetal poles are seen to be closely associated and do not change relative position from one another (Fig. 48-9). Other clues are more than three vessels in the umbilical cord, fewer limbs than expected, spine hyperflexion, bifid fetal pole, and increased nuchal thickness. Three-dimensional ultrasound, color Doppler, and MR imaging are valuable adjuncts to clarify shared organs (Baken, 2013).

Postnatal surgical separation may be successful if essential organs are not shared. Conjoined twins may have discordant structural anomalies that further complicate decisions about whether to continue the pregnancy. Consultation with a pediatric surgeon often assists with parental decisions.

Viable-aged conjoined twins should be delivered by cesarean. For pregnancy termination, however, vaginal delivery is possible because the union is often pliable. Still, dystocia is common, and vaginal delivery may be traumatic to the uterus or cervix.

External Parasitic Twins and Fetus-in-fetu

Attached to a relatively normal twin, an *external parasitic twin* is a grossly defective fetus or merely fetal parts. It usually consists of externally attached supernumerary limbs, often with some viscera. Classically, however, a functional heart or brain is absent. Parasitic twins are believed to derive from a dead defective twin, whose surviving tissue attaches to and receives vascular support from the normal co-twin (Spencer, 2001). In one study, parasitic twins accounted for 4 percent of all conjoined twins (Mutchinick, 2011).

With *fetus-in-fetu*, one embryo may enfold early within its co-twin and mainly intraabdominally. Normal development of this rare parasitic twin usually arrests in the first trimester. Thus, normal spatial arrangement and many organs are lacking. Classically, vertebral or axial bones are found in the fetiform mass, whereas a heart and brain are absent. These masses are thought to be a monozygotic, monochorionic diamnionic twin gestation and are typically supported by large parasitic vessels to the host (McNamara, 2016).

Monochorionic Twins and Vascular Anastomoses

All monochorionic placentas likely share some anastomotic connections. With rare exceptions, anastomoses between twins are unique to monochorionic twin placentas. However, the number, size, and direction of these seemingly haphazard connections vary markedly (Fig. 48-10). In one analysis of more than 200 monochorionic placentas, the median number of anastomoses was eight (Zhao, 2013).

Anastomoses may be artery-to-artery, vein-to-vein, or artery-to-vein communications and are located on the chorionic

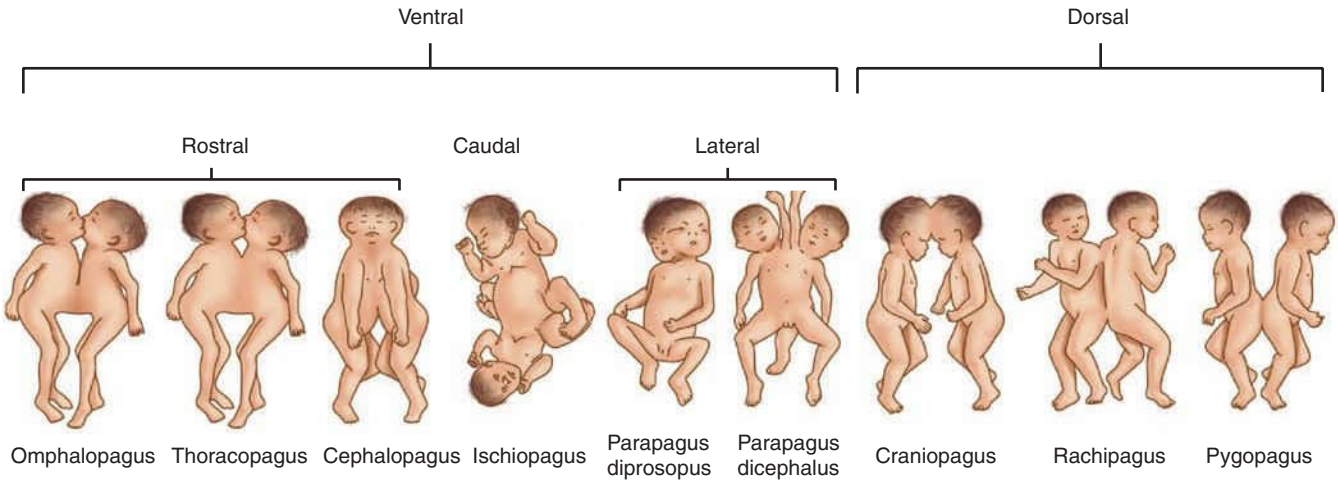

FIGURE 48-8 Types of conjoined twins.

FIGURE 48-9 Sonogram of a conjoined twin pregnancy at 13 weeks' gestation. These thoracoomphalopagus twins have two heads but a shared chest and abdomen.

surface of the placenta. In contrast to these superficial connections, deep artery-to-vein communications can extend through the capillary bed of a given villus (Fig. 48-11). These deep arteriovenous anastomoses create a common villous compartment or "third circulation" that has been identified in approximately half of monochorionic twin placentas.

Whether these anastomoses are dangerous to either twin depends on the degree to which they are hemodynamically balanced. In those with significant pressure or flow gradients, a shunt will develop between fetuses. This chronic fetofetal transfusion may result in several clinical syndromes that include *twin-twin transfusion syndrome (TTTS), twin anemia–polycythemia sequence (TAPS),* and *twin reversed-arterial-perfusion (TRAP) sequence*.

Twin-Twin Transfusion Syndrome

In this syndrome, blood is transfused from a donor twin to its recipient sibling such that the donor may eventually become

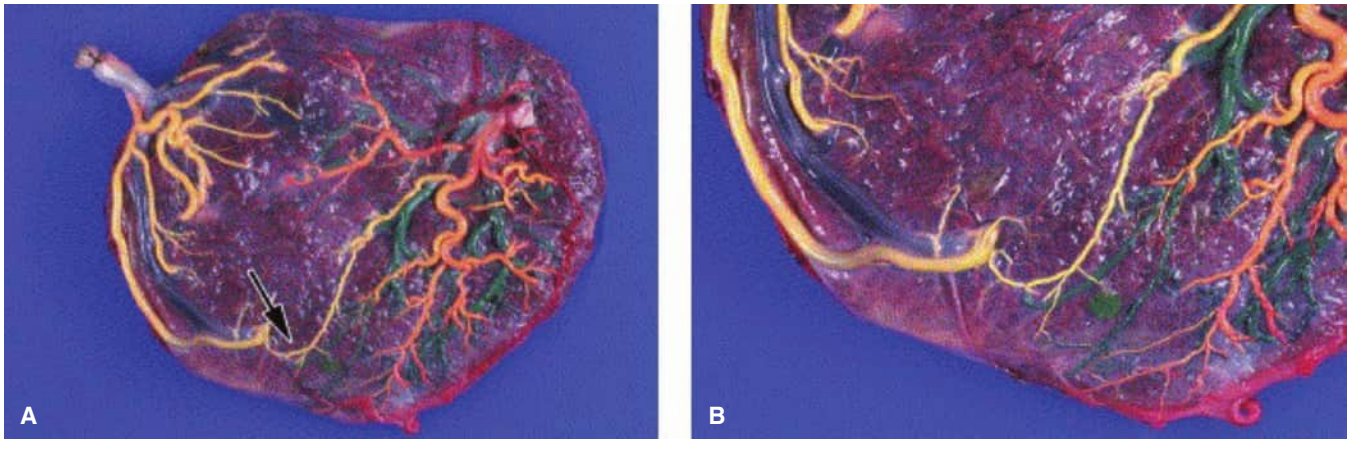

FIGURE 48-10 Shared placenta from pregnancy complicated by twin-twin transfusion syndrome. The following color code was applied for injection. Left twin: yellow = artery, blue = vein; right twin: red = artery, green = vein. **A.** Part of the arterial network of the right twin is filled with yellow dye, due to the presence of a small artery-to-artery anastomosis (*arrow*). **B.** Close-up of the lower portion of the placenta displays the yellow dye-filled anastomosis. (Reproduced with permission from De Paepe ME, DeKoninck P, Friedman RM: Vascular distribution patterns in monochorionic twin placentas, Placenta. 2005 Jul;26(6):471–475.)

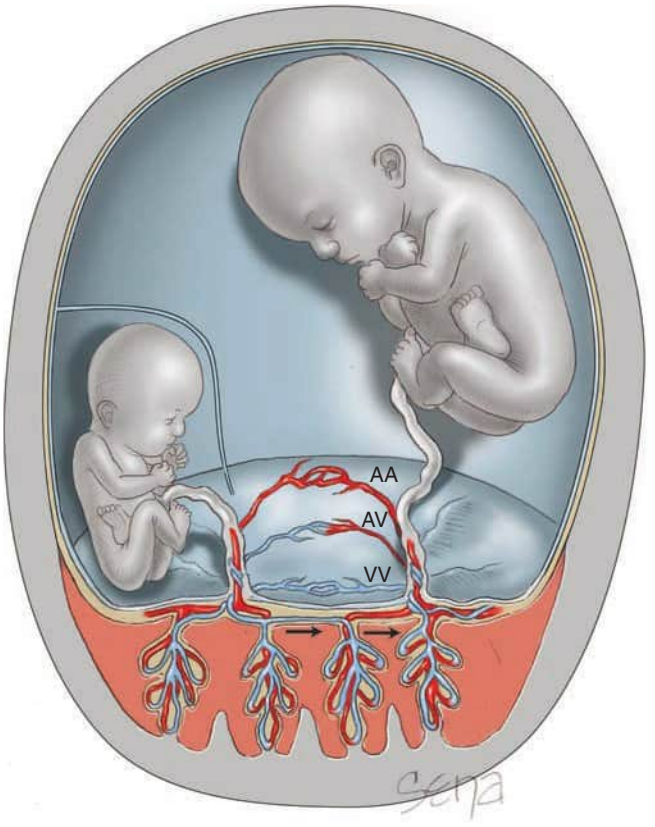

FIGURE 48-11 Anastomoses between twins may be artery-to-vein (AV), artery-to-artery (AA), or vein-to-vein (VV). Schematic representation of an AV anastomosis in twin-twin transfusion syndrome that forms a "common villous district" or "third circulation" deep within the villous tissue. Blood from a donor twin may be transferred to a recipient twin through this shared circulation. This transfer leads to a growth-restricted discordant donor twin (*left*) with markedly reduced amnionic fluid, causing it to be "stuck."

anemic and its growth may be restricted. In contrast, the recipient becomes polycythemic and may develop circulatory overload with heart failure manifest as hydrops. Classically, the donor twin is smaller and pale, and its recipient sibling is larger and has volume excess. As a result, the recipient neonate may suffer hyperviscosity and occlusive complications. Polycythemia in the recipient twin may also lead to severe hyperbilirubinemia and kernicterus (Chap. 33, p. 606). TTTS complicates 10 to 15 percent of monochorionic twins (Marwan, 2019).

Chronic TTTS results from unidirectional flow through deep arteriovenous anastomoses. Deoxygenated blood from a *donor* placental artery is pumped into a cotyledon shared by the recipient (see Fig. 48-11). Once oxygen exchange is completed in the chorionic villus, the oxygenated blood leaves the cotyledon via a placental vein of the *recipient* twin. Unless compensated—typically through superficial arterioarterial anastomoses—this unidirectional flow leads to volume depletion in the donor and volume excess in the recipient (Lewi, 2013).

TTTS typically presents in midpregnancy when the donor fetus becomes oliguric from hypovolemia and decreased renal perfusion (Society for Maternal-Fetal Medicine, 2013). This fetus develops oligohydramnios, and the recipient fetus develops severe hydramnios, presumably due to increased urine production from hypervolemia. Virtual absence of amnionic fluid in the donor sac prevents fetal motion, giving rise to the descriptive term *stuck twin* or *polyhydramnios–oligohydramnios syndrome—"poly–oli."* This amnionic fluid imbalance is associated with growth restriction, contractures, and pulmonary hypoplasia in the donor twin, and premature rupture of the membranes and heart failure in the recipient.

Fetal Brain Damage. Cerebral palsy, microcephaly, porencephaly, and multicystic encephalomalacia are serious complications associated with placental vascular anastomoses. The exact pathogenesis of neurological damage is not fully understood but is likely caused by ischemic necrosis leading to cavitary brain lesions. In the donor twin, ischemia results from hypotension, anemia, or both. In the recipient, ischemia develops from blood pressure instability and episodes of profound hypotension (Lopriore, 2011). Cerebral lesions may also be associated with preterm delivery (Chap. 34, p. 618). In one review of 315 liveborn fetuses from pregnancies with TTTS, cerebral abnormalities were found in 8 percent (Quarello, 2007).

If one twin of an affected pregnancy dies, blood is acutely transfused from high-pressure vessels of the living twin through anastomoses to low-resistance vessels of the dead twin. This leads rapidly to hypovolemia and possible ischemic antenatal brain damage in the survivor (Fusi, 1990, 1991). A less likely cause is emboli of thromboplastic material originating from the dead fetus.

The acuity of hypotension following the death of one twin with TTTS makes successful intervention for the survivor nearly impossible. Even with delivery immediately after a co-twin demise is recognized, the hypotension that occurs at the moment of death has likely already caused irreversible brain damage (Langer, 1997; Wada, 1998). As such, immediate delivery is not considered beneficial in the absence of another indication.

Diagnosis. TTTS is diagnosed based on two sonographic criteria (Society for Maternal-Fetal Medicine, 2013). First, a monochorionic pregnancy is identified. Second, hydramnios defined by a largest vertical pocket >8 cm in one sac and oligohydramnios defined by a largest vertical pocket <2 cm in the other twin is found. Growth discordance or growth restriction may be found with TTTS, but these per se are not considered diagnostic criteria.

Organizations that include the American College of Obstetricians and Gynecologists (2021b), Society for Maternal–Fetal Medicine (2013), and North American Fetal Therapy Network recommend sonographic surveillance of pregnancies at risk for TTTS (Emery, 2015). These examinations begin at approximately 16 weeks' gestation, and studies are performed every 2 weeks. In one study of 108 monochorionic twin pairs, a sonographic evaluation interval >2 weeks was associated with a higher Quintero stage at the time of TTTS diagnosis (Thorson, 2011).

Once identified, TTTS is typically classified by the Quintero (1999) staging system (Fig. 48-12):

- Stage I—discordant amnionic fluid volumes as described in the earlier paragraph, but urine is still visible sonographically within the bladder of the donor twin

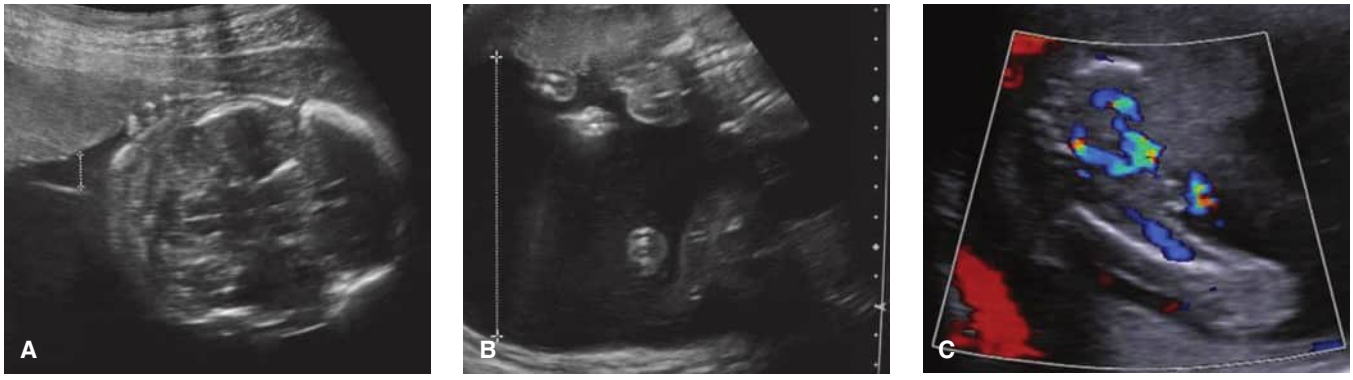

FIGURE 48-12 A. Sonogram of stage I TTTS at 19 weeks' gestation. Oligohydramnios in the donor twin sac causes the membrane to essentially wrap around the "stuck twin" and suspend it from the anterior uterine wall. **B.** In this same pregnancy, hydramnios is seen in the recipient twin sac. The measured pocket exceeds 10 cm. **C.** Stage II TTTS in a donor twin at 17 weeks' gestation. Color Doppler highlights the arteries that outline the fetal bladder, which contains no urine.

- Stage II—criteria of stage I, but urine is not visible within the donor bladder
- Stage III—criteria of stage II and abnormal Doppler studies of the umbilical artery, ductus venosus, or umbilical vein
- Stage IV—ascites or frank hydrops in either twin
- Stage V—demise of either fetus.

In addition to these criteria, cardiac function of the recipient twin also declines with TTTS (Wohlmuth, 2018). Although fetal echocardiographic findings are not part of the Quintero staging system, many centers routinely perform fetal echocardiography for TTTS. Theoretically, earlier diagnosis of fetal cardiomyopathy may identify pregnancies that would benefit from early intervention (Votava-Smith, 2015). One measure, the *myocardial performance index (MPI)*, is a Doppler index of each ventricle's function. Scoring systems that include cardiac function have been developed, but their usefulness to predict outcomes remains controversial (Miller, 2021b; Society for Maternal-Fetal Medicine, 2013).

Management and Prognosis. The prognosis for multifetal gestations complicated by TTTS is related to Quintero stage and gestational age at presentation. Some stage I cases remain stable or regress without intervention. However, 60 percent progress (Emery, 2016; Stirnemann, 2021). Conversely, outcomes in those identified at stage III or higher are much worse, and the perinatal loss rate is 70 to 100 percent without intervention (Miller, 2021b; Society for Maternal-Fetal Medicine, 2013).

Several therapies available for TTTS include laser ablation of vascular placental anastomoses, amnioreduction, and selective feticide. Similar to amniocentesis (Chap. 17, p. 344), amnioreduction is needle drainage of excess amnionic fluid.

These techniques have been evaluated in randomized trials. The Eurofetus trial included 142 women with severe TTTS diagnosed before 26 weeks' gestation. Participants were randomly assigned to laser ablation of vascular anastomoses or to serial amnioreduction (Senat, 2004). Laser ablation yielded a 76-percent rate of survival to age 6 months for at least one twin compared with a 51-percent rate with amnioreduction. Analyses of most randomized studies confirm better neonatal outcomes with laser therapy compared with selective amnioreduction (Marwan, 2019; Roberts, 2008; Rossi, 2008, 2009). However, evaluation of twins from the Eurofetus trial through 6 years of age did not demonstrate an additional survival benefit beyond 6 months or improved neurological outcomes in those treated with laser (Salomon, 2010). At this time, laser ablation of anastomoses is preferred for severe TTTS (stages II–IV). Optimal therapy for stage I disease is controversial, and laser ablation or expectant surveillance is an option (Emery, 2015; Stirnemann, 2021).

Of techniques, an ablation method may laser individual anastomoses or may ablate the entire vascular equator. This equator is the border between twin vasculature on the chorionic surface. Equatorial ablation, which is referred to as a *Solomon technique*, reduces the likelihood of TTTS recurrence. This method also lowers rates of TAPS, which can be a laser-therapy sequelae and described next (Slaghekke, 2014).

After laser therapy, close ongoing surveillance is necessary. Weekly ultrasound and Doppler studies are recommended (Marwan, 2019; Miller 2021b). These evaluations monitor fetal growth, amnionic fluid volumes, placental function, and anemia. Delivery timing is usually influenced by TTTS recurrence, fetal-growth restriction, or by abnormal Doppler velocimetry values, which reflect poor placental function (Chap. 47, p. 830).

Another treatment option, selective fetal reduction, has generally been considered if severe amnionic fluid and growth disturbances develop before 20 weeks. In such cases, both fetuses typically will die without intervention. Any substance injected into one twin may affect the other twin because of shared circulations. Thus, for the fetus chosen for reduction, feticidal methods aim to occlude the umbilical vein or umbilical cord. Radiofrequency ablation, fetoscopic ligation, or coagulation with laser, monopolar, or bipolar energy are options (Challis, 1999; Chang, 2009; Parra-Cordero, 2016). Even after these procedures, however, risks to the remaining fetus are still appreciable (Rossi, 2009). Early termination of the entire pregnancy is yet another option.

Twin Anemia–Polycythemia Sequence

Chronic fetofetal transfusion underlies this form, which is characterized by significant hemoglobin differences between donor and recipient twins. Similar to TTTS, the donor twin

in spontaneous TAPS is anemic and usually smaller than the recipient twin, which is polycythemic. However, TAPS lacks the discrepancies in amnionic fluid volumes typical of TTTS. *Spontaneous* TAPS can develop at any gestational age and complicates 1 to 6 percent of monochorionic twins (Marwan, 2019). *Iatrogenic* TAPS develops in up to 13 percent of pregnancies after laser ablation of the placenta and usually develops within 5 weeks of a procedure (Lewi, 2013; Tollenaar, 2021). In iatrogenic TAPS, the former TTTS recipient twin usually becomes anemic, whereas the former donor becomes polycythemic (Tollenaar, 2016).

Sonographically measuring blood flow velocity in the fetal middle cerebral artery (MCA) can accurately identify fetal anemia (Chap. 14, 262). Antenatally, TAPS is diagnosed by discordant MCA peak systolic velocity (PSV) values between twins. Specifically, an MCA-PSV value that is >1.5 multiples of the median (MoM) in the donor twin and <1.0 MoM in the recipient twin (Society for Maternal-Fetal Medicine, 2013). Others have suggested alternative threshold values (Khalil, 2020; Tollenaar, 2019).

A staging system for TAPS has been proposed, and higher stage is associated with increased perinatal mortality rate (Slaghekke, 2010; Tollenaar, 2021). Screening for *spontaneous* TAPS is controversial, as improvements in perinatal outcomes have not been demonstrated (Khalil, 2016; Society for Maternal-Fetal Medicine, 2013).

Management options include expectant care, delivery, laser surgery, intrauterine transfusion, selective feticide, and pregnancy termination. A clinical trial evaluating fetoscopic laser therapy for TAPS is currently ongoing. Antenatal surveillance mirrors that just described for TTTS. Again, delivery timing is usually influenced by worsening fetal growth or by abnormal Doppler velocimetry values. Postnatal treatment often requires blood transfusion for the donor twin and partial exchange transfusion of the recipient twin.

Twin Reversed-arterial-perfusion Sequence

Also known as *acardiac twinning*, this rare, serious complication of monochorionic multifetal gestation has an estimated incidence of 1 case in 35,000 births. With classic TRAP sequence, the twin pair is a normally formed donor twin that shows features of heart failure and a grossly malformed recipient twin that lacks a heart (acardius) and other structures. In one theory, the TRAP sequence is caused by a large artery-to-artery placental shunt, often also accompanied by a vein-to-vein shunt (Fig. 48-13). Within the single, shared placenta, arterial perfusion pressure of the donor twin exceeds that in the recipient twin. The recipient thus receives reversed blood flow containing deoxygenated arterial blood from its co-twin (Lewi, 2013). This "used" arterial blood reaches the recipient twin through its umbilical arteries and preferentially goes to its iliac vessels. Thus, only the lower body is perfused, and disrupted growth and development of the upper body follows. In these cases, failed head growth is called *acardius acephalus*; a partially developed head with identifiable limbs is called *acardius myelacephalus*; and failure of any recognizable structure to form is *acardius amorphous,* which is shown in Figure 48-14. Because of this vascular connection, the normal donor twin must not

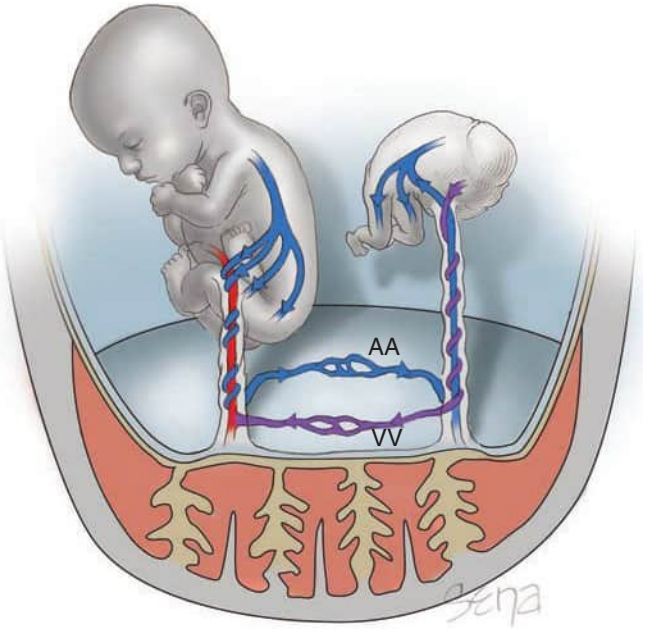

FIGURE 48-13 Twin reversed-arterial-perfusion sequence. In the TRAP sequence, there is usually a normally formed donor twin that has features of heart failure, and a recipient twin that lacks a heart. It is hypothesized that the TRAP sequence follows a large artery-to-artery placental shunt, often also accompanied by a vein-to-vein shunt. Within the single, shared placenta, perfusion pressure of the donor twin overpowers that in the recipient twin, who thus receives reverse blood flow from its twin sibling. The "used" arterial blood that reaches the recipient twin preferentially goes to its iliac vessels and thus perfuses only the lower body. This disrupts growth and development of the upper body.

FIGURE 48-14 Photograph of an acardiac twin weighing 475 grams. The underdeveloped head is indicated by the black arrow, and its details are shown in the inset. A yellow clamp is seen on its umbilical cord. Its viable donor co-twin was delivered vaginally at 36 weeks and weighed 2325 grams. (Reproduced with permission from Dr. Michael D. Hnat.)

only support its own circulation but also must pump blood to and through the underdeveloped acardiac recipient. This may lead to cardiomegaly and high-output heart failure in the donor twin (Fox, 2007; Marwan, 2019).

In the past, the donor-twin mortality rate exceeded 50 percent. This stemmed largely from complications of prematurity or from a prolonged high-output state leading to cardiac failure (Dashe, 2001). Risk is directly related to size of the acardiac twin. When the acardiac twin is large, treatment is generally offered. Radiofrequency ablation (RFA) is the preferred modality of therapy, and contemporary reports now suggest improved perinatal outcomes. The North American Fetal Therapy Network reviewed their experiences with 98 cases from 1998 to 2008 in which RFA of the umbilical cord was performed. Median gestational age at delivery was 37 weeks' gestation, and 80 percent of donor neonates survived (Lee, 2013).

Hydatidiform Mole with Coexisting Normal Fetus

This rare gestation contains one normal fetus, and its co-twin is a complete molar pregnancy. It must be differentiated from a partial molar pregnancy, which is a singleton, triploid fetus and its placenta composed of molar tissue (Fig. 13-4, p. 238).

Diagnosis in the first half of pregnancy is common. Sonographically, a normal-appearing twin is accompanied by its co-twin, which is a large placenta containing multiple small anechoic cysts. Often, these pregnancies are terminated, but pregnancy continuation is increasingly adopted. The live birth rate from one review was 50 percent (Zilberman, 2020). The risk of gestational trophoblastic neoplasia (GTN), which is a malignant sequelae of hydatidiform mole, is similar whether the pregnancy is terminated or not (Massardier, 2009; Sebire, 2002). Given the limited number of cases, robust data for firm recommendations are lacking. Discussed in Chapter 13 (p. 237), complications of expectant management include vaginal bleeding, hyperemesis gravidarum, thyrotoxicosis, and early-onset preeclampsia. Many of these complications result in preterm birth with its attendant adverse perinatal outcomes. Logically, close antepartum and postpartum surveillance is needed for those continuing the pregnancy. Postpartum GTN surveillance is essential and described in Chapter 13 (p. 240).

DISCORDANT GROWTH

Fetal size inequality develops in approximately 15 percent of twin gestations (Miller, 2012). Generally, as the weight difference within a twin pair grows, the perinatal mortality rate rises proportionately. Earlier discordancy and monochorionicity pose increased mortality risks for the smaller twin. Specifically, with discordant growth identified at or before 20 weeks' gestation in studies, 8 to 15 percent of the growth-restricted fetuses die (Couck, 2020; Curado, 2020; D'Antonio, 2018).

Pathogenesis

The etiology of growth discordance in monochorionic twins likely differs from that in dichorionic twins. First, in monochorionic twins, the single placenta is not always equally shared, and this leads to higher discordant growth rates than in dichorionic pairs (Fig. 48-15). In cases with TTTS, discordancy in monochorionic twins is usually attributed to placental anastomoses that cause a perfusion imbalance between twins. Reduced perfusion of the donor twin can diminish placental and fetal growth (Lewi, 2013). Last, monochorionic twins at times can be discordant in size because they are discordant for structural anomalies.

FIGURE 48-15 Marked growth discordance in monochorionic twins. (Reproduced with permission from Dr. Laura Greer.)

In dichorionic twins, discordancy may result from various factors. Dizygotic fetuses may have different genetic growth potential, especially if they are of opposite genders. Second, because the placentas are separate and require more implantation space, one placenta might have a suboptimal implantation site. Additionally, umbilical cord abnormalities such as velamentous insertion, marginal insertion, or vasa previa may play a role (Chap. 6, p. 114). One study showed that the incidence of severe discordancy is twice as great in triplets as it is in twins (Bagchi, 2006). This supports the view that in-utero crowding promotes multifetal growth restriction. Placental pathology may be contributory. In one study of 668 twin placentas, a strong relationship between histological placental abnormalities and birthweight discordancy was observed in dichorionic but not monochorionic twin pregnancies (Kent, 2012).

Diagnosis

Antenatal size discordancy between twins can be best determined sonographically. Crown-rump length differences are not reliable predictors for birthweight discordance (Miller, 2012). Thus, most discordancy surveillance begins after the first trimester. One common method uses sonographic fetal biometry to compute an estimated weight for each twin (Chap. 15, p. 274). Percent discordancy is then calculated as the weight of the larger twin minus the weight of the smaller twin, divided by the weight of the larger twin. The American College of Obstetricians and Gynecologists (2021b) defines discordance as an estimated fetal weight difference >20 percent.

Management

The risk for adverse perinatal outcomes in the setting of growth discordance remains controversial. Some suggest that twin gestations with discordant growth between two fetuses that are appropriately grown for gestational age are not at increased risk for adverse outcomes (American College of Obstetricians and Gynecologists, 2021b; Appleton, 2007). Others have shown an increased risk for adverse fetal outcomes but not for poor neonatal outcomes (Amaru, 2004; D'Antonio, 2018). However, accumulated data suggest that weight discordancy exceeding 25 to 30 percent most accurately predicts an adverse perinatal outcome (Cohen, 2001; Chen, 2019). At Parkland Hospital, twin weight-discordancy values from 1370 delivered twin pairs were stratified by percentage increments (Hollier, 1999). The incidence of respiratory distress syndrome, intraventricular hemorrhage, seizures, periventricular leukomalacia, sepsis, and necrotizing enterocolitis rose directly with the percentage of weight discordancy. Rates of these conditions grew substantially if discordancy exceeded 25 percent. The relative risk of fetal death increased significantly to 5.6 if weight discordancy was >30 percent and rose to 18.9 if >40 percent.

Nonstress testing and biophysical profile assessment have all been recommended in management of twin growth discordancy. If significant discordancy is identified in a monochorionic twin pair, umbilical artery Doppler studies in the smaller fetus may help guide management (Gratacós, 2007). Data are limited to establish the optimal timing of delivery of twins with size discordancy alone. At advanced gestational ages, delivery can be pursued.

Selective Fetal-growth Restriction

Restricted growth of one twin fetus is termed *selective fetal-growth restriction (sFGR)* and usually develops late in the second and early third trimester. Some diagnose sFGR if the abdominal circumference (AC) measurement difference exceeds 20 mm or if fetal-growth discordance is >20 percent (Khalil, 2019). If sFGR is diagnosed, weekly testing of fetal well-being, evaluation of amnionic fluid volume, and umbilical artery Doppler velocimetry are undertaken. Investigators have correlated Doppler results with placental findings and with the degree of sFGR to predict fetal outcome (Gratacós, 2012). These correlations have yielded categories of sFGR.

- Type I shows positive end-diastolic flow, a smaller degree of weight discordance, and a relatively benign clinical course.
- Type II displays persistently absent end-diastolic flow in the smaller twin and carries a high risk of deterioration and demise.
- Type III has intermittently absent or reversed end-diastolic flow. Because of large artery-to-artery anastomoses associated with the placentas in this last category, type III is associated with a lower risk of deterioration than type II. In all evaluated cases, unequally shared placenta was noted to some degree.

Serial evaluation of fetal growth is performed every 3 weeks (Chap 47, p. 829). At Parkland Hospital, daily inpatient surveillance is undertaken in women with fetal-growth restriction in one twin or with twin discordancy exceeding 25 percent in the setting of a twin with restricted growth.

FETAL DEMISE

At any time during multifetal pregnancy, one or more fetuses may die, either simultaneously or sequentially. Most causes stem from complications of fetal anomaly or chorionicity. Related to the latter, compared with dichorionic twins, monochorionic pairs suffer higher rates of sFGR, TTTS, or TAPS from unequal vascular anastomoses, and monoamnionic pairs can die from cord entanglement.

When death is early, it may manifest as a vanishing twin (p. 843). For the survivor, the risk of death after the first trimester is not increased, and the pregnancy requires no additional surveillance for this specific indication. In a slightly more advanced gestation, the dead fetus may be compressed appreciably—*fetus compressus,* or it may be flattened remarkably through desiccation—*fetus papyraceus* (Fig. 48-16).

In gestations past 20 weeks, the stillbirth rate in twins in the United States was 1.4 percent of live births and exceeded the 0.6-percent rate in singletons (MacDorman, 2015). After a *single intrauterine fetal demise (sIUFD)* in these later gestations, risks to the remaining co-twin include death, preterm birth, and neurological injury (D'Antonio, 2017; Mackie, 2019). With the last, acute hypovolemia from volume shifts within placental anastomoses occurs immediately, and neurological injury is not preventable.

Related to co-twin death, monochorionic diamnionic twins with an sIUFD were 16 times more likely to experience death of the co-twin than were dichorionic twins with an sIUFD in one large series (Morikawa, 2012). In most studies, the rate of co-twin demise after sIUFD declines after 26 to 28 weeks' gestation and with advancing gestational age (Mackie, 2019; McPherson, 2012; Southwest Thames Obstetric Research Collaborative, 2012; Wood, 2014).

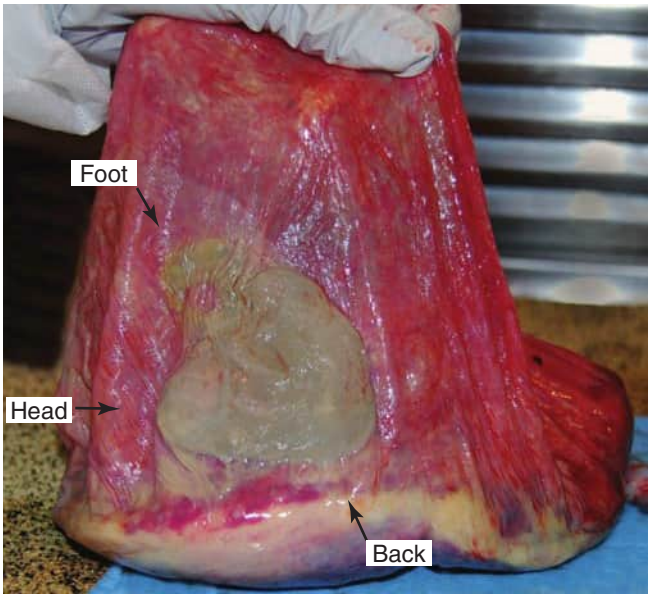

FIGURE 48-16 This fetus papyraceus is a tan ovoid mass compressed against the fetal membranes. Anatomical parts can be identified as marked. Demise of this twin had been noted during sonographic examination performed at 17 weeks' gestation. Its viable co-twin delivered at 40 weeks. (Reproduced with permission from Dr. Michael V. Zaretsky.)

The rate of preterm birth following sIUFD is increased but is similar between mono- and dichorionic twins. Advancing rates are seen at later gestational ages (D'Antonio, 2017; Ong, 2006).

The neurological prognosis for a surviving co-twin is influenced by chorionicity. In one review of diamnionic twin pregnancies complicated by sIUFD *before* 34 weeks, neurodevelopmental morbidity was 29 percent in monochorionic twins and was threefold higher than in dichorionic gestations (Mackie, 2019). In other series with sIUFD *after* 34 weeks, the likelihood of neurological deficits was essentially the same between monochorionic and dichorionic twin pregnancies (Hillman, 2011).

Because of this significant neurological risk, if one fetus of a monochorionic twin gestation dies after the first trimester but before viability, pregnancy termination can be considered (Blickstein, 2013). After viability, ultimate delivery timing balances the risk of prematurity against co-twin demise. Early management emphasizes maternal and co-twin safety and gestation prolongation (American College of Obstetricians and Gynecologists, 2021b). Antenatal corticosteroids for survivor lung maturity can be considered. For sIUFD occurring after 34 weeks' gestation, delivery is reasonable (Spong, 2011).

Last, the death of one fetus could theoretically trigger coagulation defects in the mother. Only a few cases of maternal coagulopathy after a single fetal death in a twin pregnancy have been reported. This is probably because the surviving twin is usually delivered within a few weeks of the demise (Eddib, 2006).

PRENATAL CARE

At Parkland Hospital clinics, women with multifetal gestations are seen every 2 weeks beginning at 22 weeks' gestation. One imperative is preterm delivery prevention, and a digital cervical examination is performed at each visit to screen for cervical shortening or dilation.

The maternal diet should provide additional requirements for calories, protein, minerals, vitamins, and essential fatty acids. The Institute of Medicine (IOM) (2009) recommends a 37- to 54-lb weight gain for women with twins and a normal body mass index. The daily recommended augmented caloric intake for women with twins is 40 to 45 kcal/kg/d. Diets contain 20 percent protein, 40 percent carbohydrate, and 40 percent fat divided into three meals and three snacks daily. Based on upper-intake levels from the Food and Nutrition Board of the IOM, one review endorsed supplementation of calcium, magnesium, zinc, and vitamins C, D, and E (Goodnight, 2009).

Discussed in Chapter 40 (p. 705), low-dose aspirin prophylaxis is recommended in women at high risk of preeclampsia, which includes those with a multifetal pregnancy (LeFevre, 2014). An 81-mg oral daily dose is initiated between 12 and 28 weeks' gestation and is continued until delivery (American College of Obstetricians and Gynecologists, 2020b).

Prenatal screening for fetal aneuploidy is carried out as described in Chapter 17 (p. 334). Thus, the combined test or secondary screening is done and interpreted with value thresholds set for multifetal pregnancies. Noninvasive prenatal screening with cfDNA also is acceptable (American College of Obstetricians and Gynecologists, 2020d; Judah, 2021; Khalil, 2021). Interpretation caveats for those with a vanishing twin were described earlier (p. 844).

To screen for structural anomalies, a midpregnancy anatomic sonography survey is performed. In addition, monochorionic twins undergo echocardiography because of an increased risk for cardiac anomalies (Bahtiyar, 2007). As noted earlier (p. 844), fetal growth is assessed with sonography. Amnionic fluid volume is quantified using the deepest vertical pocket in each sac. A measurement <2 cm is considered oligohydramnios, and a measurement >8 cm is considered hydramnios (Duryea, 2017; Hernandez, 2012).

Twin pregnancies are at increased risk for stillbirth compared to singleton gestations. The intrauterine fetal death rate is two- to threefold higher in monochorionic pregnancies compared with dichorionic gestations (Lee, 2008; Morikawa, 2012). Cheong-See and colleagues (2016) reported a higher stillbirth rate in monochorionic gestations compared with dichorionic gestations beyond 34 weeks' gestation. Outpatient weekly nonstress test or biophysical profile may help lower the rate of intrauterine death in twin gestations (Booker, 2015; Burgess, 2014). Weekly antenatal surveillance is undertaken at 36 weeks' gestation for uncomplicated dichorionic pregnancies and at 32 weeks' gestation or uncomplicated monochorionic gestations (American College of Obstetricians and Gynecologists, 2021a). However, all antenatal testing schemes have high false-positive rates. In cases of abnormal testing in one twin and normal results in another, iatrogenic preterm delivery remains a major concern. Therefore, patients are carefully counseled prior to initiating antenatal testing in twins.

PRETERM BIRTH

Gestational length shortens and preterm birth risk rises with accruing fetal number. In 2019 in the United States, the preterm birth rate in twins and triplets was 60 and 98 percent, respectively (Martin, 2021). One review showed that approximately 60 percent of preterm births in twins are indicated, a third result from spontaneous labor, and 10 percent follow preterm prelabor rupture of membranes (PPROM) (Chauhan, 2010).

Of risks, preterm birth rates vary with chorionicity and are higher with monochorionic compared with dichorionic twins. Other implicated factors are prior preterm birth, adolescence, nulliparity, obesity, and diabetes (Marleen, 2018, 2021).

Prediction

One goal of multifetal prenatal care is to identify women likely to experience preterm delivery. To and associates (2006) sonographically measured cervical length in 1163 twin pregnancies at 22 to 24 weeks' gestation. Rates of preterm delivery before 32 weeks were 66 percent in those with cervical lengths of 10 mm; 24 percent for lengths of 20 mm; and only 1 percent for lengths of 40 mm. In one review, a cervical length <20 mm was most accurate for predicting birth before 34 weeks' gestation. The specificity was 97 percent, and positive likelihood ratio was 9.0 (Conde-Agudelo, 2010). Notably, a closed

internal os by digital examination predicted postponed delivery equally well as the combination of a normal sonographically measured cervical length and negative fetal fibronectin test result (McMahon, 2002).

Unfortunately, cervical length assessment in twin pregnancies has not led to improved outcomes (Gordon, 2016). The Society for Maternal–Fetal Medicine (2016) recommends against routine cervical length screening in multifetal gestations.

Fetal fibronectin levels also may predict preterm birth (Marleen, 2020). Again, neonatal outcomes are not improved in twins, and this screening tool is not recommended (American College of Obstetricians and Gynecologists, 2021b).

Prevention

Bed Rest

In general, most strategies for preterm birth prevention are ineffective for singleton and multifetal pregnancies (American College of Obstetricians and Gynecologists, 2021b). Of options, bed rest with or without hospitalization does not prolong multifetal pregnancy. In one metaanalysis, the practice did not reduce the risk of preterm birth (da Silva Lopes, 2017). At Parkland Hospital, elective hospitalization was compared with outpatient management, and no advantages were found (Andrews, 1991). Importantly, however, almost half of women managed as outpatients required admission for specific indications such as hypertension or threatened preterm delivery.

Limited physical activity, early work leave, more frequent health-care visits, serial sonographic examinations, and structured maternal education regarding preterm delivery risks have been advocated to reduce preterm birth rates in women with multiple fetuses. However, little evidence suggests that these practices substantially change this outcome.

Prophylactic Tocolysis

This has not been studied extensively in multifetal pregnancies. In one review of prophylactic oral beta-mimetic therapy that included 374 twin pregnancies, treatment did not reduce the rate of twins delivering before 37 or before 34 weeks' gestation (Yamasmit, 2015). In light of the Food and Drug Administration warning against the use of oral terbutaline because of maternal side effects, the prophylactic use of beta-mimetic drugs in multifetal gestations seems unwarranted.

Progesterone Therapy

17-alpha-hydroxyprogesterone caproate (17-OHPC) injections are not effective for multifetal gestations (Caritis, 2009; Combs, 2011; Rouse, 2007). Moreover, women carrying twins and having a cervical length <36 mm or a length <25 mm did not benefit despite their greater risk for preterm birth (Durnwald, 2010; Senat, 2013).

Vaginal micronized progesterone in various formulations in randomized studies has also proved ineffective for preterm birth prevention before 34 weeks in a general twin population (Norman, 2009; Rode, 2011). For women with a short cervix, subgroup analysis and a metaanalysis show conflicting results regarding benefits (D'Antonio, 2021; Klein, 2011; Rehal, 2021). At Parkland Hospital, current management of multifetal gestations does not typically include any progesterone therapy.

Cervical Cerclage

Prophylactic cerclage does not improve perinatal outcome in women with twin pregnancies. Studies have included women with and without a short cervix (D'Antonio, 2021; Jarde, 2017; Newman, 2002). *Physical examination–indicated cerclage* in women with a second-trimester twin gestation and a dilated cervix may be beneficial. Roman and coworkers (2016, 2020) reported that women undergoing rescue cerclage plus prophylactic antibiotic and indomethacin administration before 24 weeks' gestation had lower preterm birth and perinatal mortality rates than those without a cerclage.

Pessary

The silicone Arabin vaginal pessary encircles and theoretically compresses the cervix, alters the inclination of the cervical canal, and relieves direct pressure on the internal cervical os. In a study of its use in women with a short cervix between 18 and 22 weeks' gestation, a subgroup analysis of 23 women with twins showed a significant reduction in the delivery rate before 32 weeks compared with the rate in 23 control pregnancies (Arabin, 2003). In another randomized trial of twins, women treated with a cervical pessary had significantly fewer births before 34 weeks (Goya, 2016).

Other randomized studies comparing pessary against expectant care are less favorable. In one trial with 1180 uncomplicated twin pregnancies, pessary use failed to alter the preterm birth rate (Nicolaides, 2016). Another trial of 813 unselected women had similar findings. However, delivery rates before 32 weeks were lower—29 versus 14 percent—in a subset of women with a cervical length <38 mm (Liem, 2013). Instead, other trials show no benefit from pessary use in this subgroup (Nicolaides, 2016; Norman, 2021). At this time, pessary use is not recommended by the American College of Obstetricians and Gynecologists (2021b).

Treatment

Tocolytic therapy to help halt preterm labor in multifetal pregnancy does not measurably improve neonatal outcomes (Canadian Preterm Labor Investigators Group, 1992; Yamasmit, 2015). Moreover, tocolytic therapy in women with a multifetal pregnancy entails higher maternal risk than in singleton pregnancy. This stems in part from augmented pregnancy-induced hypervolemia, which raises cardiac demands and increases the susceptibility to iatrogenic pulmonary edema (Chap. 50, p. 883). In one study, all women with a multifetal gestation treated with a beta-mimetic drug for preterm labor had more cardiovascular complications—43 versus 4 percent—than women with singletons (Gabriel, 1994). In a retrospective analysis, nifedipine tocolysis in 58 singleton and 32 twin pregnancies led to higher incidences of side effects such as maternal tachycardia in women with twins—19 versus 9 percent (Derbent, 2011).

Antenatal corticosteroids for fetal lung maturation have not been well studied in multifetal gestations. Of studies, many compare outcomes among singletons and twins whose

mothers either did or did not receive this therapy. In one large retrospective study evaluating betamethasone, neonatal morbidity rates were reduced in both twin and singleton treated groups (Melamed, 2016). Another similar comparison found reduced rates of periventricular hemorrhage rates in treated groups but not improved respiratory distress syndrome (RDS) rates (Gonçalves-Ferri, 2021). Similarly, in another study, short-term neurological outcome was better in treated twin and singletons, but rates of mortality, RDS, and cerebral palsy were not reduced (Ushida, 2020). However, in one study solely with twins, the rate of RDS or of composite neonatal morbidity was not lower with corticosteroid therapy (Viteri, 2016). These authors posited pharmacokinetics in twin gestation as a potential explanation. Currently, recommended use of agents is the same for multifetal and singleton gestations (American College of Obstetricians and Gynecologists, 2021b). This therapy is described fully in Chapter 45 (p. 802).

Preterm Prelabor Membrane Rupture

The frequency of PPROM rises with increasing plurality. In a population-based study of more than 290,000 live births, the proportion of preterm birth complicated by PPROM was 13 percent in singletons. This rate was 17, 20, 20, and 100 percent in twins, triplets, quadruplets, and higher-order multiples, respectively (Pakrashi, 2013). For both twin and singleton pregnancies, most studies show comparable neonatal risk with expectant management, which is outlined in Chapter 45 (p. 798) (Kibel, 2017). However, the time between births, often termed *latency*, is shorter with twins. With PPROM after 24 weeks' gestation, the median number of days to subsequent delivery was 4 days for twins compared with 7 days for singletons in one study (Madden, 2021). After 30 weeks' gestation, this latency for twins is significantly shortened (Mercer, 1993).

Delayed Delivery of Second Twin

Rarely, after preterm birth of one fetus, it may be advantageous for undelivered fetus(es) to remain in utero. This may be especially so at periviable gestational ages. However, this advantage must be balanced against substantial maternal risk. In one systematic review, nearly 40 percent of mothers suffered complications with delayed delivery (Cheung, 2020). These include infection, postpartum hemorrhage, and placental abruption.

From population-based data of delayed deliveries, the median latency duration was 6 days (range 6 to 107 days) in 200 twin pregnancies (Zhang, 2004). In all studies, retained fetuses had better overall survival rates than the first-born neonate. In one series of 38 twins, the mean latency was 19 days. Of first-born twins born at <25 weeks' gestation, none survived, but 50 percent of their co-twins did. Beyond 25 weeks, survival rates were 65 for first-born and 95 percent for second-born twins (Arabin, 2009). In their series of 28 twin pairs, cerclage, antibiotic therapy, and tocolysis did not improve outcomes (Fayad 2003).

If delayed delivery is attempted, counseling should include the potential for serious maternal complications. The range of gestational age for which benefits outweigh the risks for delayed delivery is likely narrow, and gestations of 22 to 24 weeks would seem the most probable to benefit (Oyelese, 2005). In our experience, good candidates for delayed delivery are rare.

LABOR AND DELIVERY

Delivery Timing

Several factors affect this timing and include gestational age, fetal growth, maternal complications, lung maturity, and stillbirth risk. The substantially greater stillbirth rate in monochorionic monoamnionic twins was discussed earlier (p. 845). In dichorionic diamnionic twins, stillbirth rates rose to 10.6 deaths per 1000 pregnancies at $38^{6/7}$ weeks' gestation in a systematic review of more than 30,000 twin pairs. The peak rate in monochorionic diamnionic twins was 9.6 deaths per 1000 pregnancies at $37^{6/7}$ weeks (Cheong-See, 2016).

In uncomplicated twins, stillbirth risk is balanced against the morbidity of prematurity. Pulmonary maturation is usually synchronous in twins and occurs several weeks earlier than in singletons (Leveno, 1984). However, in some cases, pulmonary function may differ. With sFGR, the smaller, stressed twin has lower rates of RDS but higher rates of bronchopulmonary dysplasia (Groene, 2021).

The American College of Obstetricians and Gynecologists (2021b) recommends delivery at $38^{0/7}$ to $38^{6/7}$ weeks' gestation for uncomplicated dichorionic diamnionic twin pregnancies. Uncomplicated monochorionic diamnionic twin pregnancies can be delivered between $34^{0/7}$ and $37^{6/7}$ weeks. For monochorionic monoamnionic twin pregnancies, delivery is recommended at $32^{0/7}$ to $34^{0/7}$ weeks. At Parkland Hospital, we generally follow these recommendations and do not routinely deliver monochorionic diamnionic twin pregnancies before 37 weeks unless another obstetrical indication develops.

Preparations

A litany of complications may be encountered during labor and delivery of multiple fetuses. Rates of uterine contractile dysfunction, abnormal fetal presentation, umbilical cord prolapse, placenta previa, placental abruption, emergent operative delivery, and postpartum hemorrhage rates from uterine atony are higher. Moreover, second twins at term have worse composite neonatal outcomes compared with outcomes of their co-twin regardless of delivery method (Smith, 2007; Thorngren-Jerneck, 2001). All of these must be anticipated, and thus certain precautions and special arrangements are prudent. These include the following:

1. An appropriately trained obstetrical attendant should remain with the mother throughout labor. Continuous electronic monitoring is preferable. If membranes are ruptured and the cervix dilated, the presenting fetus is monitored internally.

2. An intravenous infusion system capable of delivering fluid rapidly is established. In the absence of hemorrhage, lactated Ringer or an aqueous dextrose solution is infused at a rate of 60 to 125 mL/hr.
3. Blood for transfusion is readily available if needed.
4. An obstetrician skilled in intrauterine identification of fetal parts and in intrauterine manipulation of a fetus should be present.
5. A sonography machine is readily available to evaluate the presentation and position of the fetuses during labor and to image the remaining fetus after delivery of the first.
6. An anesthesia team is immediately available in the event that emergent cesarean delivery is necessary or that intrauterine manipulation is required for vaginal delivery.
7. For each fetus, at least one attendant who is skilled in resuscitation and care of newborns and who has been appropriately informed of the case should be immediately available.
8. The delivery area should provide adequate space for the nursing, obstetrical, anesthesia, and pediatric team members to work effectively. Equipment must be on site to provide emergent anesthesia, operative intervention, and maternal and neonatal resuscitation.

Analgesia and Anesthesia

For multifetal pregnancies, decisions regarding analgesia and anesthesia must factor planned route of delivery. Other potential problems may stem from preterm labor, preeclampsia, desultory labor, need for intrauterine manipulation, and postpartum uterine atony and hemorrhage.

Labor epidural analgesia is ideal because it provides excellent pain relief and can be rapidly extended cephalad if internal podalic version or cesarean delivery is required. If general anesthesia becomes necessary for intrauterine manipulation during vaginal birth, uterine relaxation can be accomplished rapidly with a halogenated inhalation agent (Chap. 25, p. 481). Some clinicians use intravenous or sublingual nitroglycerin or intravenous terbutaline to achieve uterine relaxation. If used, these agents are usually best administered by the anesthesia team.

Fetal Presentation

For labor and delivery, the fetal presentations are best determined sonographically. If active labor is confirmed, the decision for vaginal or cesarean delivery is reached, and fetal presentation is a major factor. Among the possible presentation combinations, those most common at admission for delivery are cephalic-cephalic, cephalic-breech, and cephalic-transverse. At Parkland Hospital between 2008 and 2013, 71 percent of twin pregnancies had a cephalic presentation of the first fetus at the time of labor and delivery admission. During parturition, fetal presentation of a second twin can be unstable. For them, compound or footling breech presentations and face or brow attitudes are relatively common and even more so if fetuses are small or numerous, amnionic fluid is excessive, or maternal parity is high. Cord prolapse also is frequent in these circumstances.

Delivery Route

Cephalic First Twin

With *cephalic–cephalic presentation*, general consensus supports consideration of vaginal birth in a laboring woman near term (American College of Obstetricians and Gynecologists, 2021b; D'Alton, 2010). From studies, planned cesarean delivery does not improve neonatal outcome when both twins are cephalic (de Castro, 2016; Schmitz, 2017). With trials of labor, vaginal delivery rates approximate 80 percent.

With *cephalic–noncephalic* presentation, the optimal delivery route remains controversial. Patient selection and provider expertise with vaginal breech delivery is crucial and described in Chapter 28 (p. 527). As a result, one common option is cesarean delivery of both twins. Less often, after spontaneous vaginal delivery of a first twin, intrapartum external cephalic version of the second twin can be performed. In case series, this practice, compared with internal podalic version, was associated with higher rates of intrapartum cesarean delivery and fetal distress (Gocke, 1989; Smith 1997). With internal podalic version, a hand placed into the uterus grasps fetal feet to deliver the fetus by breech extraction (Fig. 48-17). Last and least desirable is vaginal delivery of the first but cesarean delivery of the second twin due to intrapartum complications. These are umbilical cord prolapse, placental abruption, contracting cervix, or nonreassuring fetal heart rate. Most but not all studies report the worst composite fetal outcomes for this scenario (Alexander, 2008; Rossi, 2011).

For cephalic–noncephalic twins, each with birthweights >1500 g and gestational ages >32 weeks, several reports attest to the safety of vaginal delivery. In one study of 5915 pregnancies with a cephalic first twin and either cephalic or noncephalic second twin, 25 percent planned for cesarean delivery (Schmitz, 2017). The other 75 percent planned a trial of vaginal delivery, which was successful in 80 percent. Interestingly, perinatal mortality and morbidity rates were significantly higher in the planned cesarean delivery group delivered at <37 weeks—5.2 versus 3.0 percent, respectively. Additionally, for those delivered vaginally, neonatal outcomes were similar for second

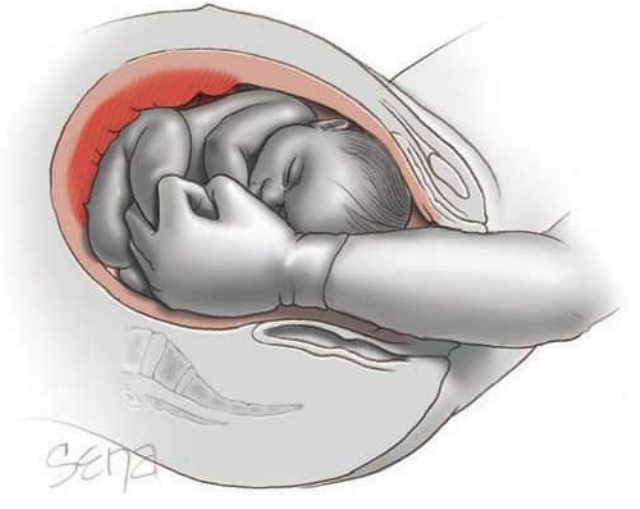

FIGURE 48-17 Internal podalic version. Upward pressure on the head by an abdominal hand is applied (not shown) as downward traction is exerted on the feet.

twins that were cephalic or noncephalic (Schmitz, 2018). The Twin Birth Study had similar inclusion criteria and randomly assigned women to planned vaginal or planned cesarean delivery. Perinatal outcomes were similar in both groups. For those delivered vaginally, neonatal outcomes were similar for second twins that were cephalic or noncephalic (Barrett, 2013).

For neonates weighing <1500 g compared with those weighing more, comparable or even better fetal outcomes with vaginal delivery compared with cesarean delivery have been reported (Mol, 2020; Sentilhes, 2015). However, rates of urgent operations for the second twin may be higher (Hiersch, 2021).

Other investigators advocate cesarean delivery for both fetuses of a cephalic–noncephalic twin pair (Armson, 2006; Hoffmann, 2012). Yang and coworkers (2005a,b) studied 15,185 cephalic–noncephalic pairs. The risks of asphyxia-related neonatal deaths and morbidity were higher in the group in which both twins were delivered vaginally compared with the group in which both twins were delivered surgically.

Breech First Twin

Problems with the first twin presenting as a breech are similar to those encountered with a singleton breech fetus. First, the fetal body can be small, and delivery of the extremities and trunk through an inadequately effaced and dilated cervix can leave the relatively larger head trapped above the cervix. This is more likely when disproportion between the head and body is significant. Examples are preterm or growth-restricted fetuses or those with macrocephaly from hydrocephaly. Second, umbilical cord prolapse is an ever-present risk. Last, twin fetuses may become locked together during delivery if the first presents breech and the second cephalic. As the breech of the first twin descends through the birth canal, the chin locks between the neck and chin of the second cephalic-presenting co-twin. This phenomenon is rare, and Cohen and coworkers (1965) described it only once in 817 twin gestations.

If these problems are anticipated or identified, cesarean delivery is often preferred with a viable-sized fetus. Even without these problems, many obstetricians perform cesarean delivery if the first twin presents as breech, and this is our practice. However, data support the safety of vaginal delivery for twins older than 32 weeks and weighing >1500 g (Blickstein, 2000). In one study, cesarean delivery was planned in 1169 such pairs. Vaginal delivery was planned in 298 pairs and was successful in 64 percent. Cesarean delivery of the second twin was done in 1 percent. Neonatal mortality or morbidity measures did not differ between delivery groups (Korb, 2020).

Labor Augmentation or Induction

In general, active labor with twins progresses more slowly in both nulliparas and multiparas compared with that in singletons (Hochler, 2021). Second-stage labor of the first twin also is longer (Levin, 2021).

In women with twins who meet all criteria for oxytocin administration, *labor augmentation* is suitable (Chap. 26, p. 492). For *labor induction*, studies have found that oxytocin alone or in combination with cervical ripening can safely be used in twin gestations (Hamou, 2016; Ko, 2014). Compared with prelabor cesarean delivery, others have found higher maternal morbidity rates with labor induction, and ultimate cesarean delivery rates approximate 40 percent (Dougan, 2020; Grossman, 2021). In an analysis of twin births in the United States, induction rates of twin pregnancies have declined from nearly 14 percent in 1999 to 10 percent in 2008 (Lee, 2011). Generally, at Parkland Hospital we do not augment or induce labor in women with a multifetal gestation. Concerns include risks for uterine rupture from an overdistended uterus and postpartum hemorrhage. In suitable candidates with a strong desire for vaginal birth, amniotomy induction has been one option.

Vaginal Delivery

After delivery of the firstborn, one clamp is placed near the neonate, and another is placed nearer the placenta. Until the last fetus is delivered, each cord must remain clamped to prevent fetal hypovolemia and anemia caused by blood leaving the placenta via anastomoses and then through an unclamped cord. Cord blood is generally not collected until after delivery of all fetuses. After the second neonate is delivered, *two* plastic clamps are placed on the placenta's cord to differentiate it from the first. In higher-order deliveries, color-tagged or alphabetically labeled clamps can be simpler than adding additional clamps. This same practice holds for cesarean delivery. At this time, evidence is insufficient to recommend for or against delayed umbilical cord clamping in multifetal gestations (American College of Obstetricians and Gynecologists, 2020a).

Following vaginal delivery of the first twin, the presenting part of the second twin, its size, and its relationship to the birth canal should be quickly ascertained by combined abdominal, vaginal, and, at times, intrauterine examination. Sonography is a valuable aid. If the fetal head or the breech is fixed in the birth canal, moderate fundal pressure is applied and membranes are ruptured. Immediately afterward, digital examination of the cervix is repeated to exclude cord prolapse. Labor is allowed to resume. If contractions do not begin within approximately 10 minutes, dilute oxytocin may be used to stimulate contractions.

The preferred interval between delivery of the first and second twins is frequently cited as <30 minutes. In some studies, longer intertwin intervals are associated with poorer outcome of the second twin (Leung, 2002; Stein, 2008). Others have correlated fetal heart rate tracing abnormalities during the intertwin interval rather than its length with poorer outcome (Algeri, 2019).

If the occiput or breech presents immediately over the pelvic inlet, but is not fixed in the birth canal, the presenting part can often be guided into the pelvis by one hand in the vagina, while a second hand on the uterine fundus exerts moderate pressure caudally. A presenting shoulder may be gently converted into a cephalic presentation. Alternatively, with abdominal manipulation, an assistant can guide the presenting part into the pelvis. Sonography can aid guidance and allow heart rate monitoring.

If the occiput or breech is not over the pelvic inlet and cannot be so positioned by gentle pressure or if appreciable uterine bleeding develops, delivery of the second twin can be problematic. To obtain a favorable outcome, an obstetrician skilled in intrauterine fetal manipulation and anesthesia personnel skilled

in providing anesthesia to effectively relax the uterus for vaginal delivery of a noncephalic second twin are essential (American College of Obstetricians and Gynecologists, 2021b). To take maximum advantage of the dilated cervix before the uterus contracts and the cervix retracts, delay should be avoided. Prompt cesarean delivery of the second fetus is preferred if no one present is skilled in the performance of internal podalic version or if anesthesia that will provide effective uterine relaxation is not immediately available.

Trial of Labor after Cesarean Delivery

The main concern with trial of labor after cesarean delivery (TOLAC) is uterine rupture from a distended uterus. One metaanalysis found rates of rupture and of successful vaginal birth were comparable with those for TOLAC in singleton gestations (Kabiri, 2019). Other studies also support the safety of TOLAC for selected women with twins (Cahill, 2005; Ford, 2006). In one assessment of 186 women undergoing TOLAC, two thirds delivered both twins vaginally. Of failed attempts, 45 percent underwent cesarean for delivery of the second twin (Varner, 2005). According to the American College of Obstetricians and Gynecologists (2019), evidence currently does not suggest an increased risk of uterine rupture, and women with twins and one previous cesarean delivery with a low transverse incision may be considered TOLAC candidates. At Parkland Hospital, we recommend repeat cesarean delivery.

Cesarean Delivery Technique

Several unusual intraoperative problems can arise during cesarean delivery of twins or higher-order multiples. Supine hypotension is common, and thus gravidas are positioned in a left lateral tilt to deflect uterine weight off the aorta. A low transverse hysterotomy is preferable if the incision can be made large enough to allow atraumatic delivery of all fetuses. Piper forceps can be used if a second twin is presenting breech. In some cases, a vertical hysterotomy beginning as low as possible in the lower uterine segment may be advantageous. For example, if a fetus is transverse with its back down and the arms are inadvertently delivered first, it is much easier and safer to extend a vertical uterine incision upward than to extend a transverse incision laterally or to make a "T" incision vertically.

Triplet or Higher-order Gestation

Fetal heart rate monitoring during labor with triplet pregnancies is challenging. A scalp electrode can be attached to the presenting fetus, but it is difficult to ensure that the other two fetuses are each being monitored separately. With vaginal delivery, the first neonate is usually born with little or no manipulation. Subsequent fetuses, however, are delivered according to the presenting part. This often requires complicated obstetrical maneuvers such as total breech extraction with or without internal podalic version or even cesarean delivery. Associated with malposition of fetuses is an increased incidence of cord prolapse. Moreover, reduced placental perfusion and hemorrhage from separating placentas are more likely during delivery.

Data from the Consortium on Safe Labor found that only 17 percent of women with triplet gestation attempting vaginal birth were actually delivered vaginally. In these births, composite neonatal morbidity rates were increased (Lappen, 2016). In 7000 triplet pregnancies, vaginal delivery also was associated with a higher perinatal mortality rate (Vintzeleos, 2005). For all these reasons, we deliver most pregnancies complicated by three or more fetuses by cesarean delivery. Vaginal delivery is reserved for those circumstances in which survival is not expected because fetuses are markedly immature or abnormal or maternal complications make cesarean delivery hazardous to the mother. Centers for Disease Control and Prevention (2009) national data show that 94 percent of triplets are delivered by cesarean.

Other cases series describe more positive outcomes (Grobman, 1998; Peress, 2019). In sum, the American College of Obstetricians and Gynecologists (2021b) notes vaginal birth may be considered for uncomplicated triplet pregnancies, if the first fetus is cephalic and attendants are experienced with multifetal vaginal birth. As with twins, candidate fetuses should weigh >1500 g.

REDUCING FETAL NUMBER

For multifetal gestations, *multifetal pregnancy reduction (MPR)* aims to lower fetal number to improve survival rates of the remaining fetuses. Instead, with *selective reduction*, early pregnancy intervention focuses on a fetus with an anomaly or serious health risk. With *selective termination*, the indications are analogous to those for selective reduction, but interventions are performed at a later gestational age (American College of Obstetricians and Gynecologists, 2020c).

Selective reduction or MPR is typically done in the late first trimester. This gestational age is chosen because most spontaneous abortions have already occurred, the remaining fetuses are large enough to be evaluated sonographically, the amount of devitalized fetal tissue remaining after the procedure is small, and the risk of aborting the entire pregnancy as a result of the procedure is low.

Skill in sonographically guiding needles through the mother's abdomen and uterus is required. For reductions of fetuses with their own chorion, potassium chloride is used and is injected into the fetal heart or thorax. Entering or traversing the sacs of fetuses picked for retention is avoided. For monochorionic fetuses and potentially shared vasculature, cord-occlusion is used, and with radiofrequency ablation (RFA), the needle is inserted into the intrafetal portion of the umbilical cord.

Before reduction procedures, discussion should include the morbidity and mortality rates associated with expectant care, entire pregnancy termination, or selective fetal reduction (American College of Obstetricians and Gynecologists, 2020c). With these options, specific risks include (1) loss of all remaining fetuses, (2) abortion or retention of the wrong fetus, (3) damage without death to a fetus, (4) preterm labor, (5) fetuses with discordant or growth restriction, and (6) maternal complications. With reduction procedures, uncommon potential complications are infection, hemorrhage, or disseminated intravascular coagulopathy because of retained products of conception.

Multifetal Pregnancy Reduction

In most cases of MPR, higher-order gestations are reduced by one or more fetuses. With triplets, reduction to twins or a singleton lowers the rate of preterm birth before 34 weeks compared with expectant management. Miscarriage rates are not higher (Anthoulakis, 2017; Morlando, 2015). With even higher-order multiples, spontaneous loss and preterm birth rates also decline after MPR (Evans, 2014; Liu, 2020).

Twin gestations also may be reduced to a singleton pregnancy. Maternal comorbidities or concerns for monochorionic twin complications, described earlier, are frequent indications (Rao, 2021; Vieira, 2019).

Selective Reduction or Selective Termination

If multiple fetuses are discordant for anatomical or genetic anomalies, elimination of the abnormal fetus is an option. Other indications are severe TTTS, TAPS, TRAP, or sFGR. Because abnormalities are often not fully delineated until the second trimester, selective termination is performed later in gestation than selective reduction and entails greater risk. This procedure is therefore usually not performed unless the abnormality is severe but not lethal. In some cases, termination is considered because the abnormal fetus may jeopardize the normal one.

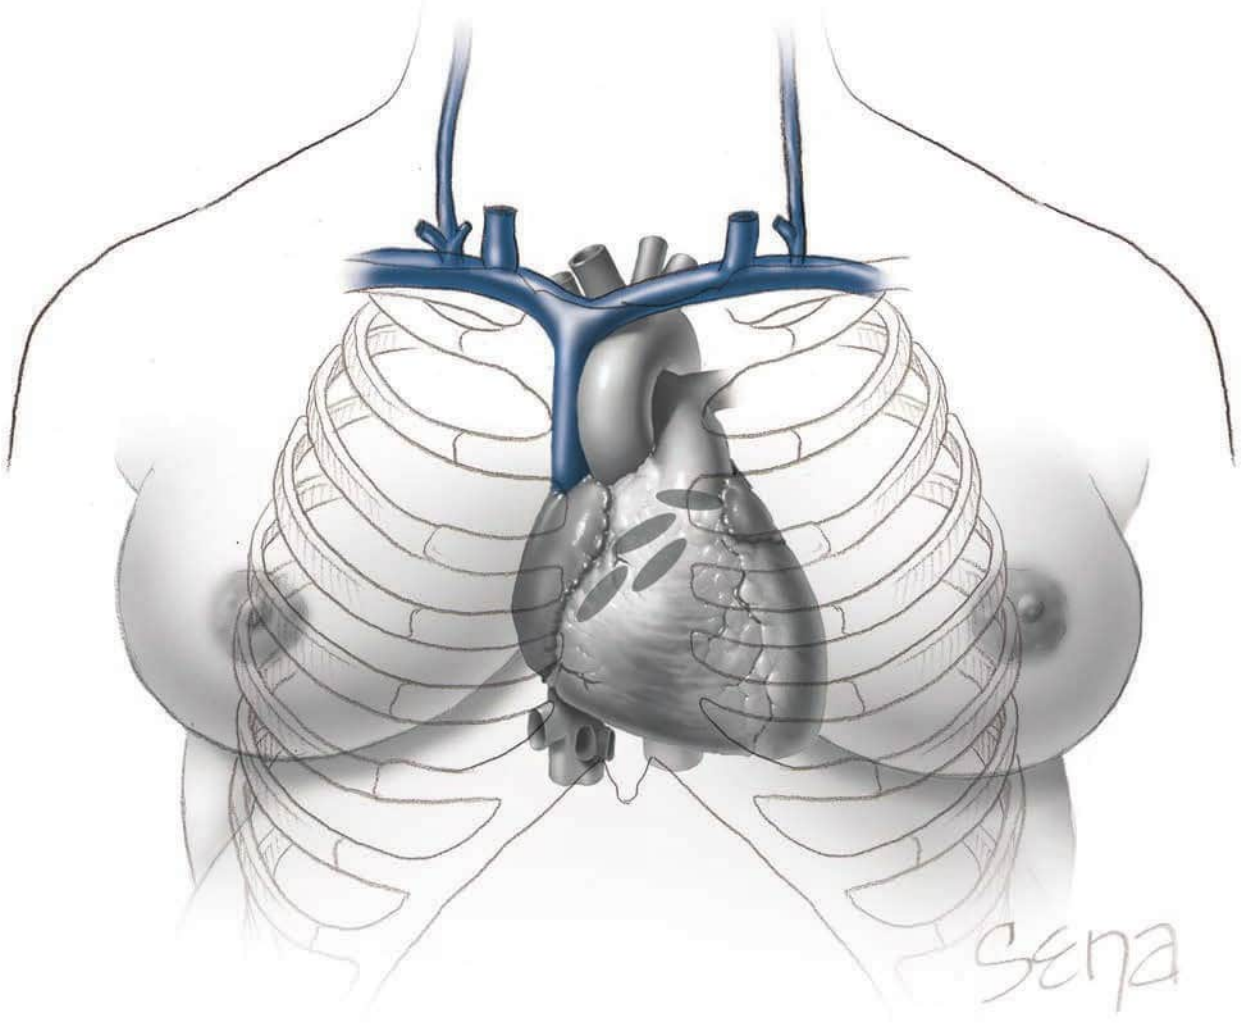
SECTION 12

MEDICAL AND SURGICAL COMPLICATIONS



CHAPTER 49

General Considerations and Maternal Evaluation

Pregnant women are susceptible to any medical and surgical disorder that can affect women of childbearing age. Chronic illnesses often precede pregnancy, and an acute condition can complicate an otherwise normal pregnancy. Both chronic and acute disorders raise the risk for antepartum hospitalization. Approximately 10 per 100 pregnant women incur an antepartum admission, and one third are for nonobstetrical conditions that include renal, pulmonary, and infectious diseases (Gazmararian, 2002). The hospitalization rate due to trauma approximates 4 admissions per 1000 deliveries (Kuo, 2007). Those with intellectual and developmental disabilities have a higher incidence of hospitalization (Mitra, 2018). Last, 1 to 2 percent of pregnant women will undergo a nonobstetrical surgical procedure (Tolcher, 2018).

Obstetricians should have a working knowledge of the wide-ranging medical disorders common to childbearing-aged women. Many of these are within the purview of the general obstetrician. Other disorders, however, will warrant consultation with specialists in maternal-fetal medicine, and still others require a multidisciplinary team. The latter may include internists and medical subspecialists, surgeons, and anesthesiologists (Levine, 2016). The Society for Maternal-Fetal Medicine (2014) has redefined aspects of maternal care and proposed conditions requiring specialized care.

Treatment should never be withheld because a woman is pregnant. To ensure this and allow for individualized care, several questions must be addressed:

- What management would be recommended if the woman were not pregnant?
- If the proposed management is different because the woman is pregnant, can this be justified?
- What are the risks and benefits to the mother and her fetus, and are they counter to each other?
- Can an individualized management plan be devised that balances risks versus benefits?

MATERNAL PHYSIOLOGY AND LABORATORY VALUES

Pregnancy induces physiological changes in virtually all organ systems. Many of these are discussed in Chapter 4 and in the subsequent chapters in this section. In turn, numerous laboratory test results also are normally altered. Some values would be considered abnormal in the nonpregnant woman. Conversely, some may appear to be within a normal range but are decidedly abnormal for the gravida. These changes may complicate the evaluation of coexisting conditions. To aid interpretation, normal laboratory values in pregnancy are listed in the Appendix (p. 1227).

MEDICATIONS

Fortunately, most medications needed to treat frequently encountered illnesses in pregnancy can be given with relative safety (Briggs, 2017). That said, notable exceptions are

considered in Chapter 8 and throughout this text. The risks and benefits of medication use during pregnancy and lactation are outlined in drug labels using the Pregnancy and Lactation Labeling Rule (PLLR) requirement from the U.S. Food and Drug Administration (FDA).

NONOBSTETRICAL SURGERY

The chances of adverse maternal and perinatal outcomes following nonobstetrical surgery during pregnancy are relatively low and cannot be separated from risks of the underlying condition (Balinskaite, 2017). However, risks are likely greater with complications. Compared with simple appendicitis, perforated appendicitis with feculent peritonitis has significantly higher maternal and perinatal morbidity and mortality rates even if surgical and anesthetic techniques are flawless. Moreover, procedure-related complications may adversely affect outcomes. For example, a woman who has uncomplicated removal of an inflamed appendix may suffer aspiration of acidic gastric contents during tracheal intubation or extubation.

Maternal Morbidity

The most frequent nonobstetrical surgical procedures performed during pregnancy are appendectomy, cholecystectomy, and adnexal surgery (Vujic, 2019; Yu, 2018). Postoperative complications in nonpregnant patients can similarly harm gravid women. However, data comparing these complications in these two groups are conflicting. The National Surgical Quality Improvement Program showed that morbidity and mortality rates from nonobstetrical surgery did not differ between pregnant and nonpregnant women (Moore, 2015). In a Taiwanese cohort of nearly 5600 gravidas, the infectious postoperative complication rate was slightly higher and the mortality rate was fourfold greater than those rates in nonpregnant women (Huang, 2016).

The reported postoperative complication rate in gravidas approximates 5 percent, and the maternal mortality rate in these cases is <1 percent (Huang, 2016; Vujic, 2019). Moreover, preoperative infection, specifically sepsis, is associated with a higher risk of maternal death (Erekson, 2012).

Perinatal Morbidity

Excessive perinatal morbidity associated with nonobstetrical surgery is also attributable in many cases to the disease itself rather than to surgery and anesthesia. Two- to threefold elevated risks for spontaneous abortion, preterm delivery, preeclampsia, and cesarean delivery have been reported (Yu, 2018). Balinskaite and associates (2017) identified a greater risk of fetal death, preterm birth, fetal-growth restriction, and cesarean delivery in 47,628 women undergoing nonobstetrical surgery. Most of these complications developed in cases performed emergently (Vujic, 2019). The Swedish Birth Registry provides valuable data comparing perinatal outcomes in women undergoing surgery with those of the general obstetrical population (Table 49-1) (Mazze, 1989). The incidences of congenital malformations and stillbirth were not significantly different from those of nonexposed newborns. However, incidences of low birthweight, preterm birth, and neonatal death were significantly higher. Increased neonatal death rates were largely due to prematurity.

TABLE 49-1. Birth Outcomes in 5405 Pregnant Women Undergoing Nonobstetrical Surgery

Outcome	Rate	*p* value[a]
Stillbirth	0.7%	NS
Major malformation	1.9%	NS
Preterm <37 wk	7.5%	<0.05
Birthweight <1500 g	1.2%	<0.05
Birthweight <2500 g	6.6%	<0.05
Neonatal death by 7 days	1.1%	<0.05

[a]Compared with 720,000 pregnancies in women without surgery.
NS = not significant.

Fetal abnormality rates are not associated with maternal surgery in early pregnancy. Källén and Mazze (1990) reported a *nonsignificant* relationship between elevated neural-tube defect rates and operations performed at 4 to 5 weeks' gestation. A large database study found no evidence that anesthetic agents were teratogenic (Czeizel, 1998). According to Briggs and coworkers (2017), most inhalation anesthetic agents appear safe.

More recently, concerns of neurodevelopmental harm with the use of anesthetics for obstetrical or fetal surgery have been raised. In 2016, the FDA issued a warning regarding impaired brain development in children following in utero exposure to inhaled isoflurane, sevoflurane, and desflurane as well as intravenous propofol and midazolam. Such risks appear to accrue after 3 hours or more of exposure (Olutoye, 2018).

LAPAROSCOPIC SURGERY

In the first trimester, laparoscopy is the most common procedure used for diagnosis and management of several surgical disorders. In 2017, the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) updated its recommendations concerning laparoscopy use in pregnant women (Table 49-2) (Pearl, 2017).

For pregnancy in general, laparotomy also is common. One 5-year study of almost 1300 pregnant women reported that open appendectomy was performed in 36 percent of 857 gravidas compared with only 17 percent of nonpregnant patients. Of those undergoing cholecystectomy, an open approach was used in 10 percent of 436 pregnant women compared with 5 percent of nonpregnant women (Silvestri, 2011). In a study from Japan, Shigemi and colleagues (2019) described 6018 pregnant women undergoing abdominal surgery—4047 by laparotomy and 1971 by laparoscopy. Operative times, hospital stay lengths, and rates of adverse fetal events and blood transfusion were all greater in the laparotomy group (Table 49-3). Others instead report equally satisfactory outcomes with either approach (Cox, 2016; Lee, 2019). Randomized

TABLE 49-2. Some Guidelines from the Society of American Gastrointestinal Endoscopic Surgeons (SAGES) for Laparoscopic Surgery in Pregnant Women

Indications—same as for nonpregnant women
Investigation of acute abdominal processes
Excision of an adnexal mass
Appendectomy, cholecystectomy, nephrectomy, adrenalectomy, splenectomy

Technique
Position: lateral recumbent
Entry: open Hasson technique, careful Veress needle, or optical trocar; fundal height may alter insertion site selection
Secondary trocars: direct visualization for placement; gravid uterus may alter insertion site selection
CO_2 insufflation pressures: 10–15 mm Hg
Monitoring: capnography intraoperatively, FHR assessment pre- and postoperatively
Perioperative pneumatic compression devices and early postoperative ambulation

CO_2 = carbon dioxide; FHR = fetal heart rate.

trials to compare benefits and risks of laparoscopy versus laparotomy during pregnancy are needed, but implementation seems unfeasible (Bunyavejchevin, 2013; Lee, 2019).

For adnexal mass surgery in pregnancy, laparoscopy is preferred, and several studies confirm its relative safety (Daykan, 2016; Webb, 2015). In addition, laparoscopic splenectomy, adrenalectomy, and nephrectomy also have been described in pregnant women (Asizare, 2014; Dong, 2014; Miller, 2012).

When first used, 26 to 28 weeks became the upper gestational-age limit recommended. However, as experience has accrued, many now describe laparoscopic surgery performed in the third trimester (Shigemi, 2019). In one report, a third of gravidas undergoing laparoscopic cholecystectomy or appendectomy were >26 weeks' gestation (Rollins, 2004). No serious adverse sequelae are linked to these procedures, and laparoscopy can safely be performed in all trimesters.

Hemodynamic Effects

Precise effects of laparoscopy in the human fetus are unknown, but animal investigations are informative. During laparoscopy, required abdominal insufflation causes hemodynamic changes that are summarized in Table 49-4. Reedy and associates (1995) studied baboons at the human equivalent of 22 to 26 weeks' gestation. No substantive physiological changes were found with insufflation pressures of 10 mm Hg, but 20 mm Hg caused significant maternal cardiovascular and respiratory changes after 20 minutes. These included faster respiratory rate, respiratory acidosis, diminished cardiac output, and increased pulmonary artery and capillary wedge pressures. In pregnant ewes, uteroplacental blood flow declines when intraperitoneal insufflation pressure exceeded 15 mm Hg (Barnard, 1995; Hunter, 1995). This stemmed from decreased perfusion pressure and elevated placental vessel resistance (see Table 49-4).

In women, cardiorespiratory changes are generally not severe if insufflation pressures remain <15 mm Hg. Despite maintaining these low insufflation pressures in women at midpregnancy, the cardiac index dropped 26 percent after 5 minutes of insufflation and 21 percent after 15 minutes (Steinbrook, 2001). Even so, mean arterial pressures, systemic vascular resistance, and heart rate did not change significantly.

TABLE 49-3. Comparative Outcomes in Pregnant Women Undergoing Abdominal Surgery

Factor	Open	LSC	*p* value
Primary outcome[a]	1.3%	0.36%	<0.05
Transfusion rate	2.3%	0.41%	0.002
Operative time	115 min	95 min	<0.001
Hospital stay	9.2 d	5.9 d	<0.001

[a]Includes miscarriage, stillbirth, or preterm delivery.
LSC = laparoscopically.

Technique

The following is an overview of laparoscopic technique in pregnancy. For a detailed description and illustrations refer to Chapter 15 in *Cunningham and Gilstrap's Operative Obstetrics,* 3rd edition (Kho, 2017).

Preparation for laparoscopy differs little from that used for laparotomy. Bowel cleansing is not needed but may aid visualization and manipulations by emptying the colon. Nasogastric or orogastric decompression reduces the risk of stomach trocar puncture and aspiration. Aortocaval compression is avoided by a left-lateral tilt of the patient's body. Positioning of the lower extremities in boot-type stirrups maintains access to the vagina for fetal sonographic assessment or *manual* uterine displacement. Intrauterine manipulators are logically avoided. Pregnancy-related hypercoagulability combined with pneumoperitoneum-associated, lower-extremity venous stasis raises venous thromboembolism risks. Prophylactic pneumatic compression devices are wrapped around the calves during patient positioning.

Most reports describe the use of general endotracheal anesthesia with monitoring of end-tidal carbon dioxide—$EtCO_2$ (Hong, 2006; Ribic-Pucelj, 2007). With controlled ventilation, $EtCO_2$ is maintained between 30 and 35 mm Hg.

Beyond the first trimester, technical modifications of standard pelvic laparoscopic entry are required to avoid uterine

TABLE 49-4. Physiological Effects of CO_2 Insufflation of the Peritoneal Cavity

System	Effects[a]	Mechanisms	Possible Maternal-Fetal Effects
Respiratory	Increased $Paco_2$; decreased pH	CO_2 absorption	Hypercarbia, acidosis
Cardiovascular	Increased: heart rate; systemic vascular resistance; pulmonary, central venous, and mean arterial pressures	Hypercarbia and increased intraabdominal pressure	Uteroplacental hypoperfusion—possible fetal hypoxia, acidosis, and hypoperfusion[b]
	Decreased cardiac output	Decreased venous return	
Blood flow	Decreased splanchnic flow with hypoperfusion of liver, kidneys, and gastrointestinal organs	Increased intraabdominal pressure	As above
	Decreased venous return from lower extremities	Increased intraabdominal pressure	As above
	Increased cerebral blood flow	Hypercarbia possibly from shunting due to splanchnic tamponade	Increased CSF pressure[b]

[a]Effects intensified when insufflation pressure >20 mm Hg in baboons (Reedy, 1995).
[b]Data primarily from animal studies.

puncture or laceration (Fig. 49-1). Many recommend open entry techniques to avoid perforations of the uterus, pelvic vessels, and adnexa. With the method described by Hasson (1971, 1974), the abdomen is incised at or above the umbilicus, and the peritoneal cavity entered under direct visualization (Fig. 49-2). At this point, the cannula is connected to the insufflation system, and a 12–mm Hg pneumoperitoneum is created. The initial insufflation should be conducted slowly to allow for prompt assessment and reversal of any untoward pressure-related effects. Gas leakage around the cannula is managed by tightening the surrounding skin with a towel clamp. Insertion of secondary trocars into the abdomen is most safely performed under direct laparoscopic viewing. Single-port surgery also has been described (Dursun, 2013).

In more advanced pregnancies, direct entry through a left upper quadrant port in the midclavicular line, 2 cm beneath the costal margin, may better avoid the fundus (Donkervoort, 2011; Stepp, 2004). Known as the *Palmer point*, this entry site is also used in gynecological laparoscopy because visceroparietal adhesions infrequently form here (Vilos, 2007).

Gasless laparoscopy is a less commonly selected alternative approach that uses a rod with intraabdominal fan-blade-shaped

retractors. When opened, these allow the abdominal wall to be lifted upward. It avoids the typical laparoscopic cardiovascular changes because abdominal wall elevation is created by retraction rather than insufflation (Phupong, 2007).

■ Complications

Risks inherent to any abdominal endoscopic procedure are probably slightly greater during pregnancy. The obvious unique one is perforation of the pregnant uterus with a trocar or Veress needle (Kizer, 2011; Mala, 2014). That said, reported complications are infrequent (Choi, 2021; Koo, 2012; Post, 2019).

■ Perinatal Outcomes

Perinatal outcomes in women are limited to observational studies. Reedy and colleagues (1997) used the updated Swedish Birth Registry database to analyze a 20-year period with more than 2 million deliveries. Of 2181 laparoscopic procedures, most were performed during the first trimester. Perinatal outcomes for these women were compared with those of all women in the database and those undergoing open surgical procedures. These investigators confirmed the earlier findings of an increased risk of low birthweight, preterm delivery, and fetal-growth restriction with surgery during pregnancy. Differences were not found, however, in outcomes of women undergoing laparoscopy versus laparotomy. An observational study of 262 women undergoing surgery for an adnexal mass noted similar findings (Koo, 2012). Although the abortion and stillbirth rates are low with abdominal surgery, laparotomy has more adverse outcomes compared with laparoscopy (see Table 49-3).

RADIOGRAPHY

Imaging modalities are used as adjuncts for diagnosis and therapy during pregnancy. Options include sonography, radiography, computed tomography (CT), and magnetic resonance (MR) imaging. Of these, radiography is the most problematic. Inevitably, some radiographic procedures are performed before recognition of early pregnancy, usually because of trauma or serious illness (Herfel, 2018). Fortunately, most diagnostic radiographic procedures are associated with minimal fetal risks. However, as with medications, these procedures may lead to a needless therapeutic abortion because of patient or physician anxiety or to litigation if pregnancy outcome is adverse.

The American College of Radiology (ACR) has addressed the growing concern of collective radiation doses in all fields of medicine (Amis, 2007). More recent publications have been in support of FDA efforts to decrease radiation exposure and to reduce the number of unnecessary examinations. Recommendations also include considerations for radiosensitive populations, such as children and pregnant or potentially pregnant women. At our institutions, special recommendations are made for gravidas. Radiation exposure values and duration are recorded and monitored in high-exposure areas such as CT and fluoroscopy units. Last, consultation with the radiologist is advised (Chansakul, 2017).

■ Ionizing Radiation

The term *radiation* refers to energy transmission and thus is applied to x-rays and also to microwaves, ultrasound, diathermy, and radio waves. Of these, x-rays and gamma rays have short wavelengths with very high energy and are ionizing radiation forms. The other four energy forms have rather long wavelengths and low energy (Brent, 2009).

Ionizing radiation can directly damage DNA or can create free hydroxyl radicals that in turn damage DNA (Hall, 1991; National Research Council, 1990). Methods of measuring the effects of x-rays are summarized in Table 49-5. The standard terms used are *exposure* (in air), *dose* (to tissue), and *relative effective dose* (to tissue accounting for biological effects). In the range of

TABLE 49-5. Some Measures of Ionizing Radiation

Exposure	Number of ions produced by x-rays per kg of air Unit: roentgen (R)
Dose	Amount of energy deposited per kg of tissue Modern unit: gray (Gy) (1 Gy = 100 rad) (1000 mGy = 1 Gy) Traditional unit: rad
Relative effective dose	Amount of energy deposited per kg of tissue normalized for biological effectiveness (1000 mSv = 1 Sv) Modern unit: sievert (Sv) (1 Sv = 100 rem) Traditional unit: rem

energies for diagnostic x-rays, the dose is now expressed in grays (Gy), and the relative effective dose is expressed in sieverts (Sv). These can be used interchangeably. For consistency, all doses discussed subsequently are expressed in currently used units of gray (1 Gy = 100 rad) or sievert (1 Sv = 100 rem). To convert, 1 Sv = 100 rem = 100 rad.

As noted, x- and gamma-radiation at high doses can damage DNA, and this yields two biological effects in the fetus (Brent, 2009). These are *deterministic effects* and *stochastic effects*.

Deterministic Effects

One potential harm of radiation exposure is deterministic, which may result in abortion, growth restriction, congenital malformations, or intellectual disability. These deterministic effects are threshold effects, and the threshold level is the *NOAEL—no observed adverse effect level* (Brent, 2009). Although controversial, the NOAEL concept supports that there is no risk below the threshold dose of 0.05 Gy or 5 rad. It also suggests that the threshold for gross fetal malformations is more likely to be 0.2 Gy (20 rad) (Lowe, 2020).

The deterministic effects of ionizing radiation have been extensively studied for cell damage that leads to disordered embryogenesis. These have been assessed in animal models as well as in Japanese atomic bomb survivors and the Oxford Survey of Childhood Cancers (Sorahan, 1995). Other sources have confirmed prior observations and provide additional information (Groen, 2012).

Animal Studies

In the mouse model, the lethality risk is highest during the preimplantation period, which extends up to 10 days postconception (Kanter, 2014). Blastomere destruction caused by chromosomal damage is the likely cause (Hall, 1991).

During organogenesis, high-dose radiation—1 Gy or 100 rad—is more likely to cause malformations and growth restriction and less likely to be lethal. Studies of brain development suggest effects on neuronal development and a window of cortical sensitivity in early and midfetal periods. Instead, acute low-dose ionizing radiation appears to have no deleterious effects (Howell, 2013).

Human Data

Data on adverse human effects of high-dose ionizing radiation mostly derive from the atomic bomb survivors of Hiroshima and Nagasaki (Greskovich, 2000; Otake, 1987). The International Commission on Radiological Protection (2003) confirmed initial studies showing that the risk of severe intellectual disability was greatest between 8 and 15 weeks' gestation (Table 49-6) (American College of Radiology, 2018). The mean decrease in intelligence quotient (IQ) scores was 25 points per Gy or 100 rad. The dose response appears linear, but it is unclear whether there is a threshold dose. At <8 weeks' or >25 weeks' gestation, a higher risk of intellectual disability in humans has not been documented, even with doses exceeding 0.5 Gy or 50 rad (International Commission on Radiological Protection, 2003). Most estimates err on the conservative side by assuming a linear nonthreshold hypothesis. In a study of fetuses exposed to a low radiation dose in the first trimester, Guilbaud and colleagues

TABLE 49-6. Deterministic Effects of Ionizing Radiation in Pregnancy

GA (wks)	CA (wks)	<50 mGy (<5 rad)	50–100 mGy (5–10 rad)	>100 mGy (>10 rad)
0–2	—	None	None	None
3–4	1–2	None	Probably none	Low risk of spontaneous abortion
5–10	3–8	None	Potential uncertain and probably too subtle to be clinically detectable	Possible malformations increasing in likelihood as dose increases
11–17	9–15	None	Potential uncertain and probably too subtle to be clinically detectable	Risk of decreased IQ or of mental retardation, increasing in frequency and severity with increasing dose
18–27	16–25	None	None	IQ deficits not detectable at diagnostic doses
>27	>25	None	None	None applicable to diagnostic exposures

CA = conceptional age; GA = gestational age; IQ = intelligence quotient.

(2019) did not find an increased risk for miscarriage, congenital anomalies, or fetal-growth restriction.

Reports have described high-dose radiation used to treat women for malignancy, menorrhagia, and uterine myomas. Dekaban (1968) described 22 infants with microcephaly, intellectual disability, or both following exposure in the first half of pregnancy to an estimated 2.5 Gy or 250 rad for *therapeutic* radiation. These doses are also carcinogenic for the fetus (Brent, 2015).

Summary of Fetal Radiation Exposure

From 8 to 15 weeks' gestation, the fetus is most susceptible to radiation-induced intellectual disability (see Table 49-6). Whether this is a threshold or nonthreshold linear function of dose is unresolved. The Committee on Biological Effects (1990) estimates the risk of severe intellectual disability to be as low as 4 percent for 0.1 Gy (10 rad) and as high as 60 percent for 1.5 Gy (150 rad). Recall that these doses are 2 to 100 times higher than those considered maximal from diagnostic radiation. Importantly, cumulative doses from multiple procedures may reach the harmful range, especially at 8 to 15 weeks' gestation. At 16 to 25 weeks' gestation, the risk is less, and there is no proven risk before 8 weeks or after 25 weeks (American College of Obstetricians and Gynecologists, 2017).

Embryofetal risks from low-dose diagnostic radiation appear to be minimal. Current evidence suggests that risks for malformations, growth restriction, or spontaneous abortion are not increased from a radiation dose of less than 0.05 Gy (5 rad). Brent (2009) concluded that gross congenital malformation rates would not be greater with exposure to less than 0.2 Gy (20 rad). Diagnostic radiographs seldom exceed 0.1 Gy (10 rad) and thus, these procedures are unlikely to cause deterministic effects (Strzelczyk, 2007). As emphasized by Groen and coworkers (2012), 0.1 Gy is the radiation equivalent to that from more than 1000 chest x-rays.

Stochastic Effects

These effects refer to random, presumably unpredictable oncogenic or mutagenic effects of radiation exposure. Stochastic effects concern associations between fetal diagnostic radiation exposure and increased risk of childhood cancers or genetic diseases. Excess cancers can result from in utero exposure to doses as low as 0.01 Sv or 1 rad (Doll, 1997; National Research Council, 2006). The estimated risk of childhood cancer following fetal exposure to 0.03 Gy or 3 rad doubles the background risk of 1 cancer in 600 exposed fetuses to that of 2 in 600 (Hurwitz, 2006).

In one report, in utero radiation exposure was linked to 10 solid cancers in adults from age 17 to 45 years. There was a dose-response relationship as previously noted at the 0.1 Sv or 10 rem threshold. These cancers likely are associated with a complex series of interactions between DNA and ionizing radiation. These interactions make it more problematic to predict cancer risk from low-dose radiation of less than 10 rem. Importantly, below doses of 0.1 to 0.2 Sv, evidence of a carcinogenic effect is not convincing (Brent, 2009, 2014; Preston, 2008; Strzelczyk, 2007).

X-Ray Dosimetry

Estimates of dose to the uterus and embryo for various frequently used radiographic examinations are summarized in Table 49-7. Imaging of maternal body parts farthest from the uterus results in a very small dose of radiation scatter to the embryo or fetus. The size of the woman, radiographic technique, and equipment performance are other variables (Wagner, 1997). Thus, data in the table serve only as guidelines. When the radiation dose for a specific individual is required, a medical physicist should be consulted. The Health Physics Society lists answers to questions commonly asked by patients (Health Physics Society, 2020).

TABLE 49-7. Dose to the Uterus for Common Radiologic Procedures

Study	View	Dose[a] per View (mGy)	No. Films[b]	Dose (mGy)
Skull[c]	AP, PA, Lat	<0.0001	4.1	<0.0005

Therapeutic Radiation

The Radiation Therapy Committee Task Group of the American Association of Physics in Medicine emphasizes careful individualization of cancer radiotherapy for the pregnant woman (Stovall, 1995). In some cases, shielding of the fetus and other safeguards can be employed (Fenig, 2001; Nuyttens, 2002). However, in other instances, the fetus will be exposed to dangerous radiation doses, and a carefully designed plan must be improvised (Prado, 2000). Models that estimate the fetal dose given during maternal brain radiotherapy or tangential breast irradiation have been developed (Mazonakis, 2017). The adverse pregnancy outcomes that occur years after abdominopelvic radiotherapy are detailed in Chapter 66 (p. 1164). (Brent, 2015; Wo, 2009).

Diagnostic Radiation

Radiographs

To estimate fetal risk, approximate x-ray dosimetry must be known. According to the American College of Radiology, no single diagnostic procedure results in a radiation dose significant enough to threaten embryo-fetal well-being (Hall, 1991).

For standard radiographs, dosimetry is presented in Table 49-7. In pregnancy, the anterior-posterior-view chest radiograph is the most common study, and fetal exposure is exceptionally small—0.0007 Gy or 70 mrad. The dose with one abdominal radiograph is higher—0.001 Gy or 100 mrad—because the embryo or fetus lies directly in the x-ray beam path. The standard intravenous pyelogram may exceed 0.005 Gy or 500 mrad because of several exposures. The one-shot pyelogram described in Chapter 56 (p. 999) is useful when urolithiasis or other causes of urinary tract obstruction are unproven by sonography. Mammography and most "trauma series" radiographs of an extremity, skull, or rib deliver low doses because of distance from the fetus (Cepeda-Martins, 2021; Shakerian, 2015).

Fluoroscopy and Angiography

Dosimetry calculations are much more difficult with these procedures because of variations in the number of radiographs obtained, total fluoroscopy time, and fluoroscopy time during which the fetus lies in the radiation field. As shown in Table 49-8, the range varies. Although the FDA limits the exposure rate for conventional fluoroscopy such as barium studies, special-purpose systems such as angiography units have the potential for much higher exposure.

Angiography and vascular embolization may occasionally be necessary for trauma and for serious maternal disorders. As before, a greater distance from the embryo or fetus lowers the exposure and risk.

Computed Tomography

In a recent report describing nearly 3.5 million pregnancies, the use of CT imaging from 1996 to 2016 increased fivefold (Kwan, 2019). These studies are usually performed by obtaining a spiral of 360-degree images that are postprocessed in multiple planes. Of these, the axial image remains the most frequently obtained. Multidetector CT (MDCT) images are now standard for common clinical indications. The most recent detectors have more channels, and these multidetector protocols may result in higher dosimetry compared with prior CT imaging techniques. Several imaging parameters have an effect on exposure (Brenner, 2007). These include pitch, kilovoltage, tube current, collimation, slice number, tube rotation, and total acquisition time. If a study is performed with and without contrast, the dose is doubled because twice as many images are obtained. Fetal exposure also varies with maternal size and fetal size and position. As with plain radiography, the closer the target area is to the fetus, the greater the delivered dose.

Cranial CT imaging for evaluation of neurological disorders and eclampsia is the most frequently performed CT study in gravidas (Chaps. 41, p. 718 and 63, p. 1126). Nonenhanced CT scanning is often used to detect acute hemorrhage within the epidural, subdural, or subarachnoid spaces (Fig. 49-3). Radiation dosage is negligible because of distance from the fetus (Goldberg-Stein, 2012).

Abdominal procedures are more problematic. Hurwitz and associates (2006) employed a 16-channel multidetector scanner to calculate fetal exposure at 0 and 3 months' gestation using a phantom model. Calculations were made for three commonly requested procedures in pregnant women (Table 49-9). The study showed their pulmonary embolism protocol has the same dosimetry exposure as the ventilation-perfusion (V/Q) lung scan discussed subsequently. Although the appendicitis protocol has the highest radiation exposure, it is very useful clinically when MR imaging is not available. Using a greater pitch markedly decreases the dosimetry and yields a sensitivity of 92 percent, a specificity of 99 percent, and a negative-predictive value of 99 percent (Lazarus, 2007). This is discussed further in Chapter 55 (p. 987).

TABLE 49-8. Estimated X-Ray Doses to the Uterus/Embryo from Common Fluoroscopic Procedures

Procedure	Dose to Uterus (mGy)	Fluoroscopic Exposure in Seconds (SD)
Cerebral angiography[a]	<0.1	—
Cardiac angiography[b,c]	0.65	223 (± 118)
Single-vessel PTCA[b,c]	0.60	1023 (± 952)
Double-vessel PTCA[b,c]	0.90	1186 (± 593)
Upper gastrointestinal series[d]	0.56	136

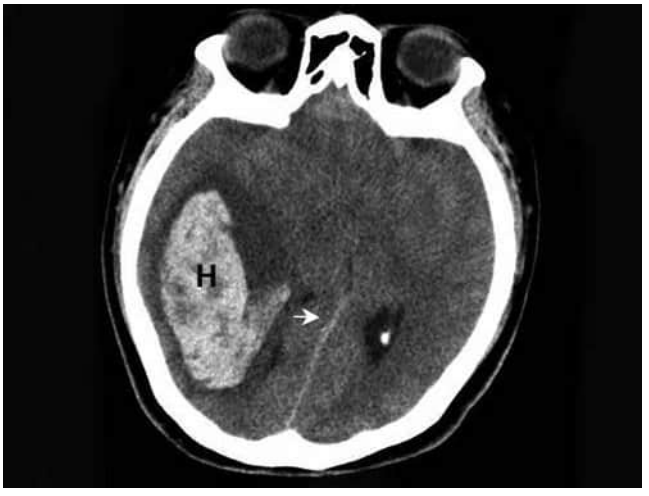

FIGURE 49-3 An image from a noncontrast computed tomography head study demonstrates a large right-sided frontoparietal temporal intraparenchymal hematoma (*H*). The midline (*arrow*) is shifted to the left due to mass effect from the hematoma. (Reproduced with permission from Dr. Amanda Zofkie.)

For suspected urolithiasis, the multidetector-scan protocol is used if sonography is nondiagnostic. White and coworkers (2007) identified urolithiasis in 13 of 20 women with gestations aged an average of 26 weeks. Last, as shown in Figure 49-4, abdominal tomography is performed if indicated in the pregnant woman with severe trauma (Herfel, 2018; Shakerian, 2015).

Most experience with chest CT imaging is with cases of suspected pulmonary embolism. Historically, pulmonary scintigraphy—the V/Q scan—was recommended for pregnant women by 70 percent of radiologists and chest CT angiography by 30 percent (Stein, 2007). However, most currently agree that multidetector-CT pulmonary angiography (CTPA) has improved accuracy because of increasingly faster acquisition times (Brown, 2014). Despite advances in technology, scintigraphy is still recommended by the American Thoracic Society for gravidas with a normal chest x-ray (Leung, 2012). A higher use rate for CTPA has been reported, and dosimetry similar to that with V/Q scintigraphy has been emphasized (Brenner, 2007; Greer, 2015; Tromeur, 2019). The rapid turnaround time with current CTPA protocols at most hospitals has advanced its selection as the preferred modality (Sheen, 2018). The algorithm in the YEARS study describes

TABLE 49-9. Estimated Radiation Dosimetry with 16-Channel Multidetector Computed-Tomographic (MDCT) Imaging Protocols

	Dosimetry (mGy)	
Protocol	Preimplantation	3 Months' Gestation
Pulmonary embolism	0.20–0.47	0.61–0.66
Renal stone	8–12	4–7
Appendix	15–17	20–40

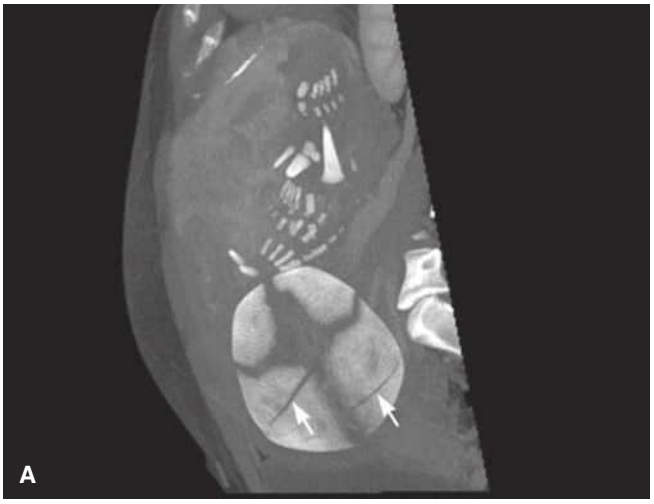

FIGURE 49-4 This woman in her third trimester was involved in a high-speed motor vehicle accident. **A.** Maximum intensity projection acquired for maternal indications readily identifies fetal skull fractures (*arrows*). **B.** 3-D reformatted CT image in a bone algorithm demonstrates the fetal skeleton from data acquired during the maternal examination. Again, the arrow marks one fracture site. (Reproduced with permission from Bailey AA, Twickler DM: Perioperative imaging. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017. Photo contributor: Dr. Travis Browning.)

the use of D-dimer values and clinical criteria to define a subgroup of gravidas warranting further imaging. Thus, the number of indicated CTPA studies resulting from this algorithm is markedly reduced (van der Pol, 2019). In pregnancy, although a negative D-dimer test is helpful, these levels may be normally elevated with increasing gestation and certain maternal complications (Chap. 55, p. 982).

Of other aspects in study selection, the fetal radiation doses are lower with CT pulmonary angiography (CTPA) compared with the V/Q scan. However, maternal chest radiation doses are substantially higher with CTPA (van Mens, 2017). The most recent ongoing Optimised Computed Tomography Pulmonary Angiography in Pregnancy Quality and Safety (OPTICA) study is a prospective trial

using a uniform low-dose CTPA protocol to enable definitive recommendations. Until results are known, our reduced-exposure CTPA protocol is recommended as the initial preferred imaging modality in suspected pulmonary embolism (Chap. 55, p. 987).

CT pelvimetry is used by some before attempting breech vaginal delivery (Chap. 28, p. 522). The fetal dose approaches 0.015 Gy or 1.5 rad, but use of a low-exposure technique may reduce this to 0.0025 Gy or 0.25 rad.

Radiographic Contrast Agents

These can be given intravenously or taken orally. Intravenous contrast agents are considered category B by the FDA. These agents are iodinated and of low osmolality, and thus they cross the placenta to the fetus. With water-soluble iodinated contrast, no cases of neonatal hypothyroidism or other adverse effects have been documented (American College of Obstetrics and Gynecology, 2017). Oral contrast preparations, typically containing iodine or barium, have minimal systemic absorption, and are unlikely to affect the fetus.

Nuclear Medicine Studies

These studies are performed by "tagging" a radioactive element to a carrier that can be injected, inhaled, or swallowed. For example, the radioisotope technetium-99m (Tc-99m) may be tagged to red blood cells, sulfur colloid, or pertechnetate. The method used to tag the agent determines fetal radiation exposure. The amount of placental transfer is obviously important, but maternal renal clearance is also factored because of fetal proximity to her bladder. Measurement of radioactive technetium is based on its decay, and the units used are the curie (Ci) or the Becquerel (Bq). Dosimetry is usually expressed in millicuries (mCi). The effective tissue dose is expressed in sievert units (Sv) with conversion of 1 Sv = 100 rem = 100 rad (see Table 49-5).

Depending on the physical and biochemical properties of a radioisotope, an average fetal exposure can be calculated (Wagner, 1997; Zanzonico, 2000). Commonly used radiopharmaceuticals and estimated absorbed fetal doses are given in Table 49-10. The radionuclide dose should be kept as low as possible (Zanotti-Fregonara, 2017). Exposures vary with gestational age and are greatest earlier in pregnancy for most radiopharmaceuticals. One exception is the later effect of iodine-131 on the fetal thyroid (Wagner, 1997).

In a V/Q scan, perfusion is measured with injected Tc-99m macroaggregated albumin, and ventilation is measured with inhaled xenon-127 or xenon-133. Fetal exposure with either is negligible (Chan, 2002; Mountford, 1997).

Thyroid scanning with iodine-123 or iodine-131 seldom is indicated in pregnancy. However, with the trace diagnostic doses used, fetal risk is minimal. In contrast, therapeutic doses of radioiodine to treat maternal Graves disease or thyroid cancer may cause fetal thyroid ablation and cretinism.

The sentinel lymphoscintigram is a commonly used preoperative study in nonpregnant women to detect the axillary lymph node most likely to have metastases from breast cancer. Tc-99m–sulfur colloid is used in this diagnostic study (Newman, 2007; Spanheimer, 2009). The calculated dose approximates 0.014 mSv or 1.4 mrad, which should not preclude its safe use during pregnancy.

SONOGRAPHY

The development of sonography for study of the fetus and mother is one of the greater achievements in obstetrics. The technique has become virtually indispensable in everyday practice. Its wide-ranging clinical uses are further discussed in Chapters 14 and 15 and in other sections of this book.

MAGNETIC RESONANCE IMAGING

Magnetic resonance technology does not use ionizing radiation, and its use in pregnancy is constantly evolving (Gopireddy, 2021; Mervak, 2019). Advantages include sharp resolution at soft-tissue interfaces, ability to characterize tissue composition, and acquisition of images in any plane—particularly axial, sagittal, and coronal. A portion of Chapter 14 (p. 263) is devoted to mechanisms that generate MR images, and imaging examples are provided throughout this book.

■ Safety

The update of the expert panel on MR safety of the ACR was summarized by Kanal and colleagues (2013). The panel concluded that no harmful human effects are reported from MR imaging. Similar conclusions were reached by the International Society for Ultrasound in Obstetrics and Gynecology (2017).

When operated within standardized limits, maternal and fetal imaging can be safely performed at clinical magnet strengths—3 tesla (T) and below. MR imaging can be used regardless of trimester: (1) if the information cannot be obtained with another nonionizing modality, namely sonography; (2) if the study results will guide maternal or fetal management during pregnancy; and (3) if the imaging cannot be delayed until the woman is no longer pregnant. The decision to use a magnetic field strength >1.5 T may be made for specific maternal indications. Early work also suggests imaging at 3 T is safe and it improves fetal assessment (Chartier, 2019; Victoria, 2016). No demonstrable fetal heart rate pattern changes occur during MR imaging of gravidas (Vadeyar, 2000). Last, studies evaluating children exposed in utero have shown no deleterious effects (Kok, 2004; Reeves, 2010).

Contraindications to MR imaging include internal cardiac pacemakers, neurostimulators, implanted defibrillators and infusion pumps, cochlear implants, shrapnel or other metal in biologically sensitive areas, some intracranial aneurysm clips, and any metallic foreign body in the eye. Of more than 51,000 nonpregnant patients scheduled for MR imaging, one study found that only 0.4 percent had an absolute contraindication to the procedure (Dewey, 2007).

TABLE 49-10. Radiopharmaceuticals Used in Nuclear Medicine Studies

Study	Estimated Activity Administered per Examination (mCi)[a]	Weeks' Gestation[b]	Dose to Uterus/ Embryo (mSv)[c]

Sentinel lymphoscintigram	5 mCi ^{99m}Tc sulfur colloid (1–3 mCi)		5

[a]mCi = millicuries. To convert to mrad, multiply by 100.
[b]Exposures are generally greater prior to 12 weeks compared with increasing gestational ages.
[c]Some measurements account for placental transfer.
[d]The uptake and exposure of ^{131}I increases with gestational age.
DPTA = diethylenetriaminepentaacetic acid; Ga = gallium; HIDA = hepatobiliary iminodiacetic acid; I = iodine; mCi = millicurie; mSv = millisievert; Tc = technetium; TcO_4 = pertechnetate; Tl = thallium.
Data from Adelstein, 1999; Bailey, 2017; Schwartz, 2003; Stather, 2002; Wagner, 1997; Zanzonico, 2000.

■ Contrast Agents

Several different elemental *gadolinium chelates* are used to create paramagnetic contrast. These cross the placenta and are found in the fetus and placenta and are concentrated in amnionic fluid (Oh, 2015). In doses approximately 10 times the normal human dose, a gadolinium-based contrast agent caused slight developmental delay in rabbit fetuses. Inadvertant fetal exposure usually occurs in early pregnancy (Bird, 2019). The American College of Radiology cites a study of 26 women given a gadolinium derivative in the first trimester without adverse fetal effects (Kanal, 2013). Despite this, routine use of gadolinium is not recommended unless potential benefits outweigh fetal risks (American College of Obstetricians and Gynecologists, 2017; American College of Radiology, 2020; Briggs, 2017). This recommendation stems from a possible dissociation of the toxic gadolinium ion from its ligand within amnionic fluid and thus potential prolonged exposure of the fetus.

■ Maternal Indications

In some cases, MR imaging may complement CT, and in others, MR imaging is preferable (Mervak, 2019). MR imaging

is also a superb tool to evaluate the maternal abdomen and retroperitoneal space. One example is evaluation of right lower quadrant pain in pregnancy, specifically with suspected appendicitis (Aguilera, 2018; Tsai, 2017). It can aid detection and localization of adrenal, renal, and gastrointestinal lesions as well as pelvic masses in pregnancy (Boyd, 2012; Raj, 2020; Tica, 2013).

Maternal central nervous system abnormalities, such as brain tumors or spinal trauma, are more clearly seen with MR imaging. This makes it invaluable in the diagnosis of neurological emergencies (Edlow, 2013). Other modalities include MR urography for renal urolithiasis and cardiac MR for investigating normal physiology, complex defects, and cardiomyopathies (Mullins, 2012; Nelson, 2015; Stewart, 2016). The application of cardiovascular MR imaging in pregnant women is expanding (Ducas, 2019).

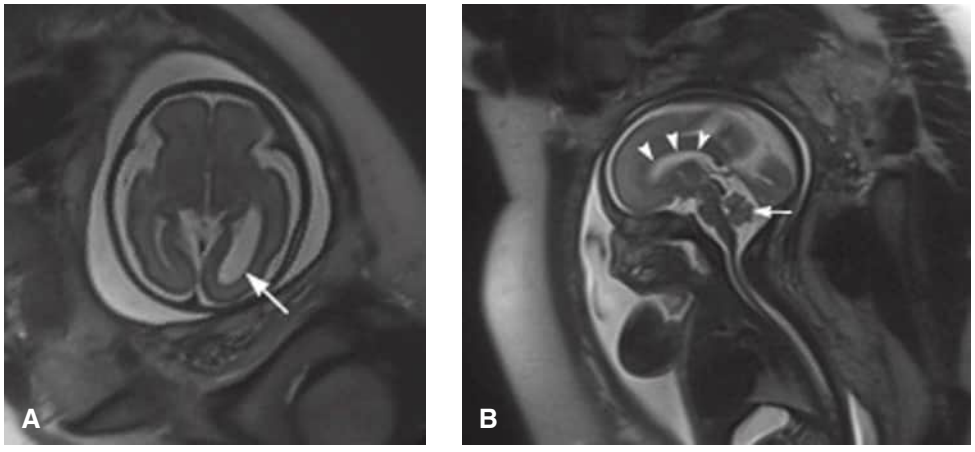

FIGURE 49-5 Nullipara with a 27 weeks' gestation. **A.** Axial T2-weighted MR image shows mild fetal unilateral ventriculomegaly involving the left lateral ventricle (*arrow*). **B.** Sagittal T2-weighted MR image demonstrates normal development of the corpus callosum (*arrowheads*) and vermis (*arrow*).

MR imaging helps also evaluate many pregnancy-specific disorders. It is chosen by many to determine the degree and extent of invasion in placenta accreta spectrum (Chap. 43, p. 762). As discussed in Chapter 40 (p. 701), MR imaging has provided important insights into the pathophysiology of preeclampsia (Nelander, 2018; Zeeman, 2014). As discussed in Chapter 37 (p. 656), CT and MR imaging are useful for puerperal infection evaluation, but MR imaging provides better visualization of the bladder flap area following cesarean delivery (Brown, 1999; Twickler, 1997). Last, preliminary studies of placental function with MR imaging are promising (Hutter, 2019).

■ Fetal Indications

Fetal MR imaging provides a complement to sonography (Laifer-Narin, 2007; Sandrasegaran, 2006). According to Zaretsky and associates (2003a), MR imaging can be used to display almost all elements of the standard fetal anatomical survey. Moreover, the quality of three-dimensional anatomical reconstruction with MR fetal imaging is superb (Werner, 2019). The most frequent fetal indications are evaluation of complex abnormalities of the brain, chest, and genitourinary systems (Williams, 2017). Reichel (2003) and Twickler (2002) and their colleagues have validated its use for fetal central nervous system anomalies and biometry (Fig. 49-5). Others have described MR imaging of fetuses with suprarenal masses or with renal anomalies and oligohydramnios (Castro, 2019; Hawkins, 2008). Fetal weight estimation may be more accurate with MR imaging than with sonography (Kadji, 2019; Zaretsky, 2003b). And MR imaging has been shown to accurately identify fetal anemia requiring transfusions (Jørgensen, 2019).

Fetal movement is problematic for MR imaging, but faster acquisitions eliminate the problem. Morphology is primarily assessed with fast T2-weighted sequences such as half-Fourier acquisition single shot turbo spin echo (HASTE) or single shot fast spin echo (SSFSE). Fetal indications and findings of MR imaging are discussed more extensively in Chapter 14 (p. 266) and throughout this book.

IMAGING DURING PREGNANCY

The American College of Obstetricians and Gynecologists (2017) has reviewed the effects of radiographic, sonographic, and magnetic-resonance exposure during pregnancy. Its suggested guidelines are shown in Table 49-11.

TABLE 49-11. Guidelines for Diagnostic Imaging During Pregnancy and Lactation

Sonography and magnetic resonance (MR) imaging are not associated with fetal risk and are preferred options for imaging in pregnancy
In general, radiation exposure during radiography, computed tomography (CT), or nuclear medicine imaging delivers a dose much lower than that associated with fetal harm. If needed to supplement sonography or MR imaging or if more readily available, these should not be withheld
With MR imaging, gadolinium contrast use should be restricted unless it significantly improves diagnostic accuracy to benefit fetal or maternal outcome
Breastfeeding should not be interrupted after gadolinium administration

CHAPTER 50

Critical Care and Trauma

Treatment of the critically ill pregnant woman has improved over the past three decades with advances in intensive care capabilities. To achieve optimal outcomes, severe medical, surgical, and obstetrical disorders complicating pregnancy are frequently managed by a multidisciplinary team. Importantly, obstetricians and these other health-care team members must have a working knowledge of the unique considerations for pregnancy (Padilla, 2021). Some discussed in Chapter 49 include pregnancy-induced physiological changes, alterations in normal laboratory values, and consideration for the second patient—the fetus. Because critically ill women are usually young and healthy, their prognosis is generally good (Gaffney, 2014).

CRITICAL CARE

Despite noted gains, evidence suggests that severe morbidity rates are increasing (Friedman, 2016). In the United States, 1 to 3 percent of pregnant women require critical care services each year. The risk of death during such admissions ranges from 2 to 11 percent (American College of Obstetricians and Gynecologists, 2019a). Black women and Medicaid recipients are disparately affected (Wen, 2020).

Those with pregnancy-associated complications—especially hemorrhage, sepsis, and hypertension—have the greatest need for intensive care (Chantry, 2015; Guntupalli, 2015a,b). That said, many antepartum admissions are for nonobstetrical reasons, and these include diabetes, pneumonia or asthma, heart disease, chronic hypertension, pyelonephritis, and thyrotoxicosis (Guntupalli, 2015b; Zeeman, 2006). Cardiac disease is the leading non-obstetrical indication for intensive care unit (ICU) admission (Small, 2012). In instances of life-threatening hemorrhage, surgical procedures may be necessary, and close proximity to an operating room is paramount. For women who are undelivered, fetal well-being also is better served by this close proximity, especially because many are delivered preterm (Kilpatrick, 2016).

Organization of Critical Care

The concept and development of critical care for all aspects of medicine and surgery began in the 1960s. As a part of this effort, the National Institutes of Health held a Consensus Conference (1983) and the Society of Critical Care Medicine (1988, 1999) established guidelines for ICUs. Especially pertinent to obstetrics, these costly units prompted the evolution of a step-down *intermediate care unit*. These latter units were designed for patients who did not require intensive care but who needed a higher level of treatment than that provided on a general ward. The American College of Critical Care Medicine and the Society of Critical Care Medicine (1998) have published guidelines for these units (Table 50-1).

Obstetrical Critical Care

Although critical care for obstetrical patients has generally evolved along the path described in the last section, no detailed guidelines

TABLE 50-1. Guidelines for Conditions That Could Qualify for Intermediate Care

Cardiac: evaluation for possible infarction, stable infarction, stable arrhythmias, mild to moderate congestive heart failure, hypertensive urgency without end-organ damage
Pulmonary: stable patients for weaning and chronic ventilation, patients with potential for respiratory failure who are otherwise stable
Neurological: stable central nervous system, neuromuscular, or neurosurgical conditions that require close monitoring
Drug overdose: hemodynamically stable
Gastrointestinal: stable bleeding, liver failure with stable vital signs
Endocrinological: diabetic ketoacidosis, thyrotoxicosis that requires frequent monitoring
Surgical: postoperative from major procedures or complications that require close monitoring
Miscellaneous: early sepsis, patients who require closely titrated intravenous fluids, pregnant women with severe preeclampsia or other medical problems

From the American College of Critical Care Medicine, 1998; Nasraway, 1998.

direct this care. Most hospitals employ a blend of these concepts, and in general, units can be divided into three types.

First, medical and surgical ICUs in most hospitals care for severely ill obstetrical patients. These are staffed by specialists often certified in critical care medicine. Admissions or transfers to these units are situation-specific and based on the acuity of care needed and on the ability of the facility to provide it. For example, pregnant women who require ventilatory support, invasive monitoring, or pharmacological support of circulation are typically transferred to an ICU (Chantry, 2015). In an earlier review of more than 25 tertiary-care referral institutions, approximately 0.5 percent of obstetrical patients were transferred to these ICU types (Zeeman, 2006).

A second option is the obstetrical *intermediate care unit*. Sometimes referred to as a *high-dependency care unit*, this type is found at Parkland Hospital. Located within the labor and delivery unit, it has designated rooms staffed by experienced personnel. This two-tiered system incorporates the guidelines for intermediate and intensive care. Care is provided by maternal-fetal medicine specialists, obstetricians, and nurses with experience in critical care obstetrics. As needed, this team is expanded to include other obstetricians and anesthesiologists, hospitalists, gynecological oncologists, pulmonologists, cardiologists, surgeons, and other medical and surgical subspecialists (Stevens, 2015). Many tertiary-care centers have developed similar intermediate care units and use selected triage to ICUs.

Last, a few services have a full-care ICU as described first. However, it is distinctly operated by obstetrical and anesthesia personnel near the labor and delivery unit (Zeeman, 2003, 2006).

The American College of Obstetricians and Gynecologists (2019a) has summarized critical obstetrical care implementation depending on hospital size and technical facilities. For intrahospital transfers, the federal Emergency Medical Treatment and Labor Act (EMTALA) guidelines must be followed. Moreover, according to the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017), the minimal monitoring required for a critically ill patient during transport includes continuous pulse oximetry, electrocardiography, and regular assessment of vital signs. Patients must have secure venous access, and those who are mechanically ventilated must have endotracheal tube position confirmed and secured. Left uterine displacement and supplemental oxygen is applied routinely during transport of antepartum patients. Continuous fetal heart rate or tocodynamic monitoring is individualized.

Severe Maternal Morbidity

Childbirth can result in significant morbidity for the pregnant woman. To help address this, *severe maternal morbidity (SMM)* was developed as a population-based monitoring standard for the most common of these complications (Callaghan, 2012). An overall SMM rate is derived from 18 SMM indicators, which are abstracted from International Classification of Diseases-10 (ICD-10) codes in administrative databases. SMM rates for an individual indicator also may be informative. Some indicators are found in Table 50-1, and the full list is available at www.cdc.gov/reproductivehealth/maternalinfanthealth/smm/severe-morbidity-ICD.htm. Several of these are included in this chapter, whereas others are addressed in specific chapters on their topic.

The goal of SMM monitoring is to identify opportunities for intervention and prevention. Despite its promise, limitations should be recognized. First, the rate does not factor underlying patient comorbidities and obstetrical risks. Thus, a tertiary-care center that serves as a referral center for women with placenta accreta spectrum will understandably have higher blood transfusion rates. Second, the ICD-10 indicators for existing SMM events are not comprehensive. For example, only codes for *total* abdominal hysterectomy are currently included in the SMM rate, whereas *supracervical* hysterectomy is not. With these limitations in mind, caution should be exercised when using SMM as a quality metric to compare hospitals (Callaghan, 2012).

Hemodynamic Changes in Pregnancy

Data obtained during pregnancy with pulmonary artery catheterization (PAC) have contributed immensely to the understanding of normal pregnancy hemodynamics and pathophysiology of common obstetrical conditions. Clark and coworkers (1989) used PAC to obtain cardiovascular measurements in healthy

TABLE 50-2. Formulas for Deriving Various Cardiopulmonary Parameters

Mean arterial pressure (MAP) (mm Hg) = [SBP + 2 (DBP)] ÷ 3
Cardiac output (CO) (L/min) = heart rate × stroke volume
Stroke volume (SV) (mL/beat) = CO/HR
Stroke index (SI) (mL/beat/m^2) = stroke volume/BSA
Cardiac index (CI) (L/min/m^2) = CO/BSA
Systemic vascular resistance (SVR) (dyn × s × cm^{-5}) = [(MAP − CVP)/CO] × 80
Pulmonary vascular resistance (PVR) (dyn × s × cm^{-5}) = [(MPAP − PCWP)/CO] × 80

BSA = body surface area (m^2); CVP = central venous pressure (mm Hg); DBP = diastolic blood pressure; HR = heart rate (beats/min); MAP = mean systemic arterial pressure (mm Hg); MPAP = mean pulmonary artery pressure (mm Hg); PCWP = pulmonary capillary wedge pressure (mm Hg); SBP = systolic blood pressure.

pregnant women and again in these same women when nonpregnant (Chap. 4, p. 64). Other evaluated conditions include preeclampsia-eclampsia, acute respiratory distress syndrome, and amnionic-fluid embolism (Clark, 1997; Cunningham, 1987; Hankins, 1985). Because of these studies, most have concluded that such monitoring is seldom necessary (American College of Obstetricians and Gynecologists, 2013, 2019a, 2020; Magder, 2015).

Formulas for deriving some hemodynamic parameters are shown in Table 50-2. These measurements can be indexed for body size by dividing by body surface area. Normal values for nonpregnant adults are used, but with the caveat that these may not necessarily reflect changes induced by the low-resistance uteroplacental circulation.

Cardiac complications are a common indication for ICU admission of pregnant women (Guntupalli, 2015b). Evaluation of cardiac function is frequently performed using echocardiography. This technology is indispensable in interrogating cardiac anatomy and especially right-ventricular function (Krishnan, 2015; Thiele, 2015). It is considered in more detail in Chapter 52 (p. 918), and some normal values are listed in the Appendix (p. 1233).

Given the association of cardiac dysfunction with maternal morbidity and mortality, efforts have strived to expand cardiac monitoring by including noninvasive cardiac output monitoring (NICOM). With this tool, a small electrical current is applied to the chest, and voltage signals are captured by four skin sensors arranged in a box on the chest. Compared with Doppler echocardiography, NICOM significantly overestimates stroke volume and cardiac output (McLaughlin, 2017). This modality has not yet been widely adopted for use in the obstetrical population.

ACUTE PULMONARY EDEMA

The incidence of pulmonary edema complicating pregnancy averages 1 in 500 deliveries at tertiary referral centers. Of the two general etiologies, *cardiogenic*, namely, *hydrostatic edema* is caused by high pulmonary capillary hydraulic pressures. The other is *noncardiogenic*, that is, *permeability edema* caused by capillary endothelial and alveolar epithelial damage. In pregnancy, noncardiogenic pulmonary edema is more common. More than half of pregnant women who develop pulmonary edema have some degree of sepsis in conjunction with tocolysis, severe preeclampsia, or obstetrical hemorrhage combined with vigorous fluid therapy (O'Dwyer, 2015; Pordeus, 2018).

In one study, the etiologies of pulmonary edema were hypertension, cardiogenic, or both, and iatrogenic fluid overload (Pordeus, 2018). In another study of 53 cases, 83 percent were caused by hypertensive disorders; 11 percent, cardiac events; and 6 percent, sepsis (O'Dwyer, 2015). Although used less commonly today, tocolytic therapy with β-mimetic drugs was the cause of up to 40 percent of pulmonary edema cases (Gandhi, 2014; Jenkins, 2003).

■ Noncardiogenic Permeability Edema

Endotheliopathy is the common denominator that is associated with preeclampsia, sepsis, and acute hemorrhage—or frequently combinations thereof—and they are the most common predisposing factors to pulmonary edema (Table 50-3). These clinical scenarios are often associated with corticosteroids given to induce fetal lung maturation along with vigorous fluid replacement and tocolytic therapy (Thornton, 2011). Parenteral β-agonists are indisputedly linked to pulmonary edema. Some studies have also associated magnesium sulfate given for preeclampsia (Gandhi, 2014; Wilson, 2014; Xiao, 2014). Combined therapy is causative.

■ Cardiogenic Hydrostatic Edema

Ventricular failure causing pulmonary edema in pregnancy is usually associated with some form of hypertension, hemorrhage and anemia, and sepsis (Cunningham, 2019; Vaught, 2018).

TABLE 50-3. Some Causes and Associated Factors for Pulmonary Edema in Pregnancy

Noncardiogenic permeability edema: endotheliopathy with capillary-alveolar leakage
Preeclampsia syndrome
Acute hemorrhage
Sepsis: pyelonephritis, metritis
Tocolytic therapy: β-mimetics, $MgSO_4$
Aspiration pneumonitis
Vigorous intravenous fluid therapy
Pancreatitis
Cardiogenic pulmonary edema: myocardial failure with hydrostatic edema from excessive pulmonary capillary pressure
Hypertensive cardiomyopathy
Obesity: adipositas cordis
Left-sided valvular disease
Vigorous intravenous fluid therapy
Pulmonary hypertension

Although it can be due to congenital or acquired anatomical defects, diastolic dysfunction is frequently from chronic hypertension, obesity, or both (Jessup, 2003; Kenchaiah, 2002). In these women, acute systolic hypertension exacerbates diastolic dysfunction and causes pulmonary edema (Dennis, 2012; Vaught, 2018). In two studies of pregnant women with preeclampsia and pulmonary edema, half of them were undelivered (Gandhi, 2014; Pordeus, 2018).

Diagnosis

Clinical examination is confirmed by chest radiographs. Bedside lung sonography may be helpful to detect fluid in the interstitial space and alveoli (Pachtman, 2017). In many cases, when echocardiography is done later, systolic function is normal as measured by ejection fraction.

In addition, ventricular myocytes and fibroblasts secrete *brain natriuretic peptide (BNP)* and *atrial natriuretic peptide (ANP)* with the distention seen in heart failure. In nonpregnant patients, concentrations <100 pg/mL have an excellent negative predictive value, and levels >500 pg/mL have an excellent positive predictive value. It is problematic that levels frequently are 100 to 500 pg/mL and thus are nondiagnostic. Moreover, concentrations of N-terminal BNP and ANP are both elevated with preeclampsia (Szabo, 2014; Tihtonen, 2007). Normal values are discussed in Chapter 4 (p. 65), and those for normal pregnancy are given in the Appendix (p. 1231).

Management

Acute pulmonary edema requires emergency care. Oxygen therapy is initiated and furosemide is given in periodic 20- to 40-mg intravenous doses as needed. For oxygen delivery, nasal cannula, simple masks, and nonrebreathing masks are first-line systems. Both nasal cannula and simple mask allow mixing of supplemental oxygen with room air. Consequently, oxygen administration is imprecise (Bateman, 1998). A nonrebreathing mask has valves that limit the mixing of exhaled gas and room air with the oxygen supply. Flow rates up to 10 to 15 L/min may be achieved, and oxygen concentrations approach 95 percent (Boumphrey, 2003). As a treatment goal, a pulse oximetry reading >92 percent reflects adequate oxygenation.

Further treatment depends on whether a woman is ante- or postpartum. A live fetus prohibits the use of cardioactive drugs that might rapidly lower peripheral resistance and in turn severely diminish uteroplacental circulation. The cause of cardiogenic failure is determined by echocardiography, which will help direct further therapy. *Importantly, acute pulmonary edema is not an indication for emergency cesarean delivery*.

ACUTE RESPIRATORY DISTRESS SYNDROME

Acute lung injury that causes a form of severe permeability pulmonary edema and respiratory failure is termed *acute respiratory distress syndrome (ARDS)*. This is a pathophysiological continuum from mild pulmonary insufficiency to dependence on high inspired oxygen concentrations and mechanical ventilation. Uniform criteria for its diagnosis are lacking, and thus the incidence is variably reported for pregnancy. Rush and colleagues (2017) queried the nationwide inpatient samples of more than 5.4 million pregnancies and cited an incidence of 60 ventilated cases per 100,000 births. They found an overall mortality rate of 9 percent. This rate is much higher if caused or complicated by sepsis. Last, if ARDS develops antepartum, the perinatal mortality rate is correspondingly high.

Definitions

Physiological criteria required for diagnosis of acute lung injury are study dependent. In general, less precise terms are used for clinical care. Clinical findings include dyspnea, tachypnea, and oxygen desaturation. Most investigators define ARDS as radiographically documented pulmonary infiltrates, a ratio of arterial oxygen tension to the fraction of inspired oxygen (Pao_2:Fio_2) <200, and no evidence of heart failure (Baron, 2018). Revised by international consensus, the *Berlin Definition* includes categories of mild, moderate, and severe (Fan, 2018).

Etiopathogenesis

ARDS begins with an acute lung injury from various causes (Table 50-4). More than half of pregnant women with ARDS have some combination of sepsis, hemorrhage, shock, and fluid overload. Diffuse infectious pneumonia and sepsis are two of the most frequent single-agent causes. Because it is common, influenza pneumonitis often is a cause. Other etiologies such as pneumococcal, metapneumovirus, and Legionnaire disease also are encountered (Close, 2016; Fuchs, 2017). Of sepsis causes, pyelonephritis, puerperal pelvic infection, and chorioamnionitis are the most frequent. The contribution of *transfusion-related acute lung injury (TRALI)* is unclear (Chap. 44, p. 774).

TABLE 50-4. Some Causes of Acute Lung Injury and Respiratory Failure

Pneumonia: bacterial, viral, aspiration
Sepsis: chorioamnionitis, pyelonephritis, puerperal infection, septic abortion
Hemorrhage: shock, massive transfusion, transfusion-related acute lung injury (TRALI)
Preeclampsia syndrome
Tocolytic therapy
Embolism: amnionic fluid, trophoblastic disease, air, fat
Connective tissue disease
Substance abuse
Irritant inhalation and burns
Pancreatitis
Drug overdose
Fetal surgery
Trauma
Sickle-cell disease
Miliary tuberculosis
Cerebral hemorrhage

From Baron, 2018; Duarte, 2014; Lapinsky, 2015; Sibai, 2014; Snyder, 2013; Zeeman, 2006.

Endothelial injury in the lung capillaries releases cytokines that recruit neutrophils to the inflammation site. Here, they elaborate more cytokines to worsen tissue injury. Three stages describe ARDS development (Baron, 2018). First, the *exudative phase* follows widespread injury to the alveolar epithelium and to the microvascular endothelium, including the pulmonary vasculature. This endotheliopathy results in increased pulmonary capillary permeability, surfactant loss or inactivation, diminished lung volume, and vascular shunting that creates arterial hypoxemia. Next, the *proliferative phase* usually begins approximately 7 days later and lasts up to 21 days. Most patients recover during this phase. Last, the *fibrotic phase* results from healing. Despite these insults, the long-term prognosis for pulmonary function is surprisingly good (Baron, 2018; Herridge, 2003).

Clinical Course

With pulmonary injury, the clinical condition depends largely on the insult magnitude, the ability to compensate for it, and the disease stage. At first, physical examination findings are absent, except perhaps hyperventilation, and arterial oxygenation usually is adequate. With worsening, clinical and radiological evidence for pulmonary edema, decreased lung compliance, and increased intrapulmonary blood shunting become apparent. Progressive alveolar and interstitial edema develops, and inflammatory cells and erythrocytes extravasate. Ideally, pulmonary injury is identified at this early stage, and specific therapy is directed at the underlying insult.

Further progression to acute respiratory failure is characterized by marked dyspnea, tachypnea, and hypoxemia. Additional functional lung volume loss results in worsening of pulmonary compliance and greater shunting. Diffuse abnormalities are heard by auscultation, and a chest radiograph characteristically demonstrates bilateral lung involvement (Fig. 50-1). At this phase, the injury ordinarily would be lethal without ventilatory support. When shunting exceeds 30 percent, severe refractory hypoxemia develops. Comorbid metabolic and respiratory acidosis can result in myocardial irritability, dysfunction, and cardiac arrest.

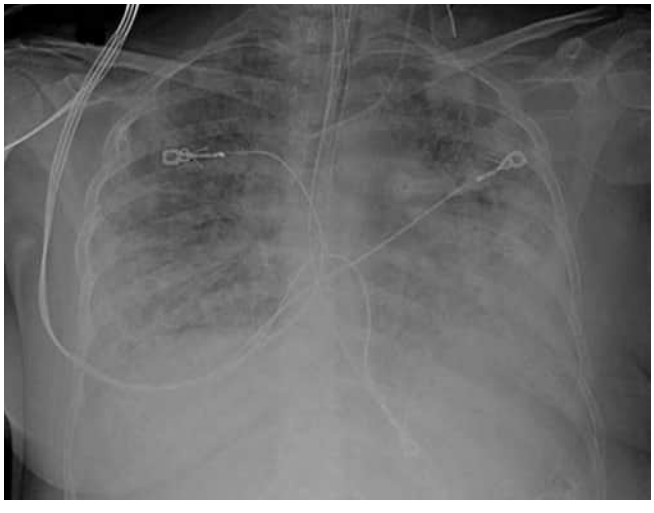

FIGURE 50-1 Anteroposterior chest radiograph of a second-trimester pregnant woman with marked bilateral parenchymal and pleural opacification secondary to acute respiratory distress syndrome (ARDS).

Management

ARDS mortality rates have declined because of advances in critical care medicine (Baron, 2018; Fan, 2018). Management requires close attention to recognizing and treating underlying medical and surgical disorders. In cases of severe acute lung injury, providing adequate oxygenation of peripheral tissues is balanced against ventilatory maneuvers that further aggravate lung injury. At least intuitively, increasing oxygen delivery should produce a corresponding rise in tissue uptake, but this is difficult to measure. Support of systemic perfusion with intravenous crystalloid and blood is imperative. Because sepsis is commonplace in lung injury, aggressive antimicrobial therapy is given for infection, and any necrotic tissues are debrided. Oxygen delivery can be greatly improved by correcting anemia. Specifically, each gram of hemoglobin carries 1.25 mL of oxygen when 90-percent saturated. By comparison, raising the arterial Pao_2 from 100 to 200 mm Hg results in the transport of only 0.1 mL of additional oxygen for each 100 mL of blood.

Reasonable goals in caring for the woman with severe lung injury are a Pao_2 of 60 mm Hg or 90-percent oxygen saturation using an inspired oxygen content <50 percent and positive end-expiratory pressures <15 mm Hg. With regard to the pregnancy, it remains controversial whether delivery of the fetus improves maternal oxygenation (Mallampalli, 2010). In a study of 29 women undergoing mechanical ventilation, 10 were delivered while intubated (Lapinsky, 2015). Respiratory function modestly improved in half, but no factors were identified that predicted a better outcome.

Mechanical Ventilation

Noninvasive ventilation, that is, positive-pressure ventilation by face mask, may be effective in some women in early stages of pulmonary insufficiency (Duarte, 2014). *Conventional ventilation* is done with tracheal intubation. Early intubation is preferred in the gravida if respiratory failure is more likely than not and especially if it appears imminent. Because of the physiological changes outlined in Chapter 4 (p. 67), $Paco_2$ is normally reduced in a gravida relative to a nonpregnant woman. Thus, intubation should be considered when $Paco_2$ levels reach 35 to 40 mm Hg.

Mechanical ventilation is used to assist or replace spontaneous respiration (Celli, 2018). It improves oxygenation by its application of high-oxygen-content gas and positive pressure. Many successful formulas for mechanical ventilation are employed, and initially a tidal volume ≤6 mL/kg is optimal (Fan, 2018; Schwaiberger, 2016). Adjustments are made to obtain a Pao_2 >60 mm Hg or a hemoglobin oxygen saturation ≥90 percent and to reach a $Paco_2$ of 35 to 45 mm Hg. Lower Pao_2 levels are avoided, because placental perfusion may be impaired.

The mode is the manner in which ventilator breaths are triggered, cycled, and limited. Three commonly used ventilation modes of include *assist-control*, *intermittent mandatory*, and *pressure-support ventilation*. Although not a support mode,

continuous positive airway pressure can be used in patients with an intact ventilatory system who require little ventilatory support.

Pregnancy

In a study of 51 women with ARDS, almost half had severe preeclampsia, and most required intubation postpartum. Eleven were delivered while being ventilated, and another six were discharged undelivered (Jenkins, 2003). Two mothers died, and this included a woman who died as a complication of tocolytic treatment. In a multicenter report, Lapinsky and associates (2015) described 29 pregnant women undergoing mechanical ventilation for various indications. Only a few had severe ARDS, and the mortality rate was 10 percent. Ten women delivered while being ventilated, but this had little beneficial effect on their respiratory status.

Positive End-Expiratory Pressure

With severe lung injury and high intrapulmonary shunt fractions, it may not be possible to provide adequate oxygenation with usual ventilatory pressures, even with 100-percent oxygen. Positive end-expiratory pressure is usually successful in decreasing the shunt by recruiting collapsed alveoli. At low levels of 5 to 15 mm Hg, positive pressure can typically be used safely. At higher levels, impaired right-sided venous return can result in decreased cardiac output, lowered uteroplacental perfusion, alveolar overdistention, falling compliance, and barotrauma (Celli, 2018; Schwaiberger, 2016).

Extracorporeal Membrane Oxygenation

As discussed in Chapter 33 (p. 600), extracorporeal membrane oxygenation (ECMO) has been successfully used for neonatal meconium aspiration syndrome. Some preliminary observations suggest that veno-venous ECMO may be useful in adults with ARDS (Combes, 2018; Ende, 2016; Matthay, 2018). In one case series, 12 pregnant women with influenza-induced lung failure were treated with ECMO, and of four maternal deaths, three were due to anticoagulation-related hemorrhage (Nair, 2011). ECMO use also has been reported for status asthmaticus (Clifford, 2018; Steinack, 2017). In multiple reviews, ECMO was used mostly for ARDS, and the maternal and perinatal mortality rate approximated 30 percent (Liu, 2018; Ramanathan, 2020; Saad, 2016). Maternal survival appears to be significantly lower compared with nonpregnant women requiring ECMO (Webster, 2019).

Fetal Oxygenation

The propensity of the hemoglobin molecule to release oxygen is described by the *oxyhemoglobin dissociation curve* (Fig. 50-2). For clinical purposes, the curve can be divided into an upper oxygen association curve representing the alveolar-capillary environment and a lower oxygen dissociation portion representing the tissue-capillary environment. Shifts of the curve have their greatest effect at the steep portion because they affect oxygen delivery. A rightward shift is associated with decreased hemoglobin affinity for oxygen and hence greater tissue-capillary oxygen interchange. Hypercapnia, metabolic acidosis, fever, and increased 2,3-diphosphoglycerate levels produce rightward

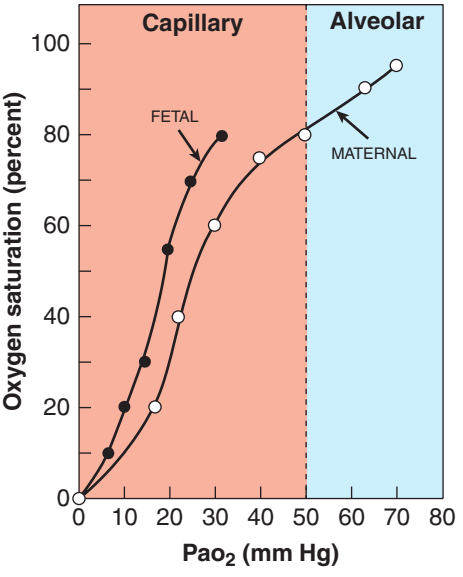

FIGURE 50-2 Oxyhemoglobin dissociation curve. With higher oxygen tension (Pao_2) in the pulmonary alveoli, adult hemoglobin is maximally saturated compared with that at the lower oxygen tension in the tissue capillaries. Note that at any given oxygen tension, fetal hemoglobin carries more oxygen than adult hemoglobin, as indicated by percent saturation.

shifts. During normal pregnancy, the erythrocyte concentration of 2,3-diphosphoglycerate rises by approximately 30 percent, which favors oxygen delivery.

Fetal hemoglobin has a higher oxygen affinity than adult hemoglobin. As seen in Figure 50-2, its oxyhemoglobin dissociation curve is positioned to the left of the adult curve. To achieve 50-percent hemoglobin saturation in the mother, the Pao_2 must be 27 mm Hg compared with only 19 mm Hg in the fetus. Under normal physiological conditions, the fetus is constantly on the dissociation, or tissue, portion of the curve. Even with severe maternal lung disease and very low Pao_2 levels, oxygen displacement to fetal tissues is favored. For example, in pregnant women who live at high altitudes, and despite a maternal Pao_2 of only 60 mm Hg, the fetal Pao_2 is equivalent to that seen at sea level (Subrevilla, 1971).

Intravenous Fluids

Although mortality rates are similar, conservative versus liberal fluid management is associated with fewer days of mechanical ventilation (Wiedemann, 2006). Some normal pregnancy-induced physiological changes predispose to a greater risk of permeability edema from vigorous fluid therapy. Serum albumin concentration determines colloid oncotic pressure (COP), and 1 g/dL exerts approximately 6 mm Hg of pressure. As discussed in Chapter 4 (p. 70), serum albumin concentrations normally drop in pregnancy. This results in a decline in COP from 28 mm Hg in the nonpregnant woman to 23 mm Hg at term and to 17 mm Hg in the puerperium (Dennis, 2012). With preeclampsia, endotheliopathy causes extravascular albumin loss and lowered serum albumin levels. These changes have a significant clinical effect on the *colloid oncotic pressure/wedge pressure gradient*. Normally, this gradient exceeds 8 mm Hg. However, when it is ≤4 mm Hg, the risk for pulmonary edema rises due

to Starling forces. Finally, no benefits are gained by albumin versus crystalloid infusions in these women (Uhlig, 2014).

Long-Term Outcomes

Most patients with ARDS regain nearly normal lung function (Baron, 2018). In nonpregnant subjects, however, risks for impaired global cognitive function at 3 and 12 months are significant (Pandharipande, 2013). Moreover, return to basic normal activity is delayed 1 to 2 years. In a 5-year follow-up study, Herridge and coworkers (2011) reported normal lung function but significant exercise limitation as well as physical and psychological sequelae. Long-term follow-up studies of pregnant women who recover from ARDS are lacking.

SEPSIS AND SEPTIC SHOCK

Sepsis is defined as infection with organ dysfunction, and *septic shock* manifests with unresponsive hypotension (Cecconi, 2018). The Third International Consensus Definition—"Sepsis-3"—denotes clinical criteria for sepsis to include suspected infection and acute organ dysfunction (Seymour, 2018). Use of the terms *systemic inflammatory response syndrome (SIRS)* and *severe sepsis* are no longer recommended. The syndrome is induced by a systemic inflammatory response to bacteria or viruses or their by-products such as endotoxins or exotoxins. Its severity is a continuum (Fig. 50-3). In an analysis of 55 million births, Kendle and associates (2019) found an incidence of 2.4 cases per 10,000 deliveries. The Society for Maternal-Fetal Medicine cites the incidence to be 4 to 10 cases per 10,000 births. According to the Centers for Disease Control and Prevention (CDC), infection and sepsis caused 12 percent of pregnancy-related deaths in the United States from 2013 to 2017 (Petersen, 2019).

Infections that most commonly cause sepsis syndrome in obstetrics are pyelonephritis (Chap. 56, p. 997), chorioamnionitis and puerperal sepsis (Chap. 37, p. 651), pneumonia (Chap. 54, p. 962), septic abortion (Chap. 11, p. 203), and necrotizing fasciitis (Chap. 37, p. 654). Septic shock is defined by the need for vasopressor therapy despite fluid resuscitation. The mortality rate for this in nonpregnant patients is 20 percent (Snyder, 2013). The maternal mortality risk from sepsis is significantly underestimated (Bauer, 2015; Chebbo, 2016). However, most evidence indicates that case-fatality rates are lower for pregnant women compared with age-matched nonpregnant controls (Kidson, 2018).

Etiopathogenesis

Most information concerning sepsis pathogenesis derives from study of lipopolysaccharide (LPS), which is the endotoxin portion of gram-negative bacteria. The lipid A moiety is bound by mononuclear blood cells, becomes internalized, and stimulates release of mediators and a series of complex downstream perturbations. Clinical aspects of sepsis manifest when cytokines that have endocrine, paracrine, and autocrine actions are released (Seymour, 2018; Suffredini, 1989).

Although sepsis in obstetrics may be caused by several pathogens, most cases stem from a small group. Sepsis and bacteremia complicating pyelonephritis are commonly caused by *Escherichia coli* and *Klebsiella* species (Cunningham, 1987; Snyder, 2013). Although pelvic infections are usually polymicrobial, bacteria that cause severe sepsis are frequently endotoxin-producing Enterobacteriaceae, and most commonly *E coli* (Eschenbach, 2015). Other pelvic pathogens are aerobic and anaerobic streptococci, *Bacteroides* species, and *Clostridium* species. Of these, group A streptococcal infections are a significant source of infection (Leonard, 2019). Some strains of group

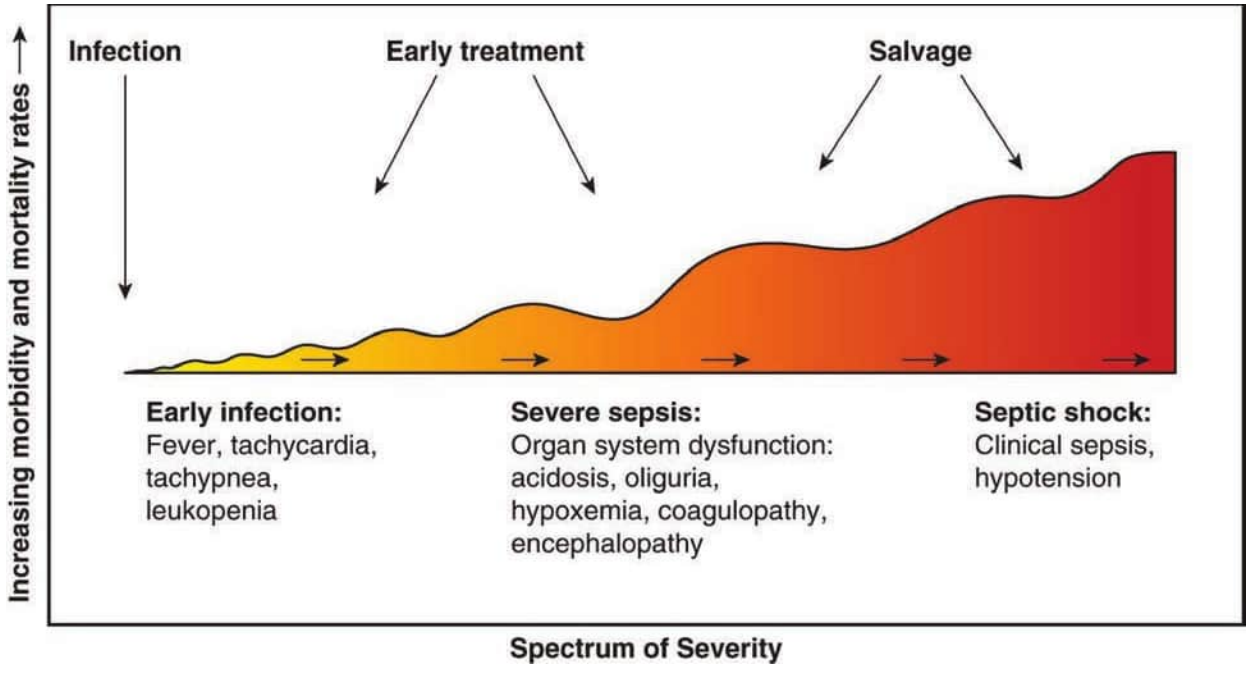

FIGURE 50-3 Sepsis begins with a systemic inflammatory response to infection that may progress to septic shock.

TABLE 50-5. Clinical Manifestations of Sepsis

Central nervous system: confusion, delirium, somnolence, coma, combativeness, fever, hypothermia
Cardiovascular: tachycardia, hypotension
Pulmonary: tachypnea, arteriovenous shunting with dysoxia and hypoxemia, exudative infiltrates from endothelial-alveolar damage, pulmonary hypertension
Gastrointestinal: gastroenteritis—nausea, vomiting, and diarrhea; ileus; hepatocellular necrosis—jaundice, transaminitis
Renal: prerenal oliguria, azotemia, acute kidney injury, proteinuria
Hematological: leukocytosis or leukopenia, thrombocytopenia, activation of coagulation with disseminated intravascular coagulation
Endocrinological: hyperglycemia, adrenal insufficiency
Cutaneous: acrocyanosis, erythroderma, bullae, digital gangrene

A β-hemolytic streptococci and *Staphylococcus aureus*—including community-acquired methicillin-resistant *S aureus* strains (CA-MRSA)—produce a superantigen that activates T cells to rapidly cause all features of sepsis. This manifests as *toxic shock syndrome*, which is discussed further in Chapter 37 (p. 659) (Moellering, 2011; Soper, 2011).

Potent bacterial exotoxins also can cause severe sepsis syndrome. Examples include exotoxins from *Clostridium perfringens* or *sordellii,* toxic shock syndrome toxin 1 (TSST-1) from *S aureus*, and toxic shock–like exotoxin from group A β-hemolytic streptococci (Herrera, 2016; Kaiser, 2018). These last exotoxins cause rapid and extensive tissue necrosis and gangrene, especially of the postpartum uterus, and may cause profound cardiovascular collapse and maternal death. In a review discussed subsequently, the maternal mortality rate from these infections was 58 percent (Yamada, 2010).

Sepsis begins with an inflammatory response that is directed against microbial endotoxins and exotoxins. CD4 T cells and leukocytes are stimulated to produce proinflammatory compounds that include tumor necrosis factor α (TNF-α), several interleukins, and other cytokines, proteases, oxidants, and bradykinin that result in a "cytokine storm." Many other cellular reactions then follow and include stimulation of pro- and anti-inflammatory compounds, procoagulant activity, gene activation, receptor regulation, and immune suppression (Seymour, 2018). It is also likely that interleukin 6 (IL-6) mediates myocardial suppression (Pathan, 2004).

The pathophysiological response to this cascade is selective vasodilation with maldistribution of blood flow. Leukocyte and platelet aggregation cause capillary plugging. Worsening endotheliopathy causes profound permeability, capillary leakage, and interstitial fluid accumulation. Depending on the degree of endothelial injury and inflammatory response, a pathophysiological and clinical continuum evolves as depicted in Figure 50-3. The clinical syndrome begins with subtle signs of sepsis from infection and terminates with septic shock. In its early stages, clinical shock results primarily from lowered systemic vascular resistance that is not compensated fully by increased cardiac output. Hypoperfusion worsens lactic acidosis, decreases tissue oxygen extraction, and leads to end-organ dysfunction that includes acute lung and kidney injury. Finally, *septic cardiomyopathy* with global involvement is common with severe sepsis (Beesley, 2018; Martin, 2018).

Clinical Manifestations

Sepsis has myriad clinical manifestations that, at least in part, are dependent on the specific invading microorganism and its particular endo- or exotoxins. Some of the general effects of LPS are shown in Table 50-5.

Thus, although capillary leakage initially causes hypovolemia, if intravenous crystalloid is given at this point, sepsis hemodynamically can be described as a high-cardiac-output, low-systemic-vascular-resistance condition (Fig. 50-4).

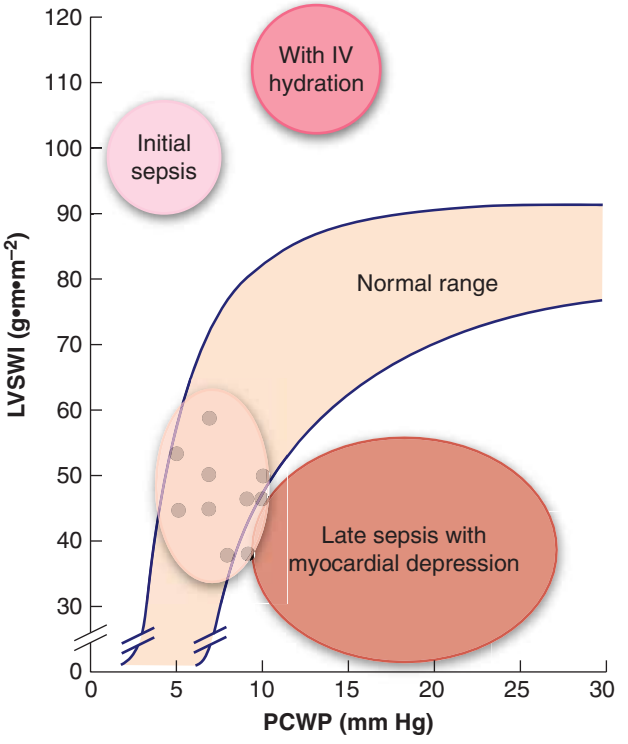

FIGURE 50-4 Hemodynamic effects of sepsis. Values for normal women at term are shown by dots. With early sepsis, there is high cardiac output and low vascular resistance. With fluid resuscitation, cardiac output increases even more, but so does capillary hydraulic pressure. With continued sepsis, there may be myocardial depression to further increase capillary hydraulic pressure. Decreased plasma oncotic pressure (serum albumin [g] × 6 mm Hg) contributes to interstitial lung fluid and endo/epithelial leak causes alveolar flooding. IV = intravenous; LVSWI = left ventricular stroke work index; PCWP = pulmonary capillary wedge pressure.

Concomitantly, pulmonary hypertension develops, and despite the high cardiac output, severe sepsis also causes myocardial depression (Seymour, 2018). This is often referred to as the *warm phase* of septic shock. These findings are the most common cardiovascular manifestations of early sepsis, but they can be accompanied by some of the other clinical or laboratory aberrations listed in the prior section.

The response to initial intravenous hydration may be prognostic. Most pregnant women who have early sepsis show a salutary response with crystalloid and antimicrobial therapy, and if indicated, debridement of infected tissue. Conversely, if following vigorous fluid infusion, septic shock results, then the prognosis is more guarded. At this juncture, if β-adrenergic inotropic agents fail to improve cardiovascular status, this indicates severe and unresponsive extracellular fluid extravasation with vascular insufficiency, overwhelming myocardial depression, or both. Oliguria and continued peripheral vasoconstriction characterize a secondary, *cold phase* of septic shock that is rarely survived. Another poor prognostic sign is continued renal, pulmonary, and cerebral dysfunction once hypotension is corrected (Chebbo, 2016; Seymour, 2018). The average risk of death rises by 15 to 20 percent with failure of each organ system.

Management

In 2004, an international consensus effort was launched as the *Surviving Sepsis Campaign* (Dellinger, 2013). The cornerstone of management was termed *early goal-directed therapy (EGDT)*, which stressed prompt recognition of serious bacterial infection and close monitoring of vital signs and urine flow. After three multicenter trials did not show that this protocol improved survival rates, this strategy is no longer recommended (PRISM Investigators, 2017; Seymour, 2018).

Similar conclusions were reached with sets of early warning systems in obstetrics (Edwards, 2015; Mhyre, 2014). *Modified Early Warning Score (MEWS)* failed to predict sepsis in obstetrical populations with positive predictive values as low as 1 to 2 percent (Lappen, 2010). Reasons for such poor performance in pregnant women include physiological changes of vital signs; relatively fewer comorbidities in a younger, healthier population; and predominantly genitourinary infections. Thus, current efforts such as the *Sepsis in Obstetrics Score* have been designed to identify women who benefit from ICU admission early in their hospital course (Albright, 2017). However, the validity of these findings beyond a single center and against controls is yet unstudied.

Still, the major tenets of EGDT are employed for sepsis treatment. Management of sepsis stresses prompt administration of broad-spectrum antimicrobials, collection of specimens for culture, serum lactate level measurement, an intravenous fluid bolus, and vasopressors as needed (Seymour, 2018). An algorithm for management of sepsis is shown in Figure 50-5. The three basic steps are performed as simultaneously as possible and include evaluation of the sepsis source and its sequelae, cardiopulmonary function assessment, and immediate management. The most important step in sepsis management is rapid infusion of 2 L and sometimes as many as 4 to 6 L of crystalloid fluids to restore renal perfusion in severely affected women (Vincent, 2013). Simultaneously, appropriately chosen broad-spectrum antimicrobials are begun, preferentially within 1 hour (Chen, 2019; Society for Maternal-Fetal Medicine, 2019). Because hemoconcentration is caused by the capillary leak, if anemia coexists, blood is given. Specific thresholds for gravidas are lacking. In a group of nonpregnant individuals admitted to an ICU, maintaining the hemoglobin concentration ≥9 g/dL did not have superior outcomes compared with levels ≥7 g/dL (Holst, 2014). That said, fetal oxygenation is improved by the higher concentration, as discussed earlier (p. 886).

The use of a colloid solution such as hetastarch is controversial (Seymour, 2018). One Scandinavian randomized trial comparing hydroxyethyl starch and Ringer acetate solutions reported a higher mortality rate with the starch solution (Perner, 2012). Another study found equivalent results with 6-percent hydroxyethyl starch compared with normal saline (Myburgh, 2012). Additionally, albumin was not found to be superior to crystalloids (Caironi, 2014).

Aggressive volume replacement ideally is promptly followed by urinary output of at least 30 and preferably 50 mL/h, as well as other indicators of improved perfusion. If not, vasoactive drug therapy is considered (Pacheco, 2014). As discussed, mortality rates are high when sepsis is further complicated by respiratory or renal failure. With severe sepsis, damage to pulmonary capillary endothelium and alveolar epithelium causes alveolar flooding and pulmonary edema. This may occur even with low or normal pulmonary capillary wedge pressures, as with the ARDS (p. 884). Therefore, in some women, mechanical ventilation is indicated.

Broad-spectrum antimicrobials are chosen empirically based on the probable source of infection. They are given promptly in maximal doses after appropriate cultures are taken of blood, urine, or exudates not contaminated by normal flora. In severe sepsis, appropriate and early empirical coverage results in better survival rates (Seymour, 2017, 2018). Acute pyelonephritis is usually caused by Enterobacteriaceae, as discussed in Chapter 56 (p. 997). For pelvic infections, empirical selection of a regimen such as ampicillin, gentamicin, plus clindamycin, which in sum covers aerobic and anaerobic pathogens, generally suffices (Chap. 37, p. 651). Associated incisional and other soft-tissue infections are increasingly likely to be caused by MRSA, thus vancomycin may be added (Klevens, 2007). With septic abortion or deep fascial infections, a Gram-stained smear may be helpful in identifying *Clostridium* species or group A streptococcal organisms.

Surgical Treatment

Continuing sepsis may prove fatal, and debridement of necrotic tissue or drainage of purulent material is crucial (Pacheco, 2014). Puerperal pelvic infections include metritis and infections of perineal lacerations or of hysterotomy or laparotomy incisions. If complicated by abscess, these may require drainage. With a septic abortion, uterine contents must be removed expeditiously by curettage as described in Chapter 11 (p. 203). Hysterectomy is seldom indicated unless gangrene has resulted.

For women with pyelonephritis, continuing sepsis should prompt a search for obstruction caused by calculi or by a perinephric or intrarenal phlegmon or abscess. Renal sonography or "one-shot" pyelography can help diagnose obstruction and calculi. With obstruction, ureteral catheterization, percutaneous nephrostomy, or flank exploration may be lifesaving (Chap. 56, p. 998).

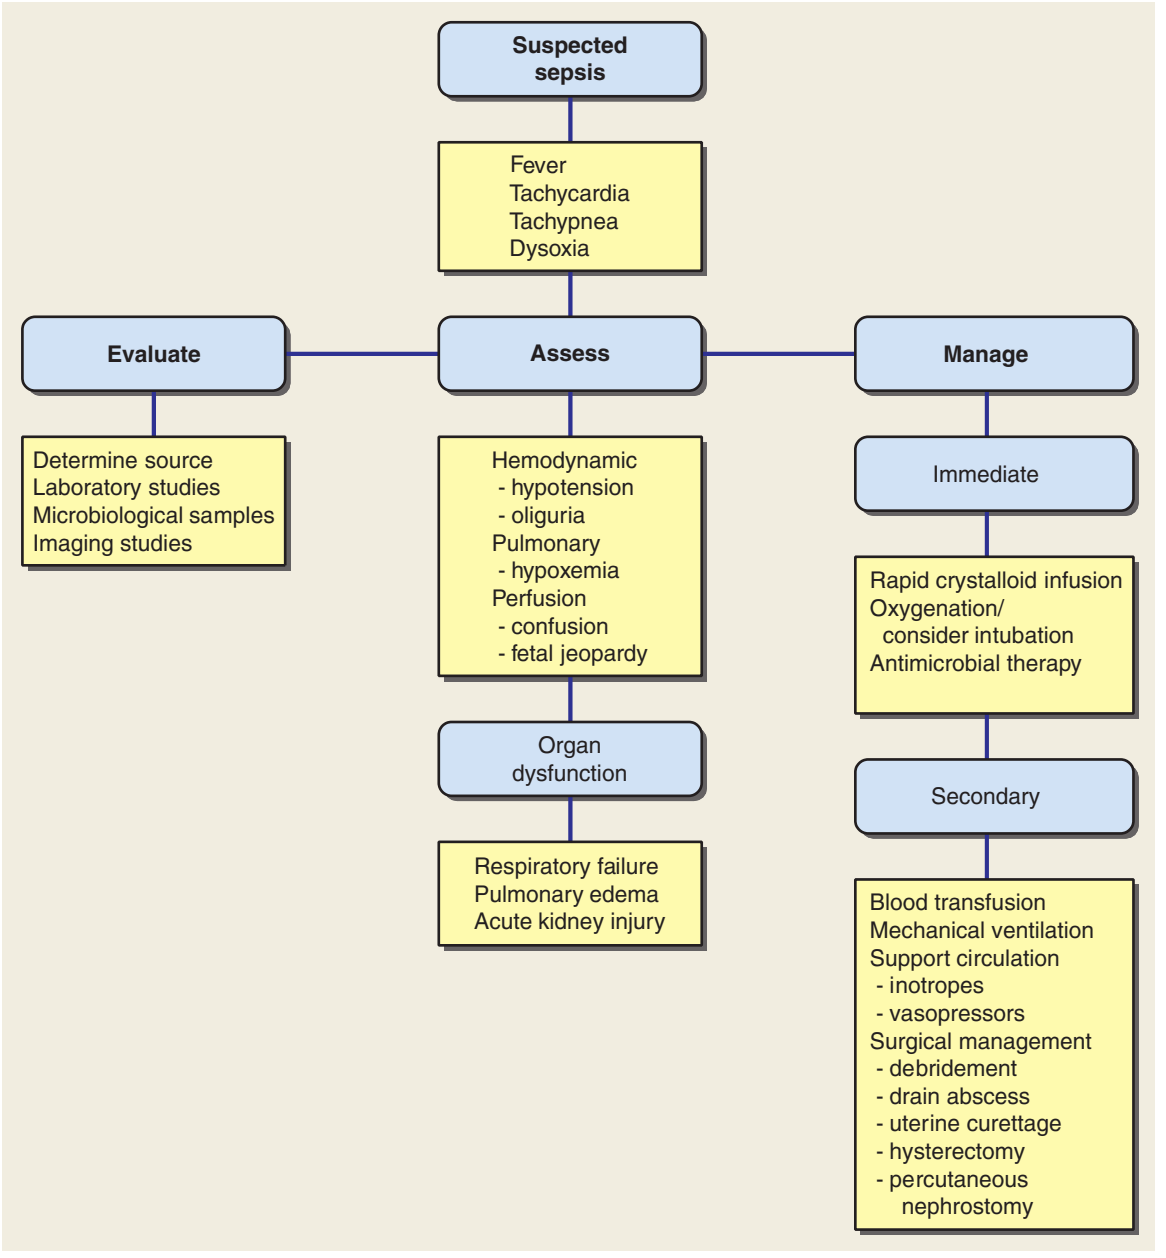

FIGURE 50-5 Algorithm for evaluation and management of sepsis. Rapid and aggressive implementation is paramount for success. The three steps—Evaluate, Assess, and Manage—are carried out as simultaneously as possible.

Computed tomography (CT) or magnetic-resonance imaging aids identification of a renal phlegmon or abscess.

Puerperal Infections. Most cases of puerperal pelvic sepsis are clinically manifested in the first several postpartum days, and intravenous antimicrobial therapy without tissue debridement is generally curative. At least four exceptions are notable.

First, massive uterine myonecrosis can be caused by group A β-hemolytic streptococcal or clostridial infections (Kaiser, 2018; Soper, 2011). Those with early-onset disease present with findings listed in Table 50-6. The mortality rate in these women with gangrene, shown in Figure 50-6 is high, and prompt hysterectomy may be lifesaving. Group A β-hemolytic streptococci and clostridial colonization or infection also cause toxic-shock syndrome without obvious gangrene (Mason, 2012). These are due to either streptococcal toxic shock syndrome–like toxin or clostridial exotoxin that evolved from *S aureus* (Chap. 37, p. 659). In many of these cases, bacteremia and widespread tissue invasion develops, but uterine and abdominal incisions are intact. If uterine necrosis can be excluded—usually by CT scanning—then in our experiences, as well as in others, hysterectomy may not be necessary (Soper, 2011). Still, these infections can be highly lethal (Chen, 2019; Yamada, 2010).

A second exception, necrotizing fasciitis of the episiotomy site or of the abdominal surgical incision, is a surgical emergency. Described by Gallup and coworkers (2002), these infections are aggressively managed as discussed in Chapter 37 (p. 655). In one instance, Sinha and colleagues (2015) described a woman with *Fournier gangrene* who required radical debridement and colostomy.

TABLE 50-6. Clinical Findings in 126 Women with Group A β-Hemolytic Streptococcal Infection

High fever
Respiratory symptoms
Gastrointestinal symptoms
Uterine hypertonus
Uterine tenderness
Capillary leak
Dyspnea, cough
Pulmonary edema
Bloating, distention
Shock

Data from Kaiser, 2018; Yamada, 2010.

Third, persistent or aggressive postpartum uterine infection with necrosis, uterine incision dehiscence, and severe peritonitis may lead to sepsis (Chap. 37, p. 651). In this regard, women following cesarean delivery who are suspected of having peritonitis should be carefully evaluated for uterine incisional necrosis or bowel perforation. These infections tend to be less aggressive than necrotizing group A streptococcal infections and develop later postpartum. CT imaging of the abdomen and pelvis can frequently disclose these. If either is suspected, timely surgical exploration is considered. With uterine incision necrosis, hysterectomy is usually necessary (Fig. 37-5, p. 657). Last, peritonitis and sepsis much less commonly may result from a ruptured parametrial, intraabdominal, or ovarian abscess (Chap. 37, p. 656).

Adjunctive Therapy

A woman with severe sepsis is supported with continuing crystalloid infusion, blood transfusions, and ventilation. In some cases, other measures are needed. Vasoactive drugs are not given unless aggressive fluid treatment fails to correct hypotension and perfusion abnormalities. First-line vasopressors are norepinephrine and vasopressin (Seymour, 2018). According to the Society for Maternal-Fetal Medicine (2019), norepinephrine has been studied most in pregnant women.

Glucocorticoid use in this setting remains controversial, and some but not all studies show a favorable effect (Marik, 2018; Venkatesh, 2018). In a recent study by Annane and colleagues (2018), hydrocortisone plus fludrocortisone compared with placebo resulted in a significantly lower mortality rate at 90 days. Thus, low-dose corticosteroid therapy can be considered with septic shock (Suffredini, 2018).

Endotoxin stimulates endothelial cells to upregulate tissue factor and thus procoagulant production (Cunningham, 2015). Consumptive coagulopathy associated with sepsis is discussed in Chapter 44 (p. 776). At the same time, endotoxin decreases the anticoagulant action of activated protein C. Several agents developed to block coagulation, however, do not improve outcomes. Last, induced hypothermia does not improve survival in patients with septic shock and respiratory failure (Itenov, 2018).

FIGURE 50-6 A fatal case of group A β-hemolytic *Streptococcus pyogenes* puerperal infection following an uncomplicated vaginal delivery at term. The infection caused uterine gangrene and overwhelming sepsis. Arrows point to overtly "ballooned-out" black gangrenous areas of the postpartum uterus at the time of laparotomy for hysterectomy.

TRAUMA

Depending on definitions used, 10 to 20 percent of gravidas suffer physical trauma (Al-Thani, 2018; Mendez-Figueroa, 2017). Moreover, injury-related deaths are the most commonly identified nonobstetrical cause of maternal mortality (Huls, 2018; La Rosa, 2020). According to Deshpande and coworkers (2017), pregnant victims of trauma are twice as likely to die compared with nonpregnant affected women. In an audit from Parkland Hospital, motor vehicle accidents and falls accounted for 85 percent of injuries sustained by gravidas (Hawkins, 2007). From the National Violent Death Reporting System, Palladino and colleagues (2011) found 2 pregnancy-associated suicides per 100,000 live births. The rate was 3 per 100,000 for pregnancy-associated homicides. Notably, intimate partner violence may be linked to these suicides (Chisholm, 2017). Last, injury prevention and education of high-risk patients may help decrease morbidity rates (Globevnik, 2018).

■ Intimate Partner Violence

According to the CDC, intimate partner violence (IPV) describes physical, sexual, or psychological harm by a current or former partner or spouse (Breiding, 2015). Such violence affects 1 in 5 women in their lifetime (Miller, 2019). One goal in violence prevention for *Healthy People 2020* is the reduction of physical abuse directed at women by male partners.

Even more appalling is that IPV continues during pregnancy (Hahn, 2018). Abuse is linked to poverty, poor education, and use of tobacco, alcohol, and illicit drugs. Unfortunately, abused women tend to remain with their abusers, and one major risk factor for intimate partner homicide is prior IPV (Globevnik, 2018). Last, women seeking pregnancy termination have a higher incidence of IPV (Bourassa, 2007).

In one study, pregnant women hospitalized in California as a result of assault had significantly increased perinatal morbidity rates (El Kady, 2005). Immediate sequelae were uterine rupture, preterm delivery, and maternal and perinatal death. Subsequent outcomes included higher rates of placental abruption, preterm

TABLE 50-7. Guidelines for Prophylaxis Against Sexually Transmitted Disease in Pregnant Victims of Sexual Assault

Prophylaxis Against	Regimen[a]	Alternative
Neisseria gonorrhoeae	Ceftriaxone 250 mg IM single dose ***plus*** Azithromycin 1 g single dose	Cefixime 400 mg single dose ***plus*** azithromycin 1 g single dose
Chlamydia trachomatis	Azithromycin 1 g single dose[b] ***or*** Amoxicillin 500 mg three times daily for 7 days	Erythromycin-base 500 mg four times daily for 7 days
Trichomonas vaginalis	Metronidazole 2 g single dose ***or*** Tinidazole 2 g single dose	Metronidazole 500 mg twice daily for 7 days
Hepatitis B (HBV)	If not previously vaccinated, give first dose HBV vaccine IM, repeat at 1–2 and 4–6 months	
Human immunodeficiency virus (HIV)	If exposure ≤72 h ago, consider antiretroviral prophylaxis if risk for HIV exposure is high	Tenofovir disoproxil fumarate/emtricitabine (Truvada) once daily plus raltegravir 400 mg (Isentress) twice daily for 28 days

[a]Oral administration unless otherwise stated.
[b]For nonpregnant women, doxycycline, 100 mg orally twice daily for 7 days, can be given instead.
IM = intramuscularly.
From Centers for Disease Control and Prevention, 2015, 2016.

and low-birthweight newborns, and other adverse outcomes. Silverman and associates (2006) reported similar results from the Pregnancy Risk Assessment Monitoring System. In a meta-analysis, women suffering IPV had threefold increased risk for perinatal death (Pastor-Moreno, 2020).

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) recommend universal screening for IPV at the initial prenatal visit, during each trimester, and again at the postpartum visit (Chap. 10, p. 180). A challenge in these recommendations is that women who refuse to answer the screening question for IPV may be most at risk (Yost, 2005). Moreover, the woman who is physically abused tends to present late, if at all, for prenatal care.

Sexual Assault

The lifetime prevalence of sexual assault in the United States is 20 percent (American College of Obstetricians and Gynecologists, 2019c; Vrees, 2017). Satin and associates (1992) reviewed more than 5700 female sexual assault victims in Dallas County and reported that 2 percent were pregnant. Associated physical trauma is common. From a forensic standpoint, the evidence collection protocol is not altered (Linden, 2011).

In addition to attention to physical injuries, exposure to sexually transmitted diseases must be considered. The CDC (2015, 2016) recommends antimicrobial prophylaxis against gonorrhea, chlamydial infection, and trichomoniasis (Table 50-7). At Parkland Hospital, we also offer at-risk exposed assault victims HIV prophylaxis. If the woman is not pregnant, another very important aspect is emergency contraception, as recommended by the American College of Obstetricians and Gynecologists (2018a; 2019c) and discussed in Chapter 38 (p. 676).

Last, the importance of psychological counseling for the rape victim and her family cannot be overemphasized. As discussed in Chapter 64 (p. 1142), a 30- to 35-percent lifetime risk each for posttraumatic stress disorder, major depression, and suicide contemplation follows sexual assault (Linden, 2011).

Automobile Accidents

At least 3 percent of pregnant women are involved in motor vehicle accidents each year in the United States. These crashes account for 90 percent of nonviolent blunt trauma in pregnancy (Sakamoto, 2019). Thus, they are the most common causes of serious, life-threatening, or fatal blunt trauma during pregnancy (Al-Thani, 2018; Greco, 2019; Petrone, 2017). Mattox and Goetzl (2005) report these accidents to be the leading cause of traumatic fetal deaths as well. This also was true from our experiences from Parkland Hospital (Hawkins, 2007). As with all motor vehicle crashes, alcohol use is often associated. Up to half of accidents occur without seat-belt use, and many of these deaths would likely be preventable by the three-point restraints shown in Figure 50-7 (Schuster, 2016). Seat belts prevent contact with the steering wheel, and they reduce abdominal impact pressure.

Original concerns regarding injuries caused by airbag deployment have been somewhat allayed. In a retrospective cohort study that included 2207 pregnant women in crashes with airbag deployment, perinatal outcomes were not clinically different from 1141 controls without airbags (Schiff, 2010). Importantly, 96 percent of both groups used seat belts. Logically, it appears that injuries with airbag deployment are related to the severity of the crash (Mendez-Figueroa, 2017).

Other Blunt Trauma

Some other common causes of blunt trauma are falls and aggravated assaults. In the California review reported by El

FIGURE 50-7 Illustration showing correct use of three-point automobile restraint. The upper belt is *above* the uterus, and the lower belt fits snugly across the upper thighs and well *below* the uterus.

Kady and associates (2005), approximately a third of pregnant women who were hospitalized for trauma suffered intentionally inflicted injuries. Less common are blast or crush injury.

With blunt trauma, intraabdominal injuries can be serious. Even so, bowel injuries are less frequent because of the protective effect of a large uterus. Still, diaphragmatic, splenic, liver, and kidney damage also may be sustained. Particularly worrisome is the specter of amnionic-fluid embolism, which has been reported with even mild trauma (Ellingsen, 2007; Pluymakers, 2007). Retroperitoneal hemorrhage is likely more common than in nonpregnant women (Takehana, 2011).

Orthopedic injuries also are encountered with some regularity (Desai, 2007). From the Parkland Hospital trauma unit, 6 percent of 1682 pregnant women evaluated had orthopedic injuries. Additionally, this subset was at increased risk for placental abruption, preterm delivery, and perinatal mortality. In a review of 101 pelvic fractures during pregnancy, the maternal mortality rate was 9 percent, and the fetal rate was 35 percent (Leggon, 2002). In another study of pelvic and acetabular fractures during 15 pregnancies, one maternal and four fetal deaths were reported (Almog, 2007). Last, head trauma and neurosurgical care raise unique issues (Qaiser, 2007).

Fetal Injury and Death

Perinatal death rates rise with the severity of maternal injuries. Fetal death is more likely with direct fetoplacental injury, maternal shock, pelvic fracture, maternal head injury, or hypoxia (Mendez-Figueroa, 2017; Pearlman, 2008). In an earlier study, motor vehicle accidents caused 82 percent of fetal deaths from trauma. Death resulted from placental injury in half and from uterine rupture in 4 percent (Weiss, 2001).

Although uncommon, fetal skull and brain injuries are more likely if the head is engaged and the maternal pelvis is fractured. Conversely, fetal head injuries, presumably from a contrecoup effect, may be sustained in unengaged vertex or nonvertex presentations. Fetal skull fractures are rare and best seen using CT imaging (Sadro, 2012). One example is shown in Figure 50-8.

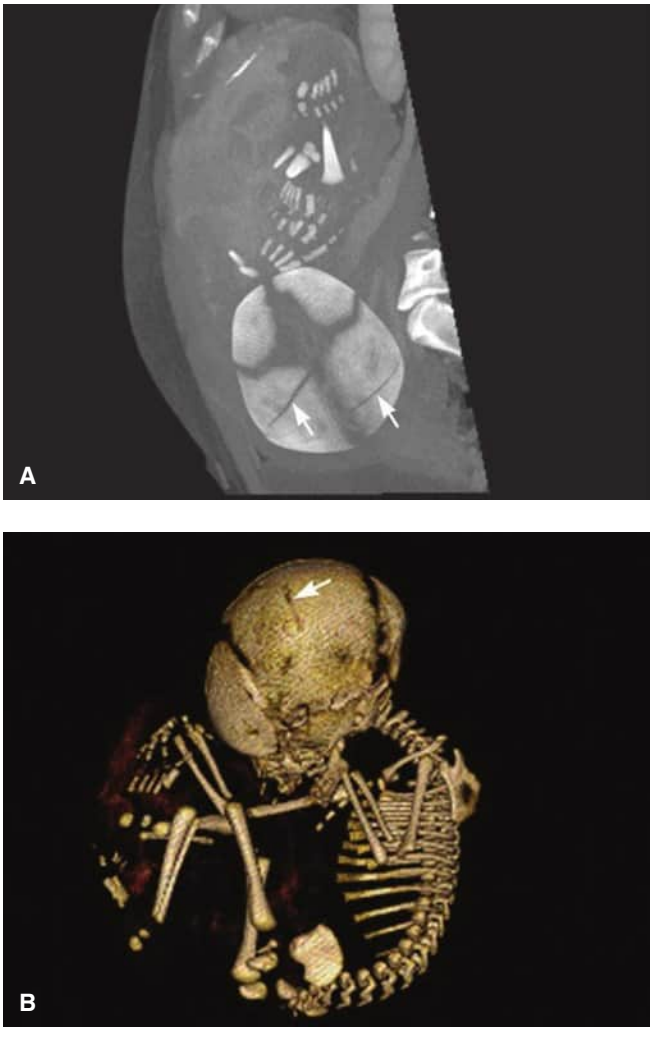

FIGURE 50-8 This woman in her third trimester was involved in a high-speed motor vehicle accident. **A.** Maximum intensity projection acquired for maternal indications readily identifies fetal skull fractures (*arrows*). **B.** Three-dimensional reformatted computed tomography (CT) image in a bone algorithm demonstrates the fetal skeleton from data acquired during the maternal examination. Again, the arrow marks one fracture site. (Photograph contributed by Dr. Travis Browning. Reproduced with permission from Bailey AA, Twickler DM: Perioperative imaging. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al [eds]: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

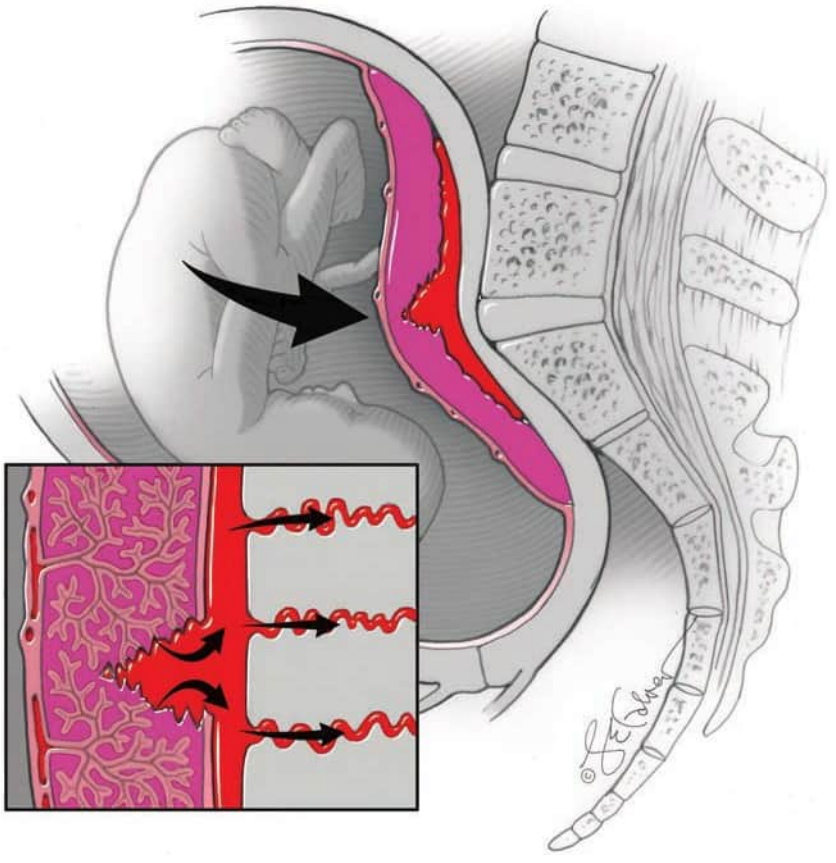

FIGURE 50-9 Mechanism of placental tear or "fracture" caused by a coup-contrecoup injury. Although not shown here, forward momentum of the uterus at the time of initial impact propels it forward. This is followed by a contrecoup, in which forces are directed backward. In this image, the inelastic placenta fractures against the sacral promontory. During each phase, tremendous intraabdominal pressure is generated that can lead to abruption, shown here as blood collecting in the retroplacental space. **Inset**. Blood can be forced into placental bed venules and enter maternal circulation. Such maternofetal hemorrhage may be identified with Kleihauer-Betke testing.

Intracranial hemorrhage may be another sequela (Gherman, 2014). Other injuries have included fetal decapitation or incomplete midabdominal fetal transection at midpregnancy (Rowe, 1996; Weir, 2008).

Placental Injuries

Catastrophic events that potentially accompany blunt trauma include placental abruption or placental tear or both. Placental abruption caused by trauma is likely due to deformation of the elastic myometrium around the relatively inelastic placenta (Crosby, 1968). This may result from a deceleration injury as the forward-moving uterus meets the immovable steering wheel or seat belt. Instead, placental injury may follow a contrecoup injury, which is illustrated in Figure 50-9.

Some degree of abruption complicates 1 to 6 percent of minor injuries and up to 50 percent of major ones (Schiff, 2002). Abruption is more likely if vehicle speed exceeds 30 mph (Reis, 2000).

Clinical findings with traumatic abruption may be similar to those for spontaneous placental abruption (Chap. 42, p. 753). Kettel and coworkers (1988) emphasized that traumatic abruption may be occult and not accompanied by uterine pain, tenderness, or bleeding. In our experiences with 13 such women at Parkland Hospital, 11 had uterine tenderness, but only five had vaginal bleeding. Because traumatic abruption is more likely to be concealed and generate higher intrauterine pressures, associated coagulopathy is more often seen than with atraumatic abruption (Cunningham, 2015). Partial separation also may generate uterine activity, which is described more fully later (p. 896). Evidence of fetal compromise such as fetal tachycardia, sinusoidal pattern, late decelerations, acidosis, and fetal death are other worrisome features. CT imaging has been shown to be accurate for diagnosis of traumatic abruption (Kopelman, 2013, 2016; Sadro, 2012). However, because routine placental evaluation by radiologists is not common, these authors did not advocate for CT screening for abruption.

With a placental tear, life-threatening fetal hemorrhage may follow, and blood enters either the amnionic sac or maternal circulation. As shown in Figure 50-10, the tear is linear or stellate. Also shown is a Kleihauer-Betke stain of maternal blood that is used to quantify fetomaternal hemorrhage. A small amount of fetal-maternal bleeding has been described in up to a third of trauma cases, and in 90 percent of these, the volume is <15 mL (Pearlman, 1990). Parenthetically, atraumatic placental abruption is much less often associated with significant fetomaternal hemorrhage because only minimal fetal blood enters into the intervillous space. With traumatic abruption, however, massive fetomaternal hemorrhage may follow. In one study, the risk of associated uterine contractions and preterm labor was 20-fold if there was evidence for a fetomaternal bleed (Muench, 2004). With severe fetal bleeding, long-term adverse neurological outcomes are frequent (Kadooka, 2014).

Uterine Rupture

Blunt trauma leads to uterine rupture in <1 percent of severe cases (American College of Obstetricians and Gynecologists, 2017a; Greco, 2019). Rupture is more likely in a previously scarred uterus and is usually associated with a direct impact of substantial force. Decelerative forces following a 25-mph collision can generate up to 500 mm Hg of intrauterine pressure in a properly restrained woman (Crosby, 1968). Clinical findings may be identical to those for placental abruption with an intact uterus, and maternal and fetal deterioration are inevitable. Weir and colleagues (2008) described supracervical uterine avulsion and fetal transection at 22 weeks.

Penetrating Trauma

In a study of 321 pregnant women with abdominal trauma, Petrone (2011) reported a 9-percent incidence of penetrating

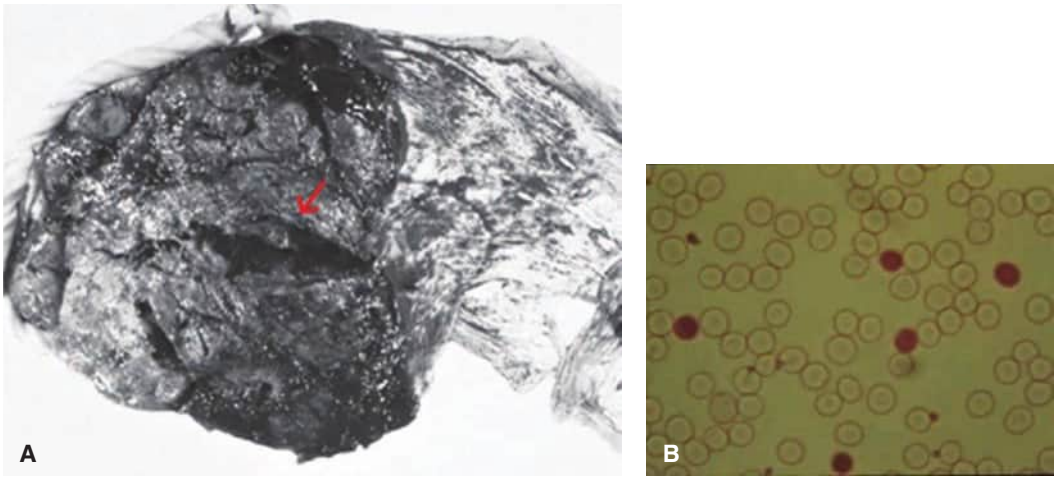

FIGURE 50-10 A. Partial placental abruption in which the adherent blood clot has been removed. Note the laceration of the placenta (*arrow*), which caused fetal death from massive fetomaternal hemorrhage. **B.** Kleihauer–Betke stain of a peripheral smear of maternal blood from the same woman. The dark cells containing hemoglobin that constituted 4.5 percent of red blood cells are fetal in origin, whereas the empty cells are maternal.

injuries. Of these, 77 percent were gunshot wounds, and 23 percent were stab wounds. The incidence of maternal visceral injury with penetrating trauma is only 15 to 40 percent compared with 80 to 90 percent in nonpregnant individuals (Stone, 1999). However, the large, intervening uterus is disproportionately involved (Awwad, 1994). When the uterus sustains penetrating wounds, the fetus is more likely than the mother to be seriously injured. The fetus sustains injury in two thirds of cases, whereas maternal visceral damage is seen in only 20 percent. Still, their seriousness is underscored in that maternal-fetal mortality rates are significantly higher than those seen with blunt abdominal injuries. Specifically, maternal mortality rates were 7 versus 2 percent, and fetal mortality rates were 73 versus 10 percent, respectively.

Management of Trauma

As discussed, maternal and fetal outcomes are directly related to injury severity. That said, commonly used methods of severity scoring do not account for the significant morbidity and mortality rates related to placental abruption and thus to pregnancy outcomes. In a study of 582 pregnant women hospitalized for injuries, the injury severity score did not accurately predict adverse pregnancy outcomes (Schiff, 2005). Importantly, relatively minor injuries were associated with preterm labor and placental abruption. In a study of 317 women at ≥24 weeks' gestation who had "minor trauma," 14 percent had clinically significant uterine contractions requiring extended fetal evaluation past 4 hours (Cahill, 2008).

With few exceptions, treatment priorities in injured pregnant women are multidisciplinary (MacArthur, 2019; Mendez-Figueroa, 2017). Primary goals are to evaluate and stabilize maternal injuries. Attention to fetal assessment during the acute evaluation may divert attention from life-threatening maternal injuries (American Academy of Pediatrics, 2017). Basic rules of resuscitation include ventilation, arrest of hemorrhage, and treatment of hypovolemia with crystalloid and blood products. After midpregnancy, the large uterus is positioned off the great vessels to relieve vessel compression, which decreases cardiac output (Nelson, 2015).

Following emergency resuscitation, fractures, internal injuries, bleeding sites, and placental, uterine, and fetal trauma are sought (Greco, 2019; MacArthur, 2019). Radiography is not proscribed, but special attention is given each indication. Not surprisingly, one report observed that pregnant trauma victims had less radiation exposure than nonpregnant controls (Ylagan, 2008). Some advocate screening abdominal sonography followed by CT scanning for positive sonographic findings (Saphier, 2014). Procedures used include the *FAST scan—focused assessment with sonography for trauma.* This is a 5-minute, four- to six-view imaging study that evaluates perihepatic, perisplenic, pelvic, and pericardial views (Mendez-Figueroa, 2017). In nonpregnant women, if fluid is seen in the upper abdominal views, the hemoperitoneum volume is >500 mL (Fig. 50-11)

FIGURE 50-11 Fast scan. Upper quadrant scans show free fluid (blood) between the liver and kidney (Morison pouch) and around the spleen. The patient had 2500 mL of blood in the peritoneal cavity. (Reproduced with permission from Mendez-Figueroa H, Rouse DJ: Trauma in pregnancy. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al [eds]: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

(Branney, 1995; Rodgerson, 2001). Importantly, this amount has not been corroborated for pregnancy. In some cases, open peritoneal lavage may be informative (Tsuei, 2006).

Penetrating injuries in most cases must be evaluated using radiography. Because clinical response to peritoneal irritation is blunted during pregnancy, an aggressive approach to exploratory laparotomy is pursued. Whereas exploration is mandatory for abdominal gunshot wounds, some clinicians advocate close observation for selected stab wounds. Diagnostic laparoscopy also has been used (Chap. 49, p. 868).

Cesarean Delivery

The necessity for cesarean delivery depends on several factors. Laparotomy itself is not an indication for hysterotomy. Some considerations include gestational age, fetal condition, extent of uterine injury, and whether the large uterus hinders adequate management of other intraabdominal injuries (Tsuei, 2006).

Electronic Monitoring

Because fetal well-being may reflect the status of the mother, fetal monitoring is another "vital sign" that helps evaluate the extent of maternal injuries. Even if the mother is stable, electronic monitoring may suggest placental abruption. In a study by Pearlman and coworkers (1990), no woman had an abruption if uterine contractions were less often than every 10 minutes within the 4 hours after trauma was sustained. Almost 20 percent of women who had contractions more frequently than every 10 minutes in the first 4 hours had an associated placental abruption. In these cases, abnormal tracings were common and included fetal tachycardia and late decelerations. Conversely, no adverse outcomes were reported in women who had normal monitor tracings (Connolly, 1997). Importantly, if tocolytics are used for these contractions, they may obfuscate findings, and we do not recommend them.

Because placental abruption usually develops early following trauma, fetal monitoring is begun as soon as the mother is stable. The ideal duration of posttrauma monitoring is not precisely known. From data just cited, observation for 4 hours is reasonable if the fetal heart rate tracing is normal and no other sentinel findings such as contractions, uterine tenderness, or bleeding are noted. Certainly, monitoring should be continued as long as there are uterine contractions, nonreassuring fetal heart patterns, vaginal bleeding, uterine tenderness or irritability, serious maternal injury, or ruptured membranes (Mendez-Figueroa, 2017). In rare cases, placental abruption has developed days after trauma (Higgins, 1984).

Fetal-Maternal Hemorrhage

It is unclear whether routine use of the Kleihauer-Betke or an equivalent test in pregnant trauma victims might modify adverse outcomes associated with fetal anemia, cardiac arrhythmias, and death (Pak, 1998). In a retrospective review of 125 pregnant women with blunt injuries, the Kleihauer-Betke test was judged to be of little value during acute trauma management (Towery, 1993). Others have reached similar conclusions, although a positive test result with fetal cells composing 0.1 percent predicted uterine contractions or preterm labor (Muench, 2003, 2004).

For the woman who is D-negative, administration of anti-D immunoglobulin should be considered (American College of Obstetricians and Gynecologists, 2017b). This may be omitted if a test result for fetal bleeding is negative. Even with anti-D immunoglobulin, alloimmunization may still develop if the fetal-maternal hemorrhage exceeds 15 mL of fetal cells. Immunoglobulin dose calculations are described in Chapter 18 (p. 357).

For the pregnant trauma patient, confirmation of current tetanus immunization status is pertinent. When indicated, a dose of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) vaccine is preferred for its neonatal pertussis immunity benefits (Chap. 10, p. 188).

THERMAL INJURY

Treatment of the burned gravida is similar to that for nonpregnant individuals (Correia-Sa, 2021). It is generally agreed that pregnancy does not alter maternal outcome from thermal injury compared with that of nonpregnant women of similar age. As perhaps expected, maternal and fetal survival parallels the percentage of burned surface area. Karimi and colleagues (2009) reported higher mortality rates for both with burns from suicide attempts and inhalational injuries. The composite mortality rate for more than 200 women from six studies rose in a linear fashion as the percentage of burned body surface area increased (Fig. 50-12). For 20-, 40-, and 60-percent burns, the maternal mortality rates were approximately 4, 30, and 93 percent, respectively. The corresponding fetal mortality rates were 20, 48, and 96 percent, respectively. With severe burns, the woman usually enters labor spontaneously within a few days to a week and often delivers a stillborn. Contributory factors are hypovolemia, pulmonary injury, septicemia, and the burn-associated, intense catabolic state (Radosevich, 2013).

Following serious abdominal burns, skin contractures that develop may be painful during a subsequent pregnancy and may even require surgical decompression and split-skin autografts (Mitsukawa, 2015; Radosevich, 2013). Loss or distortion of nipples may cause problems in breastfeeding. Mitsukawa and associates (2015) reported that contracture release was indicated with scars spanning >75 percent of the total abdominal area. Alternatively, normal abdominal tissue expansion due to

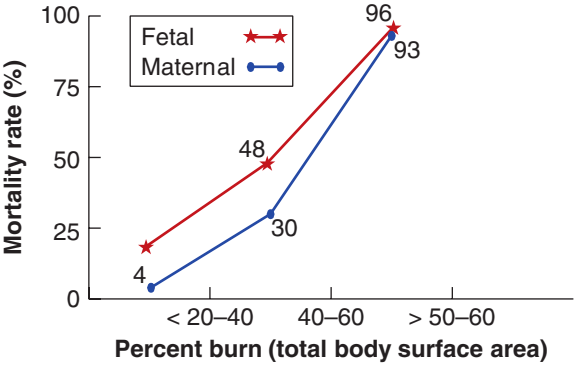

FIGURE 50-12 Maternal and fetal mortality rates by burn severity in 211 women. (Data from Akhtar, 1994; Amy, 1985; Mabrouk, 1977; Maghsoudi, 2006; Rayburn, 1984; Rode, 1990.)

pregnancy appears to be an excellent source for obtaining skin grafts postpartum to correct scar deformities at other body sites (Del Frari, 2004).

■ Electrical and Lightning Injuries

Earlier case reports suggested a high fetal mortality rate with electric shock (Fatovich, 1993). In a prospective cohort study, however, Einarson and associates (1997) showed similar perinatal outcomes in 31 injured women compared with those of noninjured controls. They concluded that traditional 110-volt North American electrical current likely is less dangerous than the 220-volt currents available in Europe. Thermal burns with electrocution may be extensive, and a woman with brain death from cardiac arrest has been described (Sparic, 2014).

The pathophysiological effects of lightning injuries can be devastating. García Gutiérrez and colleagues (2005) reviewed 13 case reports of lightning injuries during pregnancy and cited a 50-percent stillbirth rate.

CARDIOPULMONARY RESUSCITATION

Maternal cardiac arrest complicates from 1 in 12,000 to 36,000 delivery admissions (Balki, 2017; Beckett, 2017; Zelop, 2018). The most common causes are hemorrhage, anesthesia, heart failure, amnionic-fluid embolism, and sepsis. Shown in Table 50-8 is the alphabetical A–H checklist of cardiac arrest causes. General topics regarding planning and equipment have been reviewed by the American College of Obstetricians and Gynecologists (2018b) and the Society for Obstetric Anesthesia and Perinatology (Lipman, 2014).

Special considerations for cardiopulmonary resuscitation (CPR) conducted in the second half of pregnancy are outlined in the American Heart Association 2010 guidelines (Jeejeebhoy, 2015). The committee acknowledges the following as standards: (1) relieve possible vena caval compression by left lateral uterine displacement; (2) administer 100-percent oxygen; (3) establish intravenous access above the diaphragm; (4) assess for hypotension that warrants therapy, which is defined as systolic blood pressure <100 mm Hg or <80 percent of baseline; and (5) review possible causes of critical illness and treat these as early as possible.

TABLE 50-8. Possible Etiologies for Cardiac Arrest During Pregnancy

Anesthesia: high neuraxial block, intravenous local anesthetic, airway complications
Accidents: trauma
Bleeding: atony, abnormal placentation, DIC
Cardiovascular: valvar or congenital heart disease, arrhythmias, ischemia, aortic dissection
Drugs: tocolysis, overdose, anaphylaxis, uterotonics, magnesium sulfate
Embolism: venous, amnionic fluid
Fever: sepsis, viral syndromes, ARDS
General: metabolic abnormalities, hypocalcemia or hyperkalemia with massive hemorrhage
Hypertension: shock, preeclampsia syndrome, HELLP syndrome

ARDS = acute respiratory distress syndrome; DIC = disseminated intravascular coagulation; HELLP = hemolysis, elevated liver transaminases, low platelets.
Adapted from Jeejeebhoy, 2015; Soar, 2021; Zelop, 2018.

TABLE 50-9. High-Quality Cardiopulmonary Resuscitation in Pregnancy

Components
Place provider hands in lower half of sternum
Displace uterus laterally during resuscitation
Provide rapid chest compressions (100 per minute)
Achieve a compression depth of at least 2 inches
Assure adequate chest recoil between compressions
Minimize interruptions of chest compressions
Avoid prolonged pulse checks (no more than 5–10 seconds)
Resume chest compressions immediately after defibrillating
Switch provider of compressions every 2 minutes to avoid fatigue

The position of the heart for external compressions is not different from that in nonpregnant women (Holmes, 2015). In nonpregnant women, external chest compressions result in a cardiac output that is approximately 30 percent of normal. However, in late pregnancy, this may be less because of uterine aortocaval compression (Nelson, 2015). Thus, uterine displacement should accompany other resuscitative efforts. This can be accomplished by tilting the operating table laterally, by placing a wedge under the right hip, or by pushing the uterus to the left manually (Rose, 2015). Components of high-quality cardiopulmonary resuscitation in pregnancy are shown in Table 50-9 (Society for Maternal–Fetal Medicine, 2018).

■ Perimortem Cesarean Delivery

The maternal survival rate from cardiac arrest is 60 to 70 percent, and many deaths are associated with out-of-hospital arrest (Beckett, 2017; He, 2021). Because of pregnancy-induced hindrances on CPR efforts, emergent *perimortem cesarean delivery* for improved maternal resuscitation and fetal salvage is recommended by most. Specifically, the American Heart Association and the Society for Obstetric Anesthesia and Perinatology recommend operative delivery within 4 to 5 minutes of beginning CPR if the fetus is viable and circulation is not restored (Zelop, 2018). In women delivered by perimortem cesarean, neurologically intact neonatal survival and the cardiac arrest-to-delivery interval are inversely related (Beckett, 2017; Katz, 2012). Specifically, of newborns delivered within 5 minutes of arrest, 98 percent are neurologically intact; within 6 to 15 minutes, 83 percent are intact; within 16 to 25 minutes, 33 percent are intact; and within 26 to 35 minutes, only 25 percent are intact (Clark, 1997).

This serious and sometimes contentious issue is far from evidence based. For example, the American College of Obstetricians and Gynecologists (2019a) recommends *consideration* for

perimortem cesarean delivery beginning at 4 minutes. Katz and associates (2005) reviewed 38 perimortem cesarean deliveries with a "large selection bias." They concluded that these reports supported—but "fell far from proving"—that perimortem cesarean delivery within 4 minutes of maternal cardiac arrest improves maternal and fetal outcomes. Even so, as emphasized by Clark (1997) and Rose (2015) and their coworkers, and in our experiences, these goals rarely can be met in actual practice. For example, many cases of cardiac arrest occur in uncontrolled circumstances, and thus, the time to CPR initiation alone would consume the first 5 minutes. Thus "crash" cesarean delivery would supersede resuscitative efforts, would possibly be done without appropriate anesthesia or surgical equipment, and might lead to otherwise preventable maternal death. Moreover, the distinction between a perimortem versus postmortem cesarean operation is imperative (Katz, 2012; Rose, 2015). Last, in the balance, any choice *may* favor survival of the mother over the fetus, or vice versa, and thus there are immediate unresolvable ethical concerns. Katz (2012) and Zelop and colleagues (2018) have provided scholarly reviews of perimortem cesarean delivery.

Successful CPR can have morbid complications. Severe neurological injury is the most feared (Romagano, 2017). Cox and coworkers (2018) described liver lacerations in 3 of 7 survivors. Takotsubo cardiomyopathy also has been reported (Kraft, 2017).

Maternal Brain Death

Occasionally, a pregnant woman with a supposedly healthy intact fetus will be kept on somatic support to await fetal viability or maturity. This is discussed in Chapter 63 (p. 1138).

ENVENOMATION

According to their review, Brown and coworkers (2013) reported that clinically significant envenomations in pregnant women are from snakes, spiders, scorpions, jellyfish, and hymenoptera. This last group includes bees, wasps, hornets, and ants. Adverse outcomes are related to maternal effects. Available evidence supports a venom-specific approach that incorporates symptomatic care, antivenom administration when appropriate, anaphylaxis treatment, and fetal assessment (Ghosh, 2018). One management scheme for North American snakebites was provided by Lei and associates (2015).

CHAPTER 51

Obesity

Extensive weight gain is a major health problem today in many affluent societies. The Centers for Disease Control and Prevention (CDC) (2020) reported the prevalence in the United States during 2017 to 2018 to be 42 percent among all adults. The adverse health aspects of obesity are staggering and include increased risks for type 2 diabetes, heart disease, hypertension, and osteoarthritis. Importantly, obese women and their fetuses are predisposed to numerous pregnancy-related complications and to long-term morbidity and mortality.

GENERAL CONSIDERATIONS

Definitions and Prevalence

Of systems to classify obesity, the *body mass index (BMI)*, also known as the *Quetelet index*, is most often used. The BMI is calculated as weight in kilograms divided by the square of the height in meters (kg/m^2). Calculated BMI values are available in various chart and graphic forms (Fig. 51-1). The National Institutes of Health (2000) classifies adults according to BMI as follows: *normal* is 18.5 to 24.9 kg/m^2, *overweight* is 25 to 29.9 kg/m^2, and *obese* is ≥30 kg/m^2. Obesity is further divided into: *class 1* is 30 to 34.9 kg/m^2, *class 2* is 35 to 39.9 kg/m^2, and *class 3* is ≥40 kg/m^2. Class 3 obesity is often referred to as *morbid* obesity, and *supermorbid* obesity describes a BMI ≥50 kg/m^2.

Using these definitions, from 2015 to 2016 in the United States, among girls and women, the prevalence of obesity rose with age and varied among ethnicities (Fig. 51-2) (Centers for Disease Control and Prevention, 2020). Overall, severity also advances with increasing poverty. Last, a genetic predisposition has been identified (Locke, 2015; Shungin, 2015).

Adipose Pathophysiology

Fat tissue is much more complex than merely its energy storage function. Many fat tissue cells communicate with all other tissues via endocrine and paracrine factors, which are cytokines specifically termed *adipokines*, *lipokines*, and *exosomal microRNAs* (Scheja, 2019). Some of these with metabolic functions include adiponectin, leptin, tumor necrosis factor α (TNF-α), interleukin 6 (IL-6), resistin, visfatin, apelin, vascular endothelial growth factor (VEGF), lipoprotein lipase, and insulin-like growth factor. Adiponectin is a principal adipokine. It enhances insulin sensitivity, blocks hepatic glucose release, and has cardioprotective effects on circulating plasma lipids. An adiponectin deficit is linked with diabetes, hypertension, endothelial cell activation, and cardiovascular disease.

Cytokines that result in insulin resistance are leptin, resistin, TNF-α, and IL-6, and higher levels of these are found during pregnancy. Indeed, adipokines, especially the inflammatory cytokines, may be the primary stimulant of insulin resistance (Yang, 2016). Conversely, adiponectin has antiinflammatory and insulin-sensitizing roles and is negatively regulated by fat mass. Perivascular adipose tissue also serves as a signaling mediator in regulating vascular function (Ahmadieh, 2020). Placental production of these adipokines is also important (Sartori, 2016) (Chap. 5, p. 99).

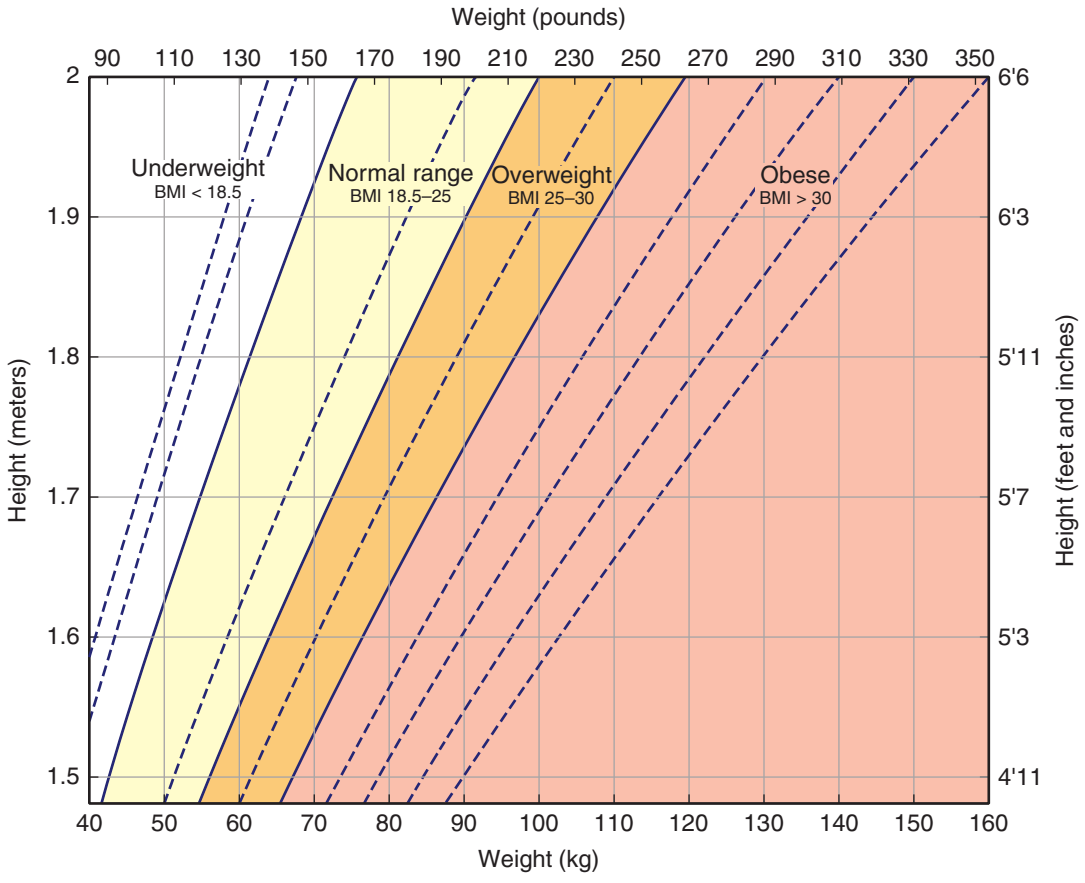

FIGURE 51-1 Chart for estimating body mass index (BMI). To find the BMI category for a particular subject, locate the point at which the height and weight intersect.

Metabolic Syndrome

Given its multifaceted endocrine and paracrine functions, the detrimental effects of excessive adipose tissue are not surprising (Gilmore, 2015). Obesity interacts with inherited factors to cause insulin resistance. This resistance is characterized by impaired glucose metabolism and a predisposition to type 2 diabetes. Insulin resistance also causes several subclinical abnormalities that predispose to cardiovascular disease and accelerate its onset. The most important among these are type 2 diabetes, dyslipidemia, and hypertension, which are constituents of the *metabolic syndrome*.

Criteria to define this syndrome are found in Table 51-1. Waist circumference is the preferred measurement for screening, but any three of five factors listed are sufficient to diagnose the metabolic syndrome. Notably, most patients with type 2 diabetes have metabolic syndrome according to these criteria. Also, obese women with hypertension typically demonstrate elevated plasma insulin levels.

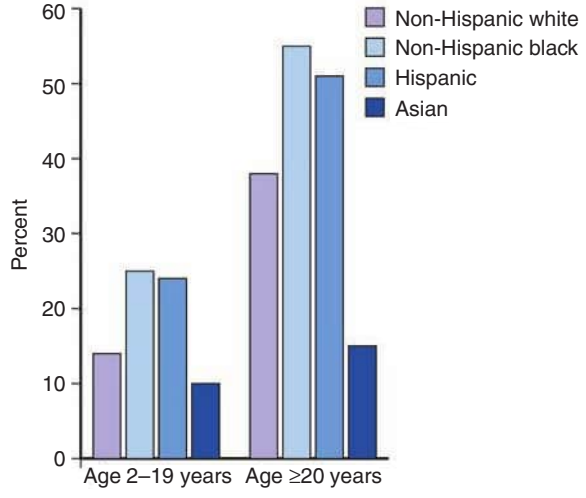

FIGURE 51-2 Prevalence of obesity in the United States by race: United States 2015–2016.

TABLE 51-1. Criteria for Diagnosis of the Metabolic Syndrome

Patients with three or more of the following:	
Elevated waist circumference[a]	
Elevated triglycerides[b]:	≥150 mg/dL
Reduced high-density lipoprotein cholesterol[b]:	
	<40 mg/dL in males
	<50 mg/dL in females
Elevated blood pressure[b]:	systolic ≥130 mm Hg and/or
	diastolic ≥ 85 mm Hg
Elevated fasting glucose[b]:	≥100 mg/dL

[a]According to country- and population-specific thresholds.
[b]Those with normal values while taking medications are considered to meet these criteria.
From the National Heart, Lung, and Blood Institute, 2019.

The National Health and Nutrition Examination Survey (NHANES) of the CDC documented an overall prevalence of 34 percent for the metabolic syndrome in the United States by 2012 (Moore, 2017). As expected, the prevalence rose with age. It was 20 percent for those aged 18 to 29 years and was 36 percent for those aged 30 to 49 years.

Nonalcoholic Fatty Liver Disease

Generally speaking, visceral adiposity correlates with hepatic fat content (Cornier, 2011). With obesity, excessive fat accumulates in the liver and is termed *hepatic steatosis*. This is also called *nonalcoholic fatty liver disease (NAFLD)*. In persons with the metabolic syndrome, steatosis can progress to *nonalcoholic steatohepatitis (NASH)* and then potentially to cirrhosis and hepatocellular carcinoma. It is the major cause of cirrhosis and liver cancer, and annual medical costs of NAFLD in the United States exceed $100 billion (Diehl, 2017). Moreover, NAFLD is strongly associated with cardiovascular disease (Targher, 2016). These interactions are explored further in Chapter 58 (p. 1040).

Obesity-associated Morbidity

Obese individuals suffer well-known consequences such as glucose intolerance, hypertension, dyslipidemia, and metabolic syndrome. Furthermore, metabolic syndrome and obesity are linked with cardiovascular disease, including myocardial infarction, atrial fibrillation, heart failure, and stroke (Koliaki, 2019). Excessive adiposity raises blood pressure and accounts for up to 75 percent of primary hypertension (Hall, 2019). Insulin resistance and metabolic syndrome cause structural cerebral changes in the hippocampus and lower executive functioning and memory in adults (Kullman, 2016). And cytokine-induced osteoarthritis has long been linked to obesity (Tu, 2019).

Because of the foregoing, it is not surprising that obesity is associated with higher rates of all-cause early mortality. Cardiovascular mortality data from 19 prospective studies are shown in Figure 51-3 (Gonzalez, 2010). In these and other studies, mortality risk from cardiovascular disease and cancer grew proportionally with increasing BMI. However, an obesity paradox—whereby certain groups actually derive a survival advantage from being obese—is hypothesized (Hainer, 2013). Despite this, the health benefits of weight normalization are well documented (Cheung, 2017).

Obesity Treatment

Weight loss is tremendously difficult. If achieved, long-term maintenance poses equally daunting challenges. Obstetrician-gynecologists are encouraged to aid weight loss in obese adult women. Successful approaches include behavioral, pharmacological, and surgical techniques or a combination of these (Dixon, 2016; Heymsfield, 2017). Dietary changes and exercise reduce weight and rates of the associated metabolic syndrome (Garvey, 2016; Martin, 2018). When used in conjunction with bariatric surgery, glucose control in those with type 2 diabetes is improved. However, both surgical and medical interventions are associated with appreciable long-term failure rates. Indeed, the failure rate is 50 percent in patients with diabetes undergoing bariatric surgery (Mingrone, 2015).

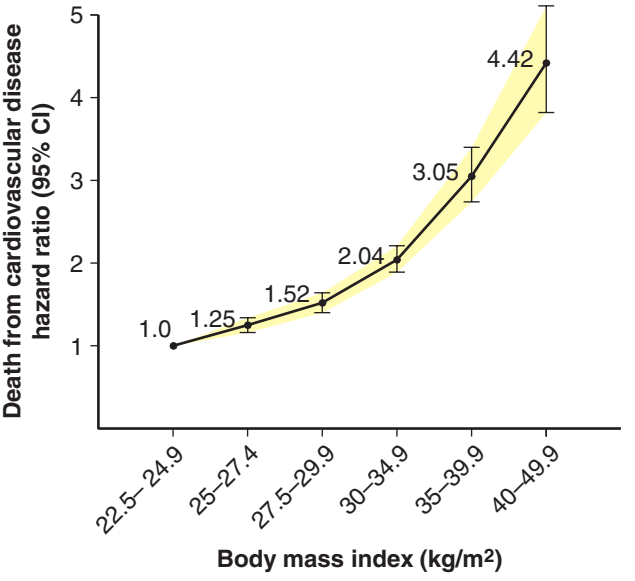

FIGURE 51-3 Estimated hazard ratios (95% CI) for death due to cardiovascular disease according to body mass index among 1.46 million white adult men and women.

PREGNANCY AND OBESITY

Obese women unequivocally have reproductive disadvantages (Lainez, 2019). This translates into difficulty in achieving pregnancy, early and recurrent pregnancy loss, preterm delivery, and several obstetrical, medical, and surgical complications with pregnancy, labor, delivery, and the puerperium (American College of Obstetricians and Gynecologists, 2021). Also, oral contraceptive pill failure and associated thromboembolism may be more likely. Second-trimester surgical abortion in obese women also carries an increased complication risk (Mark, 2018). Last, infants—and later, adult children—of obese mothers have correspondingly higher morbidity rates (Godfrey, 2017; He, 2020).

Obesity complicating pregnancy has grown substantially in this country. Our experiences at Parkland Hospital over three epochs are shown in Figure 51-4. Most recently, obese women constitute >60 percent of pregnant gravidas in our health system.

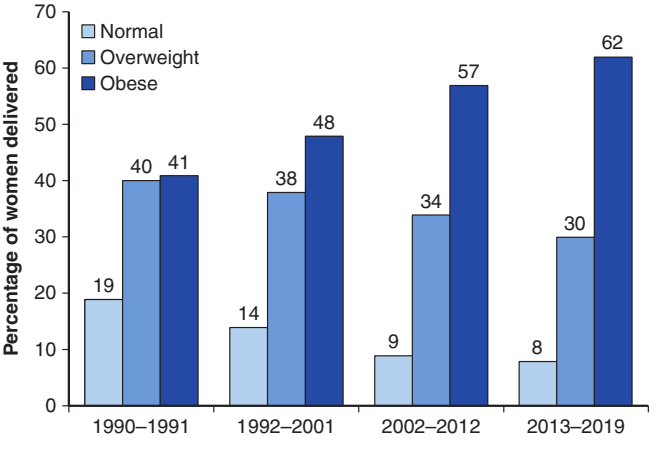

FIGURE 51-4 Increasing prevalence of obesity during four epochs in pregnant women classified at the time of their first prenatal visit at Parkland Hospital.

TABLE 51-2. Adverse Pregnancy Effects in Overweight and Obese Women

Complication	Prevalence (%) Normal BMI 18.5–24.9 n = 621,048	Prevalence (%) with Odds Ratios[a] Overweight BMI 25–29.9 n = 228,945	Obese BMI >30 n = 78,043
Gestational diabetes	2.3	4.3 (OR 1.91, 1.86–1.96)	8.6 (OR 4.04, 3.94–4.15)
Preeclampsia	2.7	4.3 (OR 1.60, 1.56–1.64)	8.1 (OR 3.17, 3.08–3.25)
Preterm birth	3.8	4.1 (OR 1.09, 1.05–1.13)	4.8 (OR 1.28, 1.23–1.34)
Labor induction	20.9	23.8 (OR 1.19, 1.17–1.21)	29.7 (OR 1.60, 1.57–1.64)
Prelabor or elective cesarean delivery	6.6	8.3 (OR 1.28, 1.26–1.31)	11.5 (OR 1.85, 1.81–1.89)
Cesarean delivery	25.2	31.5 (OR 1.37, 1.34–1.39)	39.3 (OR 1.92, 1.88–1.96)
Shoulder dystocia	2.0	2.4 (OR 1.22, 1.17–1.28)	2.3 (OR 1.14, 1.08–1.21)
Postpartum hemorrhage	6.7	8.4 (OR 1.29, 1.26–1.31)	8.7 (OR 1.34, 1.31–1.37)
Pelvic infection	0.6	0.7 (OR 1.16, 1.06–1.26)	0.8 (OR 1.28, 1.15–1.43)
Wound infection or complication	0.4	0.5 (OR.1.42, 1.28–1.58)	1.0 (OR 2.70, 2.42–3.01)
Large for gestational age	8.7	13.1 (OR 1.57, 1.54–1.61)	16.3 (OR 2.04, 1.99–2.10)
Macrosomia	2.0	3.6 (OR 1.81, 1.74–1.88)	5.1 (OR 2.60, 2.50–2.71)
Stillbirth	0.3	1.8 (OR 5.89, 5.57–6.22)	0.5 (OR 1.71, 1.56–1.87)

[a]Odds ratios with 95% CI are significant when compared to normal BMI group.
BMI = body mass index.
Data from Kim, 2016; Lisonkova, 2017; Ovesen, 2011; Santos, 2019; Schummers, 2015.

Maternal Morbidity

For *overweight* women, higher rates of adverse outcomes complicate pregnancy. Shown in Table 51-2 are results from five studies including more than 1 million singleton pregnancies. Although not as magnified as in the obese cohort, rates of almost all complications are significantly greater in *overweight* women than in those with normal BMI.

For *obese* women, definitions used in studies of adverse outcomes vary widely, and BMIs from >30 kg/m^2 to >50 kg/m^2 have served as thresholds (Crane, 2013; Pratt, 2020; Stamilio, 2014). In one study, Mariona (2017) reviewed maternal deaths in Michigan and found that the maternal mortality rate was nearly fourfold higher in obese women. Women with supermorbid obesity experience very high rates of maternal and neonatal complications including preeclampsia, macrosomia, and cesarean delivery, along with higher rates of neonatal meconium aspiration, ventilator support, and neonatal death (Marshall, 2014; Smid, 2016). Data from one large study are shown in Figure 51-5 (Weiss, 2004).

Especially striking are the markedly elevated rates of hypertension and gestational diabetes. As discussed previously, obesity and the metabolic syndrome are characterized by insulin resistance, which creates low-grade inflammation, endothelial activation, and increased sodium reabsorption (Hall, 2019). These latter effects play a central role in preeclampsia (Chap. 40, p. 691). The overwhelming association between rising maternal BMI and the incidence of preeclampsia is depicted in Figure 51-6 (HAPO Study Cooperative Research Group,

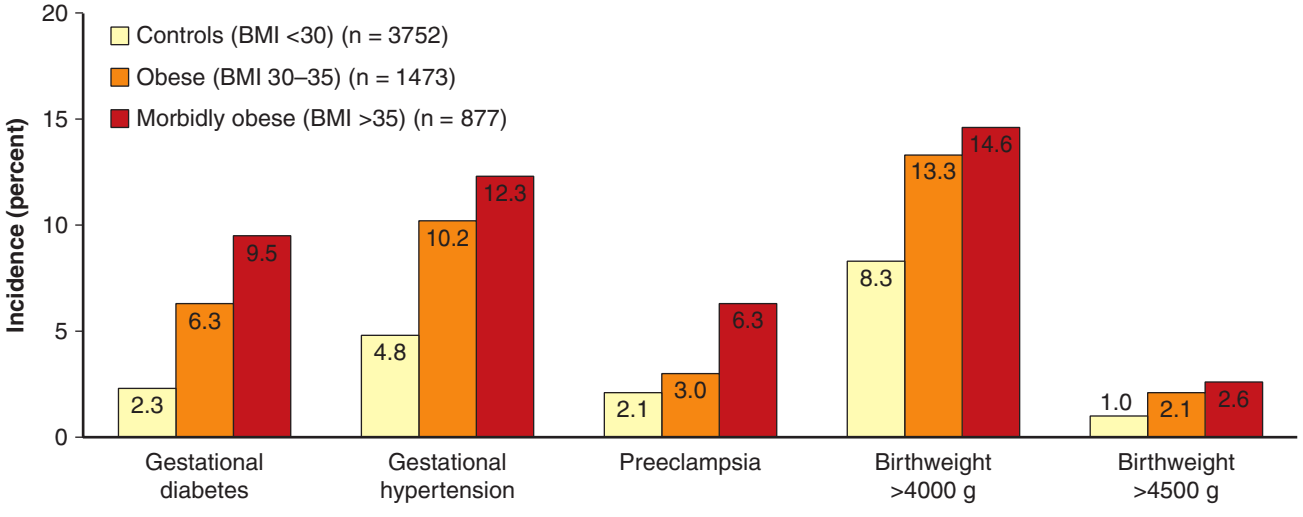

FIGURE 51-5 Incidence of selected pregnancy outcomes in women enrolled in the FASTER (First-and Second-Trimester Evaluation of Risk) trial according to BMI.

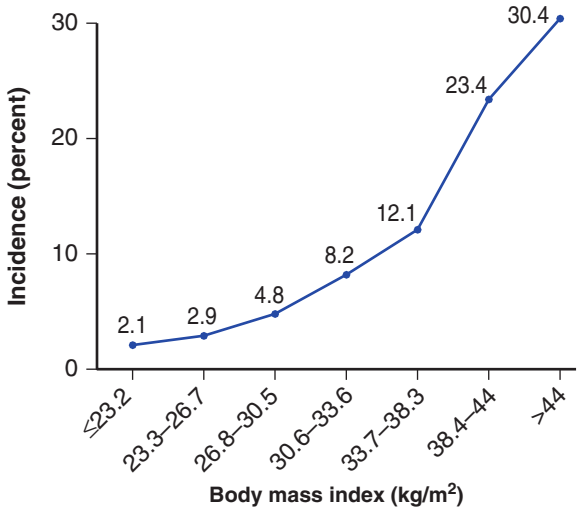

FIGURE 51-6 Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study: frequency of preeclampsia according to BMI.

2008). The risks for hypertension are highest in women with a BMI >50 kg/m^2 (Pratt, 2020). Similar observations were reported from a large Canadian study and by the Safe Labor Consortium (Kim, 2016; Schummers, 2015).

Obesity and hypertension are common cofactors in peripartum heart failure (Cunningham, 2012). Stewart and colleagues (2016) used magnetic resonance imaging to prospectively study the effect of obesity on cardiac remodeling in pregnancy. Concentric remodeling, which was considered abnormal, was greater in overweight or obese women (Fig. 51-7). This, however, regressed to normal by 3 months postpartum. Triebwasser and coworkers (2019) found that women with abnormal cardiac remodeling had a higher incidence of pregnancy-associated hypertensive disorders.

Obesity and gestational diabetes are inextricably linked as shown in Table 51-2. Their coexistence and associated adverse pregnancy outcomes are discussed in Chapter 60 (p. 1068). Nonalcoholic fatty liver disease is associated with several adverse pregnancy outcomes (Chap. 58, p. 1040). In a cohort of women

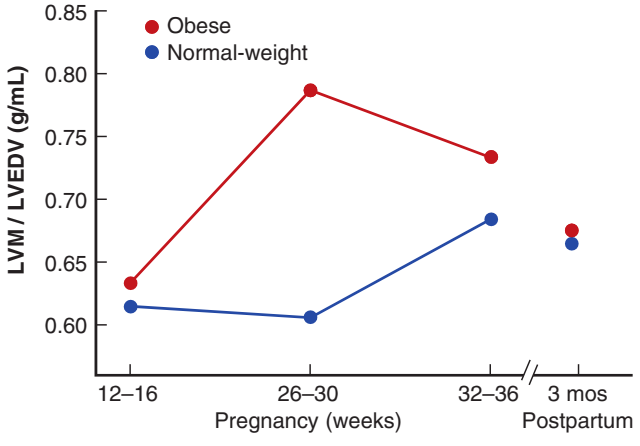

FIGURE 51-7 Geometric changes of ventricular remodeling across pregnancy in obese and normal-weight women determined by cardiac MR imaging. LVM = left ventricular mass, LVEDV = left ventricular end-diastolic volume.

with NAFLD, risks for preeclampsia, preterm birth, low-birthweight neonates, cesarean delivery, and gestational diabetes were elevated (Hagström, 2016). In one prospective study of 476 pregnancies, first-trimester sonographic evidence of maternal NAFLD was strongly associated with gestational diabetes (De Souza, 2016a,b). Meyer and associates (2013) found that overweight and obese gravidas had a higher proportion of low-density lipoprotein III (LDL-III) compared with that of normal-weight women. LDL-III predominance is a hallmark of the ectopic liver fat accumulation that is typical of NAFLD. At Parkland Hospital, we are now frequently encountering obese gravidas who have NAFLD and evidence of steatohepatitis manifest by elevated serum hepatic transaminase levels. In rare cases, liver biopsy is necessary to exclude other causes for these findings.

Quality-of-life measures also are negatively affected by obesity during pregnancy (Ruhstaller, 2017). One systematic review found significantly higher risks of depression in overweight and obese women during and after pregnancy (Molyneaux, 2014). Obese women were also significantly more likely to experience anxiety during pregnancy.

Perinatal Mortality

Stillbirths are more prevalent as the degree of obesity accrues (Schummers, 2015). In a review of almost 100 studies, obesity was the highest-ranking modifiable risk factor for stillbirth (Flenady, 2011). In women with supermorbid obesity compared with normal-weight gravidas, Yao and associates (2014) found 5.7 and 13.6-fold higher stillbirth rates at 39 and 41 weeks' gestation, respectively. Remarkably, 25 percent of term stillbirths in this study involved obese women. Chronic hypertension with superimposed preeclampsia associated with obesity is one cause of excessive stillbirths. These fetal deaths may be associated with placental lesions of decidual arteriopathy and infarctions (Avagliano, 2020).

Evaluating perinatal death rates, Lindam and coworkers (2016) reported that high maternal BMI in early pregnancy was a risk factor. The risk of neonatal death also is greater for obese women (Johansson, 2014; Meehan, 2014). Last, one study found that accruing weight between pregnancies is a risk factor for perinatal mortality, whereas weight loss between pregnancies for overweight women lowers this risk (Cnattingius, 2016).

Perinatal Morbidity

Both fetal and neonatal complication rates are increased in obese women. Two important and interrelated cofactors that contribute to excessive rates of perinatal morbidity are chronic hypertension and diabetes, both of which are associated with maternal obesity. These comorbidities each may play a role in the higher rates of fetal-growth restriction and indicated preterm birth that are seen in obese women (Liu, 2019; Tanner, 2020). Perinates of obese women with preterm prematurely ruptured membranes have a higher incidence of respiratory complications than those born to normal-weight women (Lynch, 2020). Pregestational diabetes also raises the birth defect rate, and gestational diabetes is complicated by excessive numbers of large-for-gestational-age and macrosomic fetuses (Chap. 47, p. 833).

Even when diabetes and hypertension are not considered, the prevalence of neonatal morbidity is greater in offspring

of obese women (Kim, 2016; Polnaszek, 2018; Schummers, 2015). The propensity for preterm birth may be related to increased adipokines and cytokines causing chronic inflammation (Tersigni, 2020). The group from MetroHealth Medical Center in Cleveland has extensively studied prepregnancy obesity, gestational weight gain, and diabetes and their relationship to adverse pregnancy outcomes and to greater newborn weight and fat mass (Catalano, 2015; Ma, 2016; Yang, 2016). Although each of these variables is associated with larger and more corpulent newborns, prepregnancy BMI and its effect on inflammation and placental gene expression has the strongest influence on the prevalence of macrosomic neonates.

Rates of birth defects also are higher with obesity (Auger, 2019). For neural-tube defects, elevated risks of 1.2-, 1.7-, and 3.1-fold have been described for overweight, obese, and severely obese women, respectively (Rasmussen, 2008). The National Birth Defect Prevention Study reported a correlation between BMI and congenital heart defects (Gilboa, 2010). However, this may be related to diabetes as a cofactor (Biggio, 2010). Importantly, obesity degrades the accuracy of obstetrical ultrasound examination and antepartum identification of birth defects (Adekola, 2015; Dashe, 2009; Yaqub, 2021).

Long-term Offspring Morbidity

Obese women beget obese children, who themselves become obese adults. Catalano and coworkers (2009) studied offspring at a mean age of 9 years and found a direct association with maternal prepregnancy obesity and childhood obesity. They also reported associations with central obesity, elevated systolic blood pressure, increased insulin resistance, and lipid abnormalities—all elements of the metabolic syndrome. Reynolds and associates (2013) reported higher rates of cardiovascular disease and all-cause mortality in 37,709 adult offspring of overweight and obese mothers. Similar cardiometabolic health effects in offspring were echoed by Gaillard and colleagues (2016). Other data suggest that excessive maternal weight gain in pregnancy may predict obesity in adult offspring (Lawrence, 2014). Last, rates of glucose intolerance and metabolic syndrome are higher among offspring of obese women (Gaillard, 2016).

The potential biological mechanisms of these associations are unclear. But such studies raise the possibility of *fetal programming*, that is, the fetal environment may lead to adverse adult health outcomes. Elucidation is limited by insufficient data regarding the influence of maternal and genetic predisposition compared with the diet and activity environment of the infant and child (Gluck, 2009). The science of *epigenetics* has provided some support for the possibility that perturbations of the maternal–fetal environment can adversely alter postdelivery events (Kitsiou-Tzeli, 2017).

ANTEPARTUM MANAGEMENT

Maternal Weight Gain

The Institute of Medicine (2009) has updated its previous maternal weight gain determinants (Table 10-4, p. 183). For overweight women, weight gain of 15 to 25 pounds is suggested. For obese women, the Institute recommends a gain of 11 to 20 pounds. Intuitively, maternal weight must increase sufficiently to provide for fetal and placental tissue accrual and for amnionic fluid and maternal blood volume expansion. Thus, maternal weight loss during pregnancy is discouraged. The American College of Obstetricians and Gynecologists (2021) endorses these guidelines.

It is emphasized that these recommendations were issued without firm scientific evidence to support them, and their value remains unproven (Comstock, 2019; Most, 2019). For example, recent studies differ with respect to the effect of insufficient weight gain for obese women. Bodnar and colleagues (2016) reported no greater risk for low-birthweight or small-for-gestational-age newborns among 47,494 obese women who had inadequate weight gain during pregnancy. Bogaerts and associates (2015) also found that even weight loss among obese women did not yield poor fetal growth. In contrast, however, Hannaford and coworkers (2017) reported that obese women who gained less than the Institute recommendations were almost three times more likely to deliver a small-for-gestational-age neonate. Another study similarly found an almost twofold greater risk of growth-restricted newborns among obese women who lost weight during pregnancy (Cox Bauer, 2016).

Excessive gestational weight gain may portend greater risks for the obese mother. Berggren and coworkers (2016) noted that overweight and obese women accrued maternal fat with excessive gestational weight gain. From another analysis, overall higher rates of hypertensive disorders, cesarean delivery, and fetal overgrowth and lower rates of spontaneous preterm birth and fetal undergrowth were found among women gaining more than recommended (Johnson, 2013). However, when analyzed according to BMI category, significantly higher rates of preeclampsia, cesarean delivery, and fetal overgrowth were identified among the 1937 overweight women, but not the 1445 obese women, who gained excess weight. Last, overweight and obese women have excessive postpartum weight retention (Siegel, 2020).

Dietary Intervention

Several dietary interventions can help limit and achieve the weight gain targets listed in the previous section. Options include lifestyle changes such as changes in physical activity. In one randomized trial of exercise in 300 overweight women, risks for gestational diabetes were lowered (Wang, 2017). In other trials, however, dietary intervention had no effect on weight gain (Okasene-Gafa, 2019; Seneviratne, 2016). Also, a Cochrane database analysis of 11,444 women suggests that lifestyle interventions confer only a modest reduction in maternal weight gain, and their benefits for fetal overgrowth, cesarean delivery rate, and adverse neonatal outcome are not significant (Muktabhant, 2015). Last, metformin treatment for obese pregnant women does not improve pregnancy outcomes (Dodd, 2018).

Regarding neonatal outcomes, the poor success of lifestyle interventions during pregnancy has been attributed to their late introduction. In this regard, it is presumed that early gene expression within the placenta has already been programmed (Catalano, 2015).

Prenatal Care

Close prenatal monitoring detects most early signs of diabetes or hypertension. Early gestational diabetes screening did not result in less morbidity compared with standard screening (Harper, 2020). Obstructive sleep apnea is common in obese women (Dominquez, 2018). Standard screening tests for fetal anomalies are sufficient, while remembering the sonographic limitations for fetal anomaly detection in this group. Even so, ultrasound predicts fetal weight accurately in these women (O'Brien, 2020). Accurate fetal-growth surveillance in obese women usually requires serial sonographic assessment. Dude and coworkers (2019) reported that ultrasound as a detection tool had high specificity but poor sensitivity for growth restriction and a low positive predictive value for macrosomia. Antepartum external fetal heart rate monitoring is likewise more difficult.

INTRAPARTUM MANAGEMENT

Obesity poses increased risk for multiple labor or intrapartum complications. These include postterm pregnancy or labor abnormalities (Carpenter, 2016; Shenouda, 2020). In one study of 143,519 women, the odds of spontaneous labor at term in obese women was approximately half that of normal-weight women (Denison, 2008). In an analysis of more than 5000 parturients, women with a BMI >30 kg/m^2 had a longer duration and slower early progression of first-stage labor (Norman, 2012). Epidural analgesia apparently does not affect the length of labor in obese women (Polónia Valente, 2020).

Labor Induction

As shown in Table 51-2, compared with normal-weight women, obese women are nearly twice as likely to undergo labor induction (Denison, 2008). However, obese women are more likely to experience a failed induction, and this risk rises with increasing obesity (Kerbage, 2020). The duration of labor resulting in vaginal delivery lengthens with increasing maternal BMI (Carlhäll, 2020). In a retrospective analysis of 470 nulliparous women with a BMI >30 kg/m^2, those who underwent labor induction at 39 weeks' gestation had a greater cesarean delivery rate—26 versus 40 percent compared with a cohort expectantly managed (Wolfe, 2014). In a study of 485 women with class III obesity, the overall cesarean delivery rate after failed induction was 49 percent (Paidas Teefey, 2020). The rate was 46 percent for those with a BMI 30–40, 63 percent for a BMI 40–50, and 69 percent for a BMI >60.

Although perhaps not unexpected, these findings have been challenged. Lee and associates (2016) reviewed statistics from 74,725 deliveries in obese women and reported that elective induction at 37 to 39 weeks' gestation was actually associated with a lower cesarean delivery rate. Additionally, in a secondary analysis of one randomized trial, obese nulliparas who were randomly assigned to Foley catheter cervical ripening plus misoprostol for labor induction had a reduced labor duration and lower rate of cesarean delivery compared with those given solely misoprostol (Seasely, 2021). These conflicting results highlight the difficulties faced by obstetricians as they contemplate the seemingly competing interests of the fetus and the obese mother.

Anesthesia Risks

Obese women present anesthesia challenges that include difficult epidural and spinal analgesia placement and complications from failed or difficult intubations. Evaluation of gravidas with supermorbid obesity by the anesthesiologist is recommended during prenatal care or upon arrival to the labor unit (American College of Obstetricians and Gynecologists, 2019b).

Regional analgesia for morbidly obese women is associated with longer neuraxial procedure times and more failed placement attempts (Li, 2019). Importantly, however, spinal analgesia in obese women for cesarean delivery does not appear to have greater benefits than combined spinal-epidural. One study comparing single-shot spinal analgesia and combined spinal-epidural analgesia found that both methods could be placed with equal expediency and efficacy in morbidly obese gravidas (Ross, 2014).

Obese women who undergo neuraxial analgesia that is complicated by relative hypotension more frequently have neonates with umbilical artery cord blood acidemia, which probably stems from delayed delivery. One study of 572 obese women showed that cord blood pH significantly dropped and base deficit rose with increasing BMI (Edwards, 2013). The rate of gases with a pH <7.1 doubled from 3.5 percent for a BMI <25 kg/m^2 to 7.1 percent for a BMI ≥40 kg/m^2. Anesthetic risks and complications are discussed in Chapter 25.

Cesarean Delivery

As shown in Table 51-2, rates of cesarean delivery are significantly greater in obese women compared with normal-weight gravidas. In an analysis of 226,958 women, cesarean delivery rates rose significantly for overweight (34 percent), class I (38 percent), class II (43 percent), and class III (50 percent) obesity (Schummers, 2015). Our experiences at Parkland Hospital are similar (Fig. 51-8). Moreover, obese women had less composite morbidity when labor was attempted compared with cesarean delivery (Gibbs Pickens, 2018; Grasch, 2017). More worrisome is that obese women also have higher rates of *emergency* cesarean delivery, and obesity lengthens times for decision-to-incision and for delivery (Girsen, 2014; Pulman, 2015).

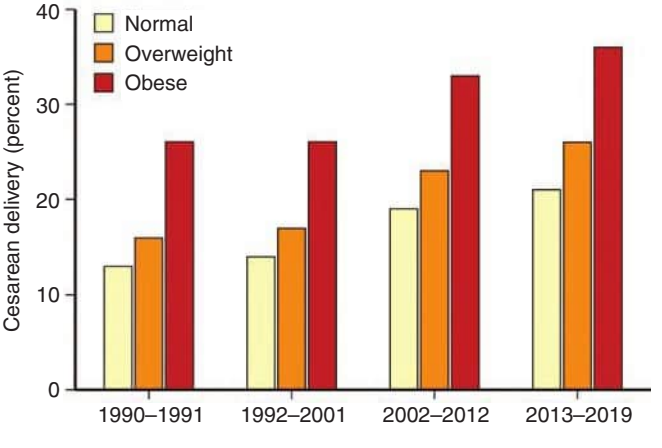

FIGURE 51-8 Cesarean delivery rates in more than 300,000 women according to BMI categories over a 30-year period at Parkland Hospital.

Discussed in Chapter 31 (p. 577), the incidence of failed trial of labor after cesarean is higher in obese women (Grasch, 2017; Wilson, 2020). Women who gain weight between pregnancies also have significantly lower rates of vaginal birth after cesarean.

Surgical Concerns

For cesarean delivery, forethought is given to optimal placement and type of abdominal incision to provide access to the fetus and to effect the best wound closure. We prefer a vertical incision in obese women to provide the most direct access (Fig. 51-9). Others prefer a low transverse abdominal incision, with or without rostral taping of the pendulous abdomen (Karimyar, 2020; Lakhi, 2018). Individual differences in maternal body habitus preclude naming any one approach as superior (Turan, 2016). Some observational studies have compared wound outcomes associated with vertical and transverse skin incisions, but results are conflicting as to a superior option (Karimyar, 2020; Marrs, 2014; Sutton, 2016).

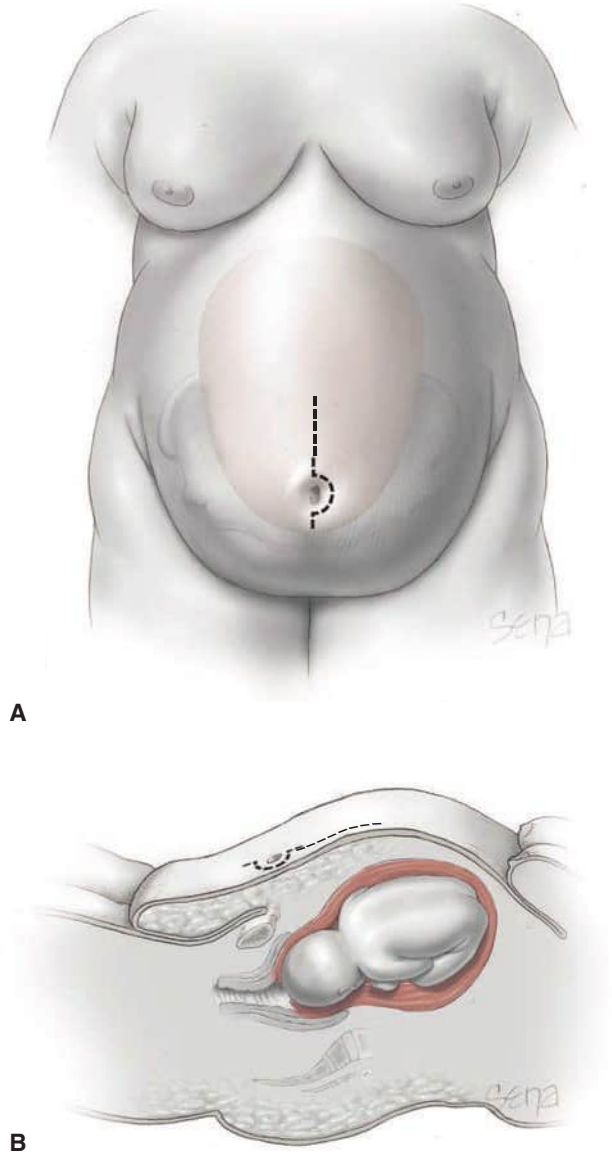

FIGURE 51-9 Abdominal incision for the obese woman. **A.** Frontal view. The dotted line indicates an appropriate skin incision for abdominal entry relative to the panniculus. As shown by the uterus in the background, selection of this periumbilical site permits access to the lower uterine segment. **B.** Sagittal view.

The frequency of abdominal wound infections is directly related to BMI. Conner and associates (2014) found the risk of wound infection is threefold higher—23 versus 7 percent—in women with supermorbid obesity compared with nonobese patients. Among women with a BMI >45 kg/m^2, reported wound complication rates range from 14 to 19 percent (Smid, 2015; Stamilio, 2014). Comorbid diabetes apparently raises this risk (Leth, 2011). Other studies describe wound complication rates ranging from 2 to >40 percent in obese women (Conner, 2014; Marrs, 2014; Smid, 2015; Thornburg, 2012).

Several interventions may be preventive. Closure of subcutaneous tissue when at least 2 cm deep reduces wound complication rates (Tipton, 2011). Steel staples and subcuticular skin closure produce identical results (Zaki, 2018). Studies have also examined the use of higher doses of perioperative prophylactic antibiotics. Pharmacokinetic studies indicate that tissue concentrations of prophylactic antibiotics are lower with increasing BMI (Pevzner, 2011; Young, 2015). One prospective study showed that a 3-g dose of cefazolin resulted in higher tissue concentrations compared with a 2-g dose (Swank, 2015). A retrospective analysis of 335 women with a median weight of 310 pounds found that the higher dose of cefazolin did not result in fewer surgical site infections (SSIs) (Ahmadzia, 2015). The American College of Obstetricians and Gynecologists (2020) recognizes either 2- or 3-g doses of cefazolin as suitable for those with weights ≥80 kg. The Centers for Disease Control and Prevention recommends a 2-g dose for weights ≥80 kg and 3-g dose for those ≥120 kg (Berríos-Torres, 2017). One pharmacokinetic analysis in obese women showed sufficient tissue levels with a 2-g dose for cesarean deliveries lasting 1.5 hours. Authors recommended consideration for redosing in obese women if surgeries were longer (Grupper, 2016). Last, some early evidence may support extending oral antibiotic prophylaxis for 48 hours postcesarean in obese women to lower SSIs (Valent, 2017). Obese women administered preoperative cephalosporin prophylaxis had a surgical infection rate of 13.4 percent compared with a rate of 6.4 percent for those given a 2-day *postoperative* course of oral cephalexin and metronidazole in addition to routine preoperative prophylaxis.

Negative-pressure wound therapy (NPWT) also has been used prophylactically (Mark, 2014). To address this, Hussamy and colleagues (2019) designed a randomized trial of NPWT versus routine dressing in 441 obese women undergoing cesarean delivery. Such therapy did not significantly lower the postoperative wound complication rate compared with routine care—17 versus 19 percent, respectively. A subsequent report confirmed these findings (Tuuli, 2020).

For the obese woman who is delivered vaginally, puerperal tubal sterilization is safe regardless of BMI (Byrne, 2020). These procedures are described in Chapter 39. The risks for postpartum venous thromboembolism are increased in obese women. This is despite the fact that velocity of lower-extremity blood flow is increased in obese pregnant women (Dutta, 2020). As discussed in Chapter 55 (p. 990), thromboprophylaxis is controversial. To lower thromboembolic complications, graduated

compression stockings, hydration, and early mobilization after cesarean delivery in obese women are recommended by the American College of Obstetricians and Gynecologists (2019b). If there are additional risk factors other than class III obesity, the Society for Maternal-Fetal Medicine (2020) recommends enoxaparin. We do not routinely use thromboprophylaxis for obesity alone at Parkland Hospital. This practice has recently been confirmed by Lu and associates (2021).

BARIATRIC SURGERY

Several surgical procedures are designed to treat morbid obesity either by diminishing gastric volume (*restrictive*) or by bypassing gastrointestinal absorption (*restrictive malabsorptive*). In nonpregnant patients, these procedures serve to improve or resolve diabetes, hyperlipidemia, hypertension, and obstructive sleep apnea and to reduce risks of myocardial infarction and death (Beamish, 2016).

Restrictive Procedures

Of options, the approved laparoscopic adjustable silicone gastric banding (LASGB) procedure—*LAPBAND*—places a band 2 cm below the gastroesophageal junction to create a small stomach pouch above the ring. The ring diameter is controlled by a saline reservoir in the band.

These procedures can have positive effects on pregnancy outcomes. One study compared pregnancy outcomes in bariatric surgery patients whose surgery was done after the first pregnancy. Following bariatric surgery, the incidences of hypertension, gestational diabetes, and preterm birth were significantly lower in the bariatric surgery patients (Ibiebele, 2020). The results from these and other studies are shown in Table 51-3.

Deflation of the band during pregnancy affects maternal and fetal weight gain. Pilone and coworkers (2014) studied 22 pregnancies after band placement and reported that all women underwent full deflation of the band in the first trimester and gained an average of 14.7 kg during pregnancy. In another study, 42 women underwent deflation of the band, whereas 54 women maintained band inflation. A deflated band was associated with higher mean maternal weight gain—15.4 kg versus 7.6 kg, increased birthweight—3712 versus 3380 g, and a twofold greater risk of macrosomia compared with an inflated band (Cornthwaite, 2015). Rarely, the band may slip due to nausea and vomiting, especially with advancing gestation or after delivery (Pilone, 2014; Schmitt, 2016; Suffee, 2012). One fetus suffered a fatal cerebral hemorrhage caused by maternal vitamin K deficiency secondary to prolonged vomiting due to band slippage that created a gastric outlet obstruction (Van Mieghem, 2008).

TABLE 51-3. Pregnancy Outcomes Following Bariatric Surgery

Outcome[a]	Gastric Banding[b]	Gastric Bypass[c]
Hypertension	11%	4%
Gestational diabetes	7%	4%
Cesarean delivery	35%	33%
Mean birthweight	3206 g	3084 g
Low birthweight	7%	11%
Stillbirth	3/1000	3/1000

Restrictive Malabsorptive Procedures

The laparoscopically performed *Roux-en-Y* gastric bypass is the most commonly used procedure for gastric restriction and selective malabsorption. Pregnancy outcomes are changed remarkably following Roux-en-Y bypass (Adams, 2015). As shown in Table 51-3, rates of hypertension, gestational diabetes, and fetal macrosomia are reduced.

Serious complications with bypass operations are uncommon, however, upper abdominal pain is frequent in pregnancy and may be associated with internal herniation, which is protrusion of the bowel through a window defect in the mesentery. Petersen and associates (2017) described outcomes in a birth cohort including 139 pregnancies. Upper abdominal pain complicated 46 percent, and a third of these had internal herniation. The preterm birth rate was 14 of 64 among those with upper abdominal pain versus 1 of 75 in those without pain. Intussusception and small bowel obstruction can develop from internal herniation, and maternal deaths from herniation and obstruction are reported (Moore, 2004; Renault, 2012). Bowel obstruction is notoriously difficult to diagnose during pregnancy (Vannevel, 2016; Wax, 2013).

Pregnancy

Because of its associated health successes, bariatric surgery is popular, and many women subsequently become pregnant (Narayanan, 2016). From studies, fertility improves and obstetrical complication rates decline in women after bariatric surgery compared with morbidly obese controls (Getahun, 2021; Kominiarek, 2017; Yi, 2015). In one of these studies, despite surgical treatment, almost half of 670 women were still obese at the time of their first pregnancy after bypass (Johansson, 2015). Nevertheless, the frequency of large-for-gestational-age newborns dropped from 22 to 8.6 percent and of small-for-gestational-age neonates rose from 7.6 to 15.6 percent. In a systematic review, Kwong and colleagues (2018) confirmed these fetal weight trends after bariatric surgery. According to Maric and colleagues (2020), fetuses are smaller because of lower maternal glucose levels rather than alterations of the fetoplacental circulation. Also, risks for diabetes and preeclampsia were reduced. Last, evidence suggests that the risk for congenital anomalies is decreased (Auger, 2019; Neovius, 2019).

Currently, the American College of Obstetricians and Gynecologists (2019b) recommends that women who have undergone bariatric surgery be assessed for vitamin and nutritional

sufficiency. When indicated, vitamins B_{12} and D, folic acid, and calcium supplementation are given. Vitamin A deficiency also is possible (Chagas, 2013). Women with a gastric band should be monitored by their bariatric team during pregnancy because band adjustments may be necessary. Last, special vigilance for signs of internal herniation with intestinal obstruction is encouraged (Stuart, 2017; Wax, 2013).

CHAPTER 52

Cardiovascular Disorders

In an analysis of maternal mortality in the United States between 2011 and 2013, deaths related to hemorrhage, hypertensive disorders, and embolism showed declining rates. In contrast, deaths attributable to cardiovascular diseases are rising and are responsible for one fourth of all pregnancy-related mortalities (Creanga, 2017; Petersen, 2019). Recent development of state-level maternal mortality review committees have emphasized this issue and highlighted the relatively protracted timeline of illness. Up to a year after delivery, cardiac events were among the leading causes of death for women in Texas in 2013 (Texas Maternal Morbidity Task Force, 2020). These disorders account also for significant maternal morbidity and are a common reason for intensive care unit admissions (Small, 2012).

Cardiovascular disease complicates 1 to 4 percent of pregnancies in the United States (American College of Obstetricians and Gynecologists, 2019). The increasing prevalence is likely multifactorial and includes the higher rates of obesity, hypertension, and diabetes (Klingberg, 2017). According to the National Center for Health Statistics, almost half of adults aged 20 and older have at least one risk factor for cardiovascular disease (Fryar, 2012). Another related reason is delayed childbearing. Last, as discussed subsequently (p. 927), an increasing number of women with congenital heart disease are now becoming pregnant.

The importance of heart disease and its adverse effect on pregnancy morbidity and mortality led the American College of Obstetricians and Gynecologists to create a Task Force on Pregnancy and Heart Disease. Its purpose is to emphasize the prevalence and effect of heart disease in pregnancy, provide guidance for risk factor identification, outline common cardiovascular disorders, provide recommendations for management, and develop a comprehensive interpregnancy plan. Multidisciplinary care is essential (Quinones, 2021).

PHYSIOLOGICAL CONSIDERATIONS IN PREGNANCY

Cardiovascular Physiology

The marked pregnancy-induced anatomical and functional changes in cardiac physiology can have a profound, negative effect on underlying heart disease. These changes are discussed in detail in Chapter 4 (p. 62), and some are listed in Table 52-1

TABLE 52-1. Hemodynamic Changes in 10 Normal Pregnant Women at Term Compared with Repeat Values Obtained 12 Weeks Postpartum

Parameter	Change (%)
Cardiac output	+43
Heart rate	+17
Left ventricular stroke work index	+17
Vascular resistance	
Systemic	−21
Pulmonary	−34
Mean arterial pressure	+4
Colloid osmotic pressure	−14

(Clark, 1989). Importantly, cardiac output increases approximately 40 percent during pregnancy. Almost half of this total takes place by 8 weeks' gestation and is maximal by midpregnancy (Capeless, 1989). This early rise stems from augmented stroke volume, which results from lowered vascular resistance. Later in pregnancy, resting pulse and stroke volume are even higher because of greater end-diastolic ventricular volume that results from augmented pregnancy blood volume. These adaptations are even more profound in multifetal pregnancies (Ghi, 2019). Intrinsic left ventricular contractility does not change, and thus normal left ventricular function is maintained during pregnancy. Namely, pregnancy is not characterized by hyperdynamic function or a high cardiac-output state.

Women with underlying cardiac disease may not always accommodate these changes, and ventricular dysfunction leads to cardiogenic heart failure. A few women with severe cardiac dysfunction can experience evidence of heart failure before midpregnancy. In others, heart failure may develop after 28 weeks' gestation, when pregnancy-induced hypervolemia and cardiac output reach their maximum. In most, however, heart failure develops peripartum, when labor, delivery, and several common obstetrical conditions add undue cardiac burdens. Some of the latter include preeclampsia, hemorrhage and anemia, and sepsis.

■ Ventricular Function in Pregnancy

Ventricular volumes and mass accrue to accommodate pregnancy-induced hypervolemia. This is reflected by greater end-systolic and end-diastolic dimensions. At the same time, however, septal thickness and ejection fraction are unchanged. This is because these alterations are accompanied by substantive ventricular remodeling—*plasticity*—which is characterized by eccentric expansion of left-ventricular mass that averages 30 to 35 percent near term. All of these adaptations return to prepregnancy values within a few months postpartum.

Certainly for clinical purposes, ventricular function during pregnancy is normal as estimated by the *Braunwald ventricular function* graph (Fig. 4-9, p. 63). Thus, for given filling pressures, cardiac output is appropriate and allows eudynamic cardiac function during pregnancy. Esoteric changes in pregnancy-related cardiac physiology continue to be clarified. In nonpregnant subjects with a normal heart who sustain a high-output state, the left ventricle undergoes *longitudinal remodeling*, and echocardiographic functional indices of its deformation show normal values. In pregnancy, the ventricle instead undergoes *spherical remodeling*, and the calculated indices that measure longitudinal deformation are depressed. Thus, normal nonpregnant indices are likely less accurate when used to assess function in pregnant women because they do not account for the spherical remodeling (Savu, 2012; Stewart, 2016).

Adjusting for these geometrical changes, Melchiorre and coworkers (2016) studied normal cardiac echocardiographic findings in 559 nulliparas at four points during pregnancy and again at 1 year postpartum. At term, significant chamber diastolic dysfunction was present in 18 percent and impaired myocardial relaxation was evident in 28 percent of the women. Also, a significant proportion of women demonstrated a drop in stroke volume index and a tendency toward eccentric remodeling. These findings suggest cardiovascular maladaptation to the expanded volume demands in a substantial proportion of apparently normal pregnancies. Significant dyspnea at rest was reported by 7.4 percent of the women at term, most of whom had chamber diastolic dysfunction. Cardiac function and all signs of dyspnea fully recovered at 1 year postpartum.

Cardiac magnetic resonance (MR) imaging increasingly is used to evaluate cardiac structure and function. Stewart and associates (2016) performed cardiac MR imaging studies in 23 women longitudinally across pregnancy and at 12 weeks postpartum. Compared with studies performed at 12 to 16 weeks' gestation, left ventricular mass grew significantly for both normal-weight and overweight women. The calculated geometrical ratio of left ventricular mass to left ventricular end-diastolic volume demonstrated concentric remodeling throughout gestation, which resolved by 12 weeks' postpartum. The right ventricle also undergoes remodeling (Martin, 2017). These observations likely mean that pregnancy causes a mixture of eccentric and concentric ventricular remodeling.

DIAGNOSIS OF HEART DISEASE

The physiological adaptations of normal pregnancy can induce symptoms and alter clinical findings that may confound the diagnosis of heart disease. For example, in normal pregnancy, functional systolic heart murmurs are common, respiratory effort is accentuated, edema frequently accrues in lower extremities after midpregnancy, and fatigue and exercise intolerance often develop. Some systolic flow murmurs can be loud, and normal changes in the various heart sounds depicted in Figure 52-1 may erroneously suggest cardiac disease. In contrast, clinical findings that are more likely to suggest heart disease are listed in Table 52-2.

■ Diagnostic Studies

Noninvasive cardiovascular studies such as electrocardiography, chest radiography, and echocardiography will provide the data necessary for cardiac functional evaluation in most women.

In the *electrocardiogram (ECG)*, an average 15-degree left-axis deviation is found as the diaphragm is elevated in advancing pregnancy. Other findings are described in Figure 52-2

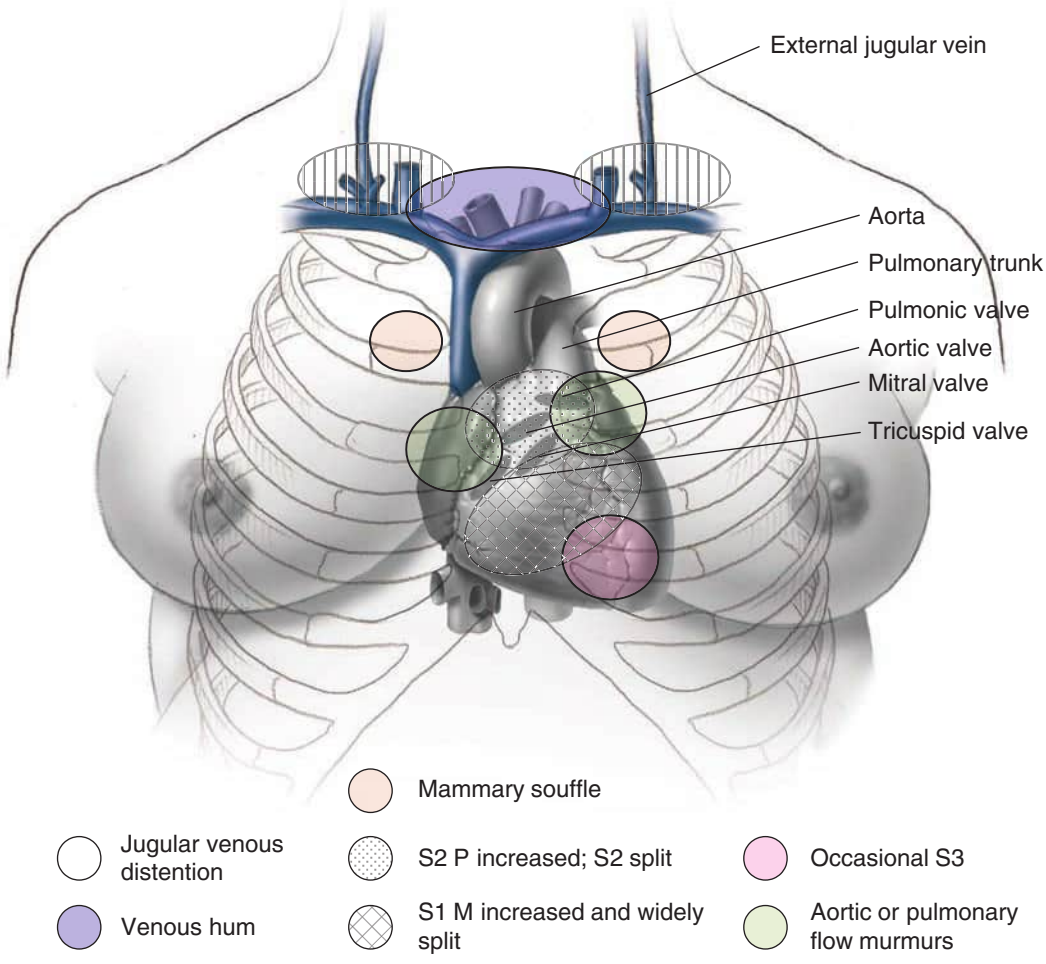

FIGURE 52-1 Normal cardiac examination findings in the pregnant woman. S_1 = first sound; M_1 = mitral first sound; S_2 = second sound; P_2 = pulmonary second sound. (Data from Gei, 2001; Hytten, 1991.)

TABLE 52-2. Clinical Indicators of Heart Disease During Pregnancy

Symptoms
Progressive dyspnea or orthopnea
Nocturnal cough
Hemoptysis
Syncope
Chest pain
Clinical Findings
Cyanosis
Clubbing of fingers
Persistent neck vein distention
Systolic murmur grade 3/6 or greater
Diastolic murmur
Cardiomegaly
Persistent tachycardia and/or arrhythmia
Persistent split second sound
Fourth heart sound
Criteria for pulmonary hypertension

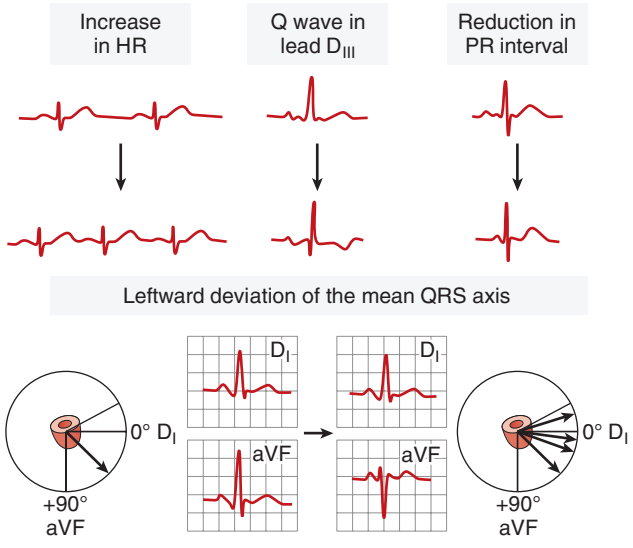

FIGURE 52-2 Normal electrocardiograph (ECG) adaptations during pregnancy, including a reduced mean PR interval, increased heart rate, left axis deviation, inverted or flattened T waves, and a Q wave in lead D_{III}. HR = heart rate. (Reproduced with permission from Angeli F, Angeli E, Verdecchia P: Electrocardiographic changes in hypertensive disorders of pregnancy, Hypertens Res 2014 Nov;37(11):973–975.)

(Angeli, 2014). Pregnancy does not alter voltage findings. Atrial and ventricular premature contractions are relatively frequent.

With *radiography*, anteroposterior (AP) and lateral chest radiographs are useful, and when a lead apron shield is used, fetal radiation exposure is minimal. Gross cardiomegaly can usually be excluded, but slight heart enlargement is poorly detected because the heart silhouette normally is larger in pregnancy. This is accentuated further with a portable posterior-anterior chest radiograph.

Echocardiography is now widely used and permits accurate diagnosis of most heart diseases during pregnancy. Some normal pregnancy-induced changes include a small increase in the dimensions of all cardiac chambers, a slight but significant growth in left ventricular mass, and greater tricuspid and mitral valve regurgitation (Grewal, 2014). Of note, systolic function normally does not change and ejection fraction is preserved. Late geometric changes such as interventricular septum dimension (IV_d) are likely to be abnormal before changes in ejection fraction. Savu (2012) and Vitarelli (2011) and their colleagues have provided normal echocardiographic parameters for pregnancy, which are listed in the Appendix (p. 1233). In some situations, such as complex congenital heart disease, *transesophageal echocardiography* may be useful.

Cardiovascular MR imaging, compared with echocardiography, is associated with higher reproducibility and is less hindered by ventricular geometry and body habitus. It is useful for assessment of the right ventricle and visualization of congenital heart lesions and myocarditis (Herrey, 2019; Martin, 2017). Ducas and coworkers (2014) have published normal reference values for pregnancy.

Exercise stress testing is an objective assessment of maternal functional capacity. It is also useful to diagnose exercise-induced arrhythmias. Stress testing can be performed in women with known heart disease prior to pregnancy or, if necessary, in the asymptomatic pregnant women (Regitz-Zagrosek, 2018). Dennis and associates (2019) have described findings in normal pregnant women using the *6-minute walk test*.

Myocardial perfusion studies using albumin or red cells tagged with technetium-99m are rarely needed during pregnancy to evaluate ventricular function. That said, the estimated fetal radiation exposure from nuclear medicine studies of myocardial perfusion is negligible (Chap. 49, p. 875). *Cardiac catheterization* with limited fluoroscopy time also is safe to perform. During coronary angiography, the mean radiation exposure to the unshielded abdomen is 1.5 mGy, and less than 20 percent of this reaches the fetus (Regitz-Zagrosek, 2018). Shortening the fluoroscopic time may help to minimize radiation exposure (Raman, 2015; Tuzcu, 2015). In women with clear indications, any minimal theoretical fetal risk is outweighed by maternal benefits, and such studies should be performed as indicated.

■ Functional Classification of Heart Disease

Pregnancy is a stress test of cardiovascular reserve. However, no clinically applicable test accurately measures functional cardiac capacity. The clinical classification of the New York Heart Association (NYHA) is based on past and present disability and is uninfluenced by physical signs:

- Class I. *Uncompromised—no limitation of physical activity:* These women do not have symptoms of cardiac insufficiency or experience anginal pain.
- Class II. *Slight limitation of physical activity:* These women are comfortable at rest, but with ordinary physical activity, discomfort in the form of excessive fatigue, palpitation, dyspnea, or anginal pain results.
- Class III. *Marked limitation of physical activity:* These women are comfortable at rest, but less than ordinary activity causes excessive fatigue, palpitation, dyspnea, or anginal pain.
- Class IV. *Severely compromised—inability to perform any physical activity without discomfort:* Symptoms of cardiac insufficiency or angina may develop even at rest. If any physical activity is undertaken, discomfort is increased.

At least four predictive systems detect and classify heart disease in pregnant women. These include CARPREG I and II, ZAHARA, and the World Health Organization (WHO) system (Wolfe, 2019). Of these, the most comprehensive risk stratification system is the modified WHO Risk Classification of Cardiovascular Disease and Pregnancy (Table 52-3). This classification system was validated in an international cohort of 2742 pregnant women with heart disease (van Hagen, 2016). It is especially useful for assessing maternal risk and for preconceptional counseling. Lu (2015) and Pijuan-Domènech (2015) and their colleagues concluded that the modified WHO classification provides the greatest predictive accuracy for cardiac complications during pregnancy.

GENERAL PREGNANCY CONSIDERATIONS

■ Preconceptional Counseling

Women with severe heart disease will benefit immensely from counseling before pregnancy, and they usually are referred for maternal-fetal medicine or cardiology consultation (Clark, 2012; Wolfe, 2019). Optimizing cardiac function to mitigate complications during pregnancy is the goal. Maternal mortality rates generally correlate directly with functional classification, however, this relationship may change as pregnancy progresses. Siu and coworkers (2001b) observed significant worsening of NYHA class in 4.4 percent of 579 pregnancies in which the baseline class was I or II.

As described later, some women have life-threatening cardiac abnormalities that can be reversed by corrective surgery, and subsequent pregnancy becomes less dangerous. In other cases, such as women with mechanical valves taking warfarin, fetal teratogenic concerns predominate. Last, because many congenital heart lesions are inherited as polygenic characteristics, some women with congenital heart lesions give birth to similarly affected neonates. This risk varies widely based on the specific abnormality (Table 52-4) (Lupton, 2002).

Risk Factors

According to the American College of Obstetricians and Gynecologists (2019), four maternal risk factors are linked to

TABLE 52-3. World Health Organization (WHO) Risk Classification of Cardiovascular Disease and Pregnancy with Management Recommendations

Risk Category	Associated Conditions
WHO 1—Morbidity or mortality risk no higher than general population	Uncomplicated, small, or mild: Pulmonary stenosis Patent ductus arteriosus Mitral valve prolapse with no more than trivial mitral regurgitation Successfully repaired simple lesions: Ostium secundum atrial septal defect Ventricular septal defect Patent ductus arteriosus Total anomalous pulmonary venous drainage Isolated ventricular extrasystoles and atrial ectopic beats
• Cardiology consultation once or twice during pregnancy. Local hospital care suitable	
WHO 2—Small increase in risk of maternal mortality and moderate increase in morbidity risk	If otherwise uncomplicated: Unoperated atrial or ventricular septal defect Repaired Fallot tetralogy Most arrhythmias Turner syndrome without aortic dilation
• Cardiology consultation each trimester. Local hospital care suitable	
WHO 2 or 3—Intermediate increase in maternal mortality risk and moderate to severe rise in morbidity risk	Mild left ventricular impairment Hypertrophic cardiomyopathy Native or tissue disease not considered WHO 1 or 4 Marfan syndrome without aortic dilation Repaired coarctation Prior heart transplantation
• Cardiology consultation bimonthly. Care at referral hospital	
WHO 3—Significantly increased risk of maternal mortality and severe increase in morbidity risk	Mechanical valve Systemic right ventricle Post-Fontan operation Unrepaired cyanotic heart disease Other complex congenital heart disease Moderate left ventricular impairment Prior peripartum cardiomyopathy with no residual effect Moderate mitral stenosis Severe asymptomatic aortic stenosis Moderate aortic dilation (40–50 mm) Ventricular tachycardia
• Cardiology consultation monthly or bimonthly. Care at tertiary-care hospital	
WHO 4—Very high risk of maternal mortality or severe morbidity; pregnancy contraindicated and termination discussed	Pulmonary arterial hypertension Severe systemic ventricular dysfunction (NYHA III–IV or LVEF <30%) Prior peripartum cardiomyopathy with residual effects Severe left heart obstruction Severe aortic dilation Severe coarctation Fontan procedure with residual complications
• Pregnancy contraindicated • If pregnancy occurs, cardiology consultation monthly. Care at tertiary-care hospital	

Summarized from European Society of Gynecology, 2018; Nanna, 2014; Thorne, 2006.

TABLE 52-4. Risks for Fetal Heart Lesions Related to Affected Family Members

Cardiac Lesion	Congenital Heart Disease in Fetus (%)		
	Previous Sibling Affected	Father Affected	Mother Affected
Aortic stenosis	2	3	15–18
Pulmonary stenosis	2	2	6–7
Ventricular septal defect	3	2	10–16
Atrial septal defect	2.5	1.5	5–11
Patent ductus arteriosus	3	2.5	4
Coarctation of the aorta	NS	NS	14
Fallot tetralogy	2.5	1.5	2–3
Marfan syndrome	NS	50	50

NS = not stated.

cardiovascular disease morbidity and mortality: (1) *race/ethnicity*, with morbidity highest in African-American women; (2) *age*, with increased morbidity in women older than 40 years; (3) *hypertension* of all varieties; (4) *obesity*, with higher morbidity associated with increasing degrees of obesity (Ackerman, 2019). To these, social and health disparities could be added because lower income, food and housing insecurity, and lack of childcare are directly linked to underutilization of prenatal care (Gadson, 2017). In turn, lack of prenatal care is a risk factor for maternal morbidity and mortality (Howland, 2019).

Antepartum Care

In most instances, management involves a team approach with an obstetrician, cardiologist, anesthesiologist, and other specialists as needed. With complex lesions or other high-risk cases, evaluation by a multidisciplinary team is recommended early in pregnancy. Both prognosis and management are influenced by the type and severity of the specific lesion and by the maternal functional classification. In some, pregnancy termination may be advisable.

With rare exceptions, women in NYHA class I and most in class II negotiate pregnancy without morbidity. Special attention is directed toward both prevention and early recognition of heart failure. Of specific risks, infection with sepsis can precipitate decompensation. Also, bacterial endocarditis is a deadly complication of valvular heart disease (p. 934). Each woman is instructed to avoid contact with persons who have respiratory infections, including the common cold, and to immediately report any evidence for infection. Pneumococcal vaccine, if not previously administered, and yearly influenza vaccine are recommended (Chap. 10, p. 188).

Cigarette smoking is prohibited. Illicit drug use may be particularly harmful, an example being the cardiovascular effects of cocaine or amphetamines. In addition, intravenous drug use raises the infective endocarditis risk.

Fortunately, gravidas in NYHA class III and IV are uncommon today. In the Canadian study, only 3 percent of the approximately 600 pregnancies were complicated by NYHA class III heart disease, and no women had class IV when first seen (Siu, 2001b). If a woman chooses pregnancy, she must understand the risks and is encouraged to be compliant with planned care. In some women, prolonged hospitalization or bed rest is often necessary.

Labor and Delivery

In general, vaginal delivery is preferred, and labor induction is usually safe (Thurman, 2017). From the large Registry on Pregnancy and Cardiac Disease, Ruys and associates (2015) compared pregnancy outcomes between 869 women who had a planned vaginal delivery and 393 gravidas who had a planned cesarean delivery. Planned cesarean delivery conferred no advantage for maternal or neonatal outcome. Similar results were reported from Brigham and Women's Hospital (Easter, 2020).

Cesarean delivery is usually limited to obstetrical indications, and considerations are given for the specific cardiac lesion, overall maternal condition, and availability of experienced anesthesia personnel and hospital capabilities. Some of these women tolerate major surgical procedures poorly and are best delivered in a unit experienced with management of complicated cardiac disease. Occasionally, pulmonary artery catheterization may be needed for hemodynamic monitoring (Chap. 50, p. 883). In our experiences, however, invasive monitoring is rarely indicated.

Based on her review, Simpson (2012) recommends cesarean delivery for women with the following: (1) dilated aortic root >4 cm or aortic aneurysm; (2) acute severe congestive heart failure; (3) recent myocardial infarction; (4) severe symptomatic aortic stenosis; (5) need for emergency valve replacement immediately after delivery; and (6) warfarin administration within 2 weeks of delivery due to fetal risk for intracerebral hemorrhage because the fetal liver takes up to 2 weeks to metabolize warfarin. Although we agree with most of these, we have some caveats. For congestive heart failure, we prefer aggressive medical stabilization of pulmonary edema followed by vaginal delivery if possible.

During labor, the mother with significant heart disease should be kept in a semirecumbent position with a lateral tilt. Vital signs are taken frequently between contractions. Elevations in pulse rate much above 100 beats per minute (bpm) or respiratory rate above 24 breaths per minute, particularly when associated with dyspnea, may suggest impending ventricular failure. For evidence of cardiac decompensation, intensive medical management must be instituted immediately. Delivery itself does not necessarily improve the maternal condition and, in fact, may worsen it. Moreover, emergency cesarean delivery may be particularly hazardous. Clearly, both maternal and fetal status must be considered in the decision to hasten delivery under these circumstances.

Analgesia and Anesthesia

Relief from pain and from apprehension is important. Although intravenous analgesics provide satisfactory pain relief for some women, continuous epidural analgesia is recommended for most. The major problem with conduction analgesia is maternal

hypotension (Chap. 25, p. 473). This is especially dangerous in women with intracardiac shunts in whom flow may be reversed. Hypotension can also be life-threatening if there is pulmonary arterial hypertension or aortic stenosis. In these, ventricular output is dependent on adequate preload. In women with these conditions, narcotic regional analgesia; low-dose, slow-infusion epidural; or general anesthesia may be preferable.

For vaginal delivery in women with only mild cardiovascular compromise, epidural analgesia given with intravenous sedation often suffices. This minimizes intrapartum cardiac output fluctuations and allows forceps or vacuum-assisted delivery. Incrementally dosed subarachnoid blockade is approached especially cautiously in women with significant heart disease due to associated hypotension. For cesarean delivery, epidural analgesia is preferred by most clinicians with caution for its use with pulmonary arterial hypertension (p. 932).

Intrapartum Heart Failure

From the Nationwide Inpatient Sample, one fourth of cases of heart failure during pregnancy were encountered intrapartum (Mogos, 2018). Women with underlying cardiovascular disorders are at higher risk (Schlichting, 2019). The physiological stress and fluid shifts associated with labor and delivery explain this risk. Catecholamine release due to pain and second stage Valsalva increase left ventricular work, which can precipitate heart failure (Anthony, 2016).

Obstetrical complications can either advance or precipitate heart failure. Preeclampsia is common and may provoke afterload failure (Vaught, 2018). Findings from the Registry on Pregnancy and Cardiac Disease indicate that women with preexisting heart disease who develop preeclampsia have a 30-percent risk of developing heart failure during pregnancy (Ruys, 2014). Obesity is another common cofactor (Vonck, 2019). Also, high-output states caused by hemorrhage and acute anemia elevate cardiac workload and magnify the physiological effects of compromised ventricular function. Similarly, infection and sepsis increase cardiac output and oxygen utilization and depress myocardial function.

Chronic hypertension with superimposed preeclampsia is the most frequent cause of heart failure in pregnancy in numerous populations. Many of these women have preexisting concentric left ventricular hypertrophy (Ambia, 2017, 2018). In some, mild antecedent undiagnosed hypertension causes covert cardiomyopathy, and when superimposed preeclampsia develops, together they may cause otherwise inexplicable peripartum heart failure. Obesity is frequently comorbid with chronic hypertension, and it also is associated with ventricular hypertrophy (Kenchaiah, 2002).

Cardiovascular decompensation during labor may manifest as pulmonary edema with hypoxia or as hypotension, or both. The proper therapeutic approach depends on the specific hemodynamic status and the underlying cardiac lesion. Continuous pulse oximetry and invasive blood pressure monitoring with an arterial line is helpful in some cases (Easter, 2020) In general, pulmonary edema due to fluid overload is often best treated with aggressive diuresis. If precipitated by tachycardia, heart rate control with β-blocking agents is preferred. However, unless the underlying pathophysiology is understood and the cause of the decompensation is clear, empirical therapy may be hazardous. Details of heart failure management and specific cardiovascular disorders are discussed below.

Puerperium

Women who have shown little or no evidence of cardiac compromise during pregnancy, labor, or delivery may still decompensate postpartum (Mogos, 2018). Fluid mobilized into the intravascular compartment and reduced peripheral vascular resistance place higher demands on myocardial performance. Therefore, meticulous care is continued into the puerperium (Sliwa, 2018; Zeeman, 2006). Postpartum hemorrhage, anemia, infection, and thromboembolism are much more serious complications with heart disease. Indeed, these factors often act in concert to precipitate postpartum heart failure. In addition, sepsis and severe preeclampsia cause or worsen pulmonary edema because of endothelial activation and capillary-alveolar leakage. For example, women with pregnancy-associated hypertensive diseases have a greater risk for readmission for heart failure within 90 days of delivery (Nizamuddin, 2019).

For puerperal tubal sterilization after vaginal delivery, the procedure can be delayed up to several days to ensure that the mother has normalized hemodynamically and that she is afebrile, not anemic, and ambulatory. For those desiring future fertility, contraception is crucial (Abarbanell, 2019; Sobhani, 2019). Detailed contraceptive advice is available in the *U.S. Medical Eligibility Criteria for Contraceptive Use* guidelines (Curtis, 2016). These are discussed in Chapter 38 (p. 664).

HEART FAILURE

Primary structural or functional cardiac disorders can lead to this clinical syndrome caused by impaired ventricular function. Mitral stenosis, pulmonary hypertension, and peripartum cardiomyopathy are some examples. Chronic pressure overload leads to ventricular dilation and impaired function over time. Associated perinatal mortality rates are high (Bright, 2021).

Diagnosis

Heart failure is best thought of as chronic underlying ventricular myopathy with episodic worsening causing clinical symptoms (Packer, 2019). Thus, failure can have a gradual onset or may present as acute "flash" pulmonary edema. In pregnant women, onset is most likely at the end of the second or beginning of the third trimester and peripartum (Ruys, 2014). Of symptoms, dyspnea is universal and others are orthopnea, palpitations, substernal chest pain, nocturnal cough, and a sudden decline in the ability to complete usual duties. Clinical findings include persistent basilar rales, hemoptysis, progressive edema, tachypnea, and tachycardia. According to Malhamé and associates (2019), serum levels of brain natriuretic peptide (BNP) are variably elevated (Appendix, p. 1231). Cardiomegaly and pulmonary edema are hallmark radiographic findings. Acutely, there is usually systolic failure. Echocardiography may show an ejection fraction <0.45 or a fractional shortening <30 percent, or both, and an end-diastolic dimension >2.7 cm/m^2 (Hibbard, 1999).

Coincidental diastolic failure also may be found, depending on the underlying cause (Redfield, 2016). Last, the cause of ventricular dysfunction—such as valvular abnormalities or concentric hypertrophy—may become apparent.

Management

Pulmonary edema from heart failure usually responds promptly with diuretic administration to reduce preload. Recall that furosemide (Lasix) is a potent venodilator in addition to its diuretic action. Hypertension is common in pregnancy, and afterload reduction is accomplished with hydralazine, nifedipine, or another vasodilator. Angiotensin-converting enzyme inhibitors are withheld until after delivery because of marked fetal effects (Chap. 8, p. 150). β-blocking agents lower mortality rates in the setting of heart failure, and carvedilol (Coreg) is commonly used in pregnancy. Last, digoxin provides inotropic support and is associated with decreased hospitalizations. With chronic heart failure, the incidence of associated thromboembolism is high, and therefore prophylactic heparin is often recommended.

Left ventricular assist devices are now employed more frequently for acute and chronic heart failure treatment. A few reports describe their use during pregnancy (Hamdan, 2017; Makdisi, 2017). *Extracorporeal membrane oxygenation (ECMO)* was reported to be lifesaving in a woman with fulminating peripartum cardiomyopathy, and it may be used in women with pulmonary hypertension (Meng, 2017; Pacheco, 2018).

SURGICALLY CORRECTED HEART DISEASE

Most clinically significant congenital heart lesions are repaired during childhood. Those frequently not diagnosed until adulthood include atrial septal defects, pulmonic stenosis, bicuspid aortic valve, and aortic coarctation (Brickner, 2014). In some cases, the defect is mild and does not require repair. In others, a significant anomaly is amenable to corrective surgery, performed ideally before pregnancy. Rarely, surgical corrections are necessary during pregnancy.

Valve Replacement Before Pregnancy

Numerous reports describe subsequent pregnancy outcomes in women who have a prosthetic mitral or aortic valve placed before pregnancy. From one review, the overall estimated maternal mortality rate was 1.2 percent (Lawley, 2015). Using the Registry of Pregnancy and Cardiac Disease, the maternal mortality rate was 1.4 percent in women with a mechanical heart valve and 1.5 percent in women with a tissue heart valve (van Hagen, 2015). Compared with the general maternal mortality rate measured per 100,000 births, this risk is more than 50-fold higher (Chap. 1, p. 4).

The type of valve, either mechanical or bioprosthetic, is paramount. From the just-described cohort, mechanical heart valve thrombosis complicated 4.7 percent. Only 58 percent of women with a mechanical heart valve had a pregnancy free of serious adverse events compared with 79 percent of patients with a tissue heart valve (Table 52-5) (van Hagen, 2015). A study of 417 women showed that pregnancy loss occurred in 61 and 15 percent with mechanical and bioprosthetic valves, respectively (Batra, 2018). Anticoagulation is a requisite with mechanical valves because of thrombosis risks, and its complications are described in the next section. Thus, pregnancy is undertaken only after serious consideration for women with a mechanical valve.

TABLE 52-5. Selected Outcomes in Pregnancies Complicated by Heart-Valve Replacement

Outcome	Mechanical Valve (n = 212)	Tissue Valve (n = 134)
Maternal mortality	3 (1.4)	2 (1.5)
Heart failure	162 (7.5)	1 (8.2)
Thrombotic complication	13 (6.1)	1 (0.7)
Hemorrhagic complication	49 (23)	7 (5.1)
Pregnancy loss <24 weeks	33 (15.6)	2 (1.5)
Stillbirth	6 (2.8)	0 (0)
Preterm birth <37 weeks	29 (18)	24 (19)

Data presented as n (%).

Bouhout and associates (2014) reported the outcomes of 27 pregnancies in 14 women who underwent an *aortic valve* replacement prior to pregnancy. Seven of the 27 pregnancies occurred in five women with a mechanical valve. Complications in this group included two embolic myocardial infarctions and one each of miscarriage, postpartum hemorrhage, placental abruption, and preterm birth. In the bioprosthetic group, there were nine miscarriages.

Adverse maternal and fetal outcomes plague also women with a *mechanical mitral valve*. In one report of 28 pregnancies, Vause and colleagues (2017) described severe maternal morbidity and mortality in 57 percent. A review of pregnancy outcomes in 800 women reported similar results (Steinberg, 2017).

Porcine tissue mitral valves are safer during pregnancy, primarily because thrombosis is rare, and anticoagulation is not required (see Table 52-5). However, valvular dysfunction with cardiac deterioration poses a serious risk. Another drawback is that bioprostheses are less durable than mechanical ones, and valve replacement longevity averages 10 to 15 years. Batra and coworkers (2018) concluded that pregnancy accelerated the risk for subsequent replacement.

Anticoagulation

This is critical for women with mechanical valves. Unfortunately, warfarin is the most effective anticoagulant for preventing maternal thromboembolism but causes harmful fetal effects. As seen in Table 52-6, anticoagulation with heparin is less hazardous for the fetus, however, the risk of maternal thromboembolic complications is increased (Steinberg, 2017). As a compromise, some use heparin in early pregnancy, and then transition to warfarin in the second trimester.

Warfarin is teratogenic and causes miscarriages, stillbirths, and fetal malformations (Chap. 8, p. 156). In one study of

TABLE 52-6. Maternal and Fetal Composite Outcomes in 800 Women with a Mechanical Heart Value Receiving Anticoagulation

Treatment	Composite Adverse Outcome (%)	
	Maternal[a]	Fetal[b]
VKA	5	39
LMWH	16	14
LMWH[c] followed by VKA	16	16
UFH[c] followed by VKA	16	34

[a]Maternal death, valve failure, thromboembolism.
[b]Miscarriage, fetal death, congenital malformation.
[c]During first trimester.
LMWH = low-molecular-weight heparin; UFH = unfractionated heparin; vitamin K antagonist.

71 women given warfarin throughout pregnancy, the rates of miscarriage were 32 percent; stillbirth, 7 percent; and embryopathy, 6 percent (Cotrufo, 2002). The risk was highest when the mean daily dose of warfarin exceeded 5 mg. Similarly, the American College of Cardiology and the American Heart Association estimate that the risk of embryopathy is dose dependent, and the risk is <3 percent if the warfarin dose is ≤5 mg/d (Nishimura, 2014). Women treated with <5 mg/d of warfarin had fetal risks similar to the low-molecular-weight heparin (LMWH) regimen (Steinberg, 2017). If the dosage is >5 mg/d, the risk of embryopathy exceeds 8 percent.

Anticoagulation for mechanical valves using *low-dose* unfractionated heparin (UFH) is definitely inadequate and carries a high associated maternal mortality rate (Chan, 2000; Iturbe-Alessio, 1986). Even *full* anticoagulation with either UFH or one of the LMWHs is associated with valvular thrombosis (Leyh, 2002, 2003; Rowan, 2001). However, compliance with dosing and therapeutic monitoring may have contributed (McLintock, 2014). Therefore, if full anticoagulation with dose-adjusted UFH or LMWH is used, meticulous monitoring is recommended. The activated partial thromboplastin time (aPTT) should be at least 2 times control or anti-Xa levels should be 0.8 to 1.2 U/mL at 4 to 6 hours postdose (Nishimura, 2014).

Recommendations for Anticoagulation

Several different treatment options exist, although all are principally based on consensus opinion, and none is completely ideal. Warfarin and LMWH are associated with fewer valve thromboses and therefore favored over subcutaneous UFH (D'Souza, 2017). In addition, therapeutic subcutaneous UFH dosing is difficult to achieve due to lower peak plasma concentrations in pregnant women, especially with advancing gestation (Barbour, 1995; Brancazio, 1995). One guideline from the American College of Cardiology and the American Heart Association offers different treatment options based on trimester and baseline warfarin dose (Nishimura, 2014). Figure 52-3 displays a treatment algorithm based on these guidelines. All recommendations also include aspirin 75 to 100 mg orally daily.

Vaginal or cesarean delivery is ideally scheduled to allow controlled discontinuation of anticoagulation and partial reversal of its effects. This also permits administration of regional anesthesia, which requires a degree of coagulation to avoid epidural hematoma formation (Chap. 25, p. 478). If delivery intervenes while the anticoagulant is still effective, and extensive bleeding is encountered, protamine sulfate is given intravenously to reverse heparin effects. Patients should be counseled that in these situations regional anesthesia may not safely be possible.

Following vaginal delivery, anticoagulant therapy with warfarin or heparin may be restarted 6 hours later, usually with no problems. Following cesarean delivery, full anticoagulation is withheld, but the optimal duration is unclear. The American College of Obstetricians and Gynecologists (2018a) recommends resuming UFH or LMWH 6 to 12 hours after cesarean delivery. At Parkland Hospital, however, we wait at least 24 hours following a major surgical procedure given inherent bleeding risks. Following first-trimester dilation and curettage heparin is begun immediately.

Warfarin, LMWH, and UFH are compatible with breastfeeding. They do not accumulate in breast milk and thus do not induce anticoagulant effects in the newborn (Briggs, 2022).

Cardiac Surgery During Pregnancy

Although usually postponed until after delivery, valve replacement or other cardiac surgery during pregnancy may be lifesaving. Several reviews confirm that such surgery is associated with major maternal and fetal morbidity (Liu, 2021). Elassy and associates (2014) described 23 women who underwent urgent open cardiac surgery for severe valve malfunction. Two women and 10 fetuses—all at a gestational age below 28 weeks—died before hospital discharge. Only six fetuses were delivered at term. In a review of 154 women undergoing bypass surgery during pregnancy, the maternal mortality rate was 11 percent, and the fetal loss rate was 33 percent (Jha, 2018). To optimize outcomes, Chandrasekhar and coworkers (2009) recommend that surgery be elective when possible, pump flow rate should remain >2.5 L/min/m^2, perfusion pressure should exceed 70 mm Hg, and hematocrit should be kept >28 percent.

Pregnancy after Heart Transplantation

Many successful pregnancies have followed cardiac transplantation (D'Souza, 2018; Macera, 2018). Current recommendations from the International Society of Heart and Lung Transplantation do not discourage pregnancy in stable heart transplant recipients who are more than 1 year posttransplant (Costanzo, 2010). Obviously, a highly specialized level of care and multidisciplinary team is necessary.

The transplanted heart appears to respond normally to pregnancy-induced alterations (Cowan, 2012). Despite this, complications are common during pregnancy. Of 103 pregnancies in 57 heart recipients from the National Transplantation Pregnancy Registry, almost half developed hypertension, and 11 percent suffered at least one rejection episode during pregnancy (Coscia, 2010). They were usually delivered by cesarean at a mean of 37 weeks' gestation. Life expectancy following heart transplantation is known to be limited. At follow-up,

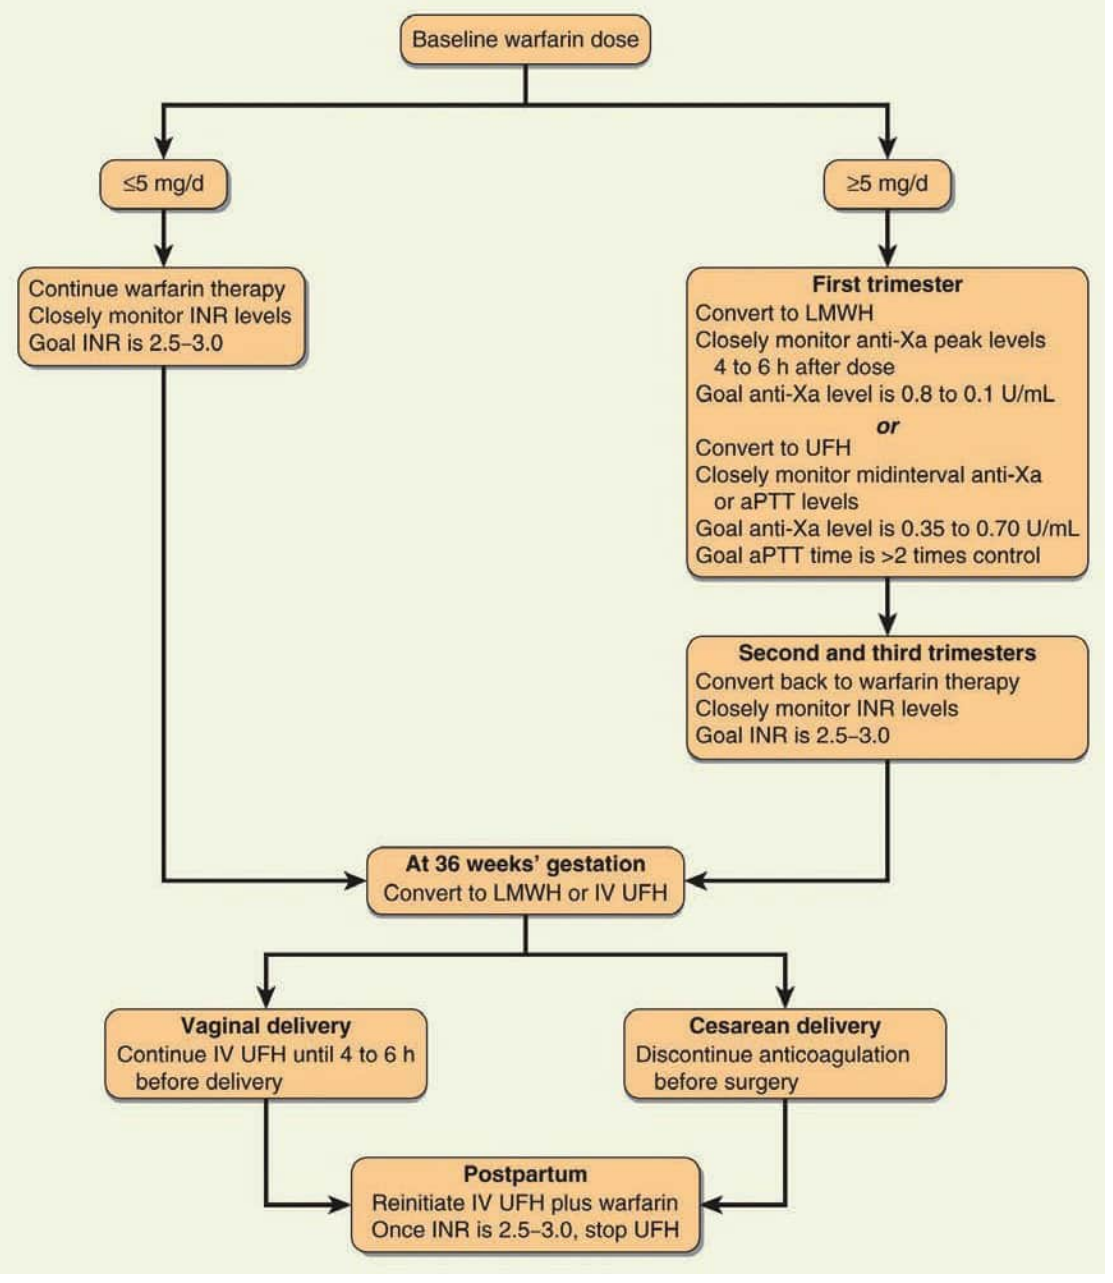

FIGURE 52-3 Algorithm for anticoagulation in gravidas with a mechanical heart valve. INR = international normalized ratio; IV = intravenous; LMWH = low-molecular-weight heparin; aPTT = activated partial thromboplastin time; UFH = unfractionated heparin. (From Elkayam, 2020; Nishimura, 2014; Roeder, 2011.)

at least 16 women had died more than 2 years postpartum. In another small study, pregnancy itself did not worsen long-term survival rates (Dagher, 2018).

VALVULAR HEART DISEASE

Rheumatic fever is uncommon in the United States because of less crowded living conditions, penicillin availability, and evolution of nonrheumatogenic streptococcal strains. Still, it remains the chief cause of serious mitral valvular disease in women of childbearing age in the nonindustrialized world (Liaw, 2021; van Hagen, 2018).

Mitral Stenosis

Rheumatic endocarditis causes most mitral stenosis lesions. The normal mitral valve surface area is 4.0 cm^2, and when stenosis narrows this to <2.5 cm^2, symptoms usually develop. The contracted valve impedes blood flow from the left atrium to the ventricle.

With more severe stenosis, the left atrium dilates, left atrial pressure is chronically elevated, and significant pulmonary hypertension develops (Table 52-7) (Galiè, 2016). These women have a relatively fixed cardiac output, and thus the increased preload of normal pregnancy and other factors that raise cardiac output may cause ventricular failure and

TABLE 52-7. Major Cardiac Valve Disorders

Type	Cause	Pathophysiology	Pregnancy
Mitral stenosis	Rheumatic valvulitis	LA dilation and passive pulmonary hypertension Atrial fibrillation	Heart failure from fluid overload, tachycardia
Mitral insufficiency	Rheumatic valvulitis Mitral valve prolapse LV dilation	LV dilation and eccentric hypertrophy	Ventricular function improves with afterload decrease
Aortic stenosis	Congenital bicuspid valve	LV concentric hypertrophy, decreased cardiac output	Moderate stenosis is tolerated; severe is life-threatening with decreased preload, e.g., obstetrical hemorrhage or regional analgesia
Aortic insufficiency	Rheumatic valvulitis Connective tissue disease Congenital	LV hypertrophy and dilation	Ventricular function improves with afterload decrease
Pulmonary stenosis	Rheumatic valvulitis Congenital	Severe stenosis associated with RA and RV enlargement	Mild stenosis usually well tolerated; severe stenosis associated with right heart failure and atrial arrhythmias

LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

pulmonary edema. Cardiac failure develops for the first time during pregnancy in one fourth of women with mitral stenosis (Caulin-Glaser, 1999). The resulting pulmonary venous hypertension and pulmonary edema create symptoms of dyspnea, fatigue, palpitations, cough, and hemoptysis. The classic murmur may not be heard in some women, and this clinical picture at term may be confused with idiopathic peripartum cardiomyopathy (Cunningham, 1986, 2019).

Also with significant stenosis, tachycardia shortens ventricular diastolic filling time and elevates the mitral gradient. This too may lead to pulmonary edema, and therefore, sinus tachycardia is often treated prophylactically with β-blocking agents. Atrial tachyarrhythmias, including fibrillation, are common in mitral stenosis and are treated aggressively. Atrial fibrillation predisposes to mural thrombus formation and cerebrovascular embolization that can cause stroke (Chap. 63, p. 1132). Atrial thrombosis can also develop despite a sinus rhythm (Hameed, 2005).

Pregnancy Outcomes

In general, complications are directly associated with the degree of valvular stenosis. Women with a mitral-valve area <2 cm^2 are at greatest risk (Siu, 2001b). In one study of 273 gravidas with mitral stenosis, 43 percent developed heart failure, and almost a fourth of these women required admission (van Hagen, 2018). For women with severe stenosis, half developed heart failure, and one woman died. Fetal-growth restriction was more common in women with a mitral valve area <1.0 cm^2.

Prognosis also is related to maternal functional capacity. Among 486 pregnancies complicated by rheumatic heart disease—predominantly mitral stenosis—8 of 10 maternal deaths were in women in NYHA classes III or IV (Sawhney, 2003).

Management

Limited physical activity is generally recommended in women with mitral stenosis. If symptoms of pulmonary congestion develop, activity is further reduced, dietary sodium is restricted, and diuretics are given. Also, β-blocker drug therapy slows the ventricular response to activity. If new-onset atrial fibrillation develops, intravenous verapamil, 5 to 10 mg, is given, or electrocardioversion is performed. For chronic fibrillation, digoxin, a β-blocker, or a calcium-channel blocker can slow ventricular response. Therapeutic anticoagulation is indicated with persistent fibrillation, left atrial thrombus, and/or a history of embolism (Nanna, 2014).

Surgical intervention is considered for women with symptomatic severe mitral stenosis. Other candidates are those with mitral-valve area 1.5 to 2.0 cm^2 complicated by recurrent systemic embolization or severe pulmonary hypertension. Balloon valvuloplasty is preferred if the valve is pliable (Bui, 2014). In one review of 71 pregnant women with severe mitral stenosis and heart failure who underwent percutaneous valvuloplasty, 98 percent were either NYHA class I or II by the time of delivery (Esteves, 2006). At a mean of 44 months, the total event-free maternal survival rate was 54 percent. However, eight women required another surgical intervention. All of the 66 newborns who were delivered at term had normal growth and development.

Labor and delivery are particularly stressful for women with symptomatic mitral stenosis. Pain, exertion, and anxiety cause tachycardia with possible rate-related heart failure. Epidural analgesia for labor is ideal. Fluid overload should be avoided, and these women are best managed on the "dry" side. As shown in Figure 52-4 uterine contractions raise cardiac output by increasing circulating blood volume. Abrupt expansion in preload may elevate pulmonary capillary wedge pressure and cause pulmonary edema. Wedge pressures rise immediately postpartum. One hypothesis for this suggests that the loss of the low-resistance placental circulation couples with venous "autotransfusion" from a now-empty, contracted uterus and from the lower extremities and pelvis (Clark, 1985). Thus, pulmonary edema may manifest immediately postpartum.

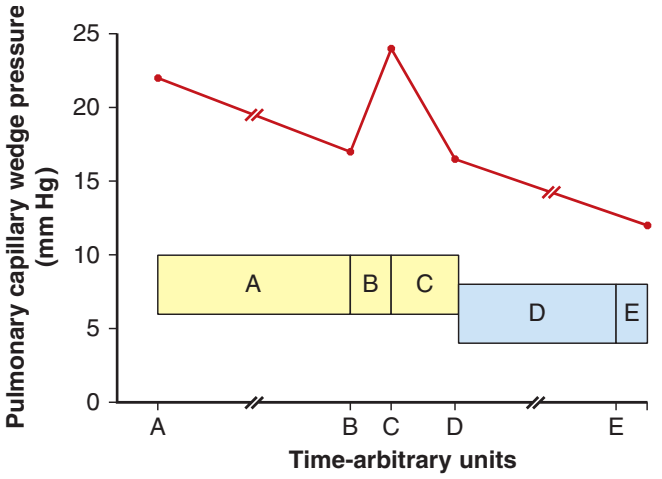

FIGURE 52-4 Mean pulmonary capillary wedge pressure measurements (*red graph line*) in eight women with mitral valve stenosis. Shaded yellow and blue boxes are mean (± 1 SD) pressures in nonlaboring normal women at term. **A.** First-stage labor. **B.** Second-stage labor 15 to 30 minutes before delivery. **C.** Postpartum 5 to 15 minutes. **D.** Postpartum 4 to 6 hours. **E.** Postpartum 18 to 24 hours. (Data from Clark, 1985, 1989.)

Most prefer vaginal delivery in women with mitral stenosis. Elective induction is reasonable so that labor and delivery are attended by a scheduled, experienced team. With severe stenosis and chronic heart failure, insertion of a pulmonary artery catheter may help guide management.

■ Mitral Insufficiency

A trivial degree of mitral insufficiency is found in most normal patients. But if mitral valve leaflets align improperly during systole, abnormal degrees of mitral regurgitation can develop. This is eventually followed by left ventricular dilation and eccentric hypertrophy (see Table 52-7). *Acute mitral insufficiency* is caused by chordae tendineae rupture, papillary muscle infarction, or leaflet perforation from infective endocarditis. *Chronic mitral regurgitation*, in contrast, may derive from rheumatic fever, connective tissue diseases, mitral valve prolapse, or left ventricular dilation of any etiology—for example, dilated cardiomyopathy. Less common causes include a calcified mitral annulus, possibly some appetite suppressants, and in older women, ischemic heart disease. Mitral valve vegetations—*Libman-Sacks endocarditis*—are relatively common in women with antiphospholipid antibodies (Shroff, 2012). These sometimes coexist with systemic lupus erythematosus (Chap. 62, p. 1114).

In nonpregnant patients, symptoms from mitral valve insufficiency are rare, and valve replacement is seldom indicated unless infective endocarditis develops. During pregnancy, mitral regurgitation is similarly well tolerated, probably because the lowered systemic vascular resistance yields less regurgitation. In the report by van Hagen and associates (2018), of 117 women with moderate or severe regurgitation, 23 percent developed heart failure during pregnancy. Occasionally tachyarrhythmias or severely depressed systolic function require treatment.

■ Mitral Valve Prolapse

This diagnosis implies the presence of a pathological connective tissue disorder—often termed *myxomatous degeneration*—which may involve the valve leaflets, the annulus, or the chordae tendineae. Mitral insufficiency may develop. Most women with mitral valve prolapse are asymptomatic and are diagnosed during routine examination or echocardiography. The few women with symptoms have anxiety, palpitations, atypical chest pain, dyspnea with exertion, and syncope (Guy, 2012).

Pregnant women with mitral valve prolapse rarely have cardiac complications. Hypervolemia may even improve alignment of the mitral valve, and women without pathological myxomatous degeneration generally have excellent pregnancy outcomes (Leśniak-Sobelga, 2004). For women who are symptomatic, β-blocking drugs diminish sympathetic tone, relieve chest pain and palpitations, and reduce the risk of life-threatening arrhythmias.

■ Aortic Stenosis

Since the decline in incidence of rheumatic disease, congenital bicuspid valve is now the most frequent cause of aortic stenosis in young women in the United States (Carabello, 2017). A normal aortic valve has an area of 3 to 4 cm^2, with a pressure gradient <5 mm Hg. If the valve area is <1 cm^2, flow is severely obstructed, and progressive pressure overload on the left ventricle develops. Concentric left ventricular hypertrophy follows, and if it is severe, end-diastolic pressures become elevated, ejection fraction decreases, and cardiac output is reduced (see Table 52-7). Severity is estimated by peak velocity of flow across the aortic valve. Mild stenosis has a peak velocity of 2–2.9 m/s, moderate 3-3.9 m/s, and severe ≥4 m/s. Corresponding mean pressure gradients are <20, 20–39, and ≥40 mm Hg, respectively (Carabello, 2017). Characteristic manifestations develop late and include chest pain, syncope, heart failure, and sudden death from arrhythmias. In asymptomatic patients, the mortality rate is 1 percent per year, but with symptoms it increases to 25 percent per year. Thus, valve replacement is indicated for symptomatic patients.

Pregnancy

In one single-center study, aortic stenosis accounted for 15 percent of cases of congenital heart disease in 178 pregnant women (Kim, 2019). That said, clinically significant aortic stenosis is infrequent during pregnancy. Mild to moderate degrees of stenosis are well tolerated. Severe disease is life-threatening and carries a 6-percent mortality risk (Lin, 2017). The principal underlying hemodynamic problem is the fixed cardiac output associated with severe stenosis. During pregnancy, several common events acutely lower preload further and thus aggravate the fixed cardiac output. These include vena caval occlusion from the gravid uterus, regional analgesia, sepsis, and hemorrhage. From the earlier-cited Canadian study, complication rates were higher if the aortic valve area measured <1.5 cm^2 (Siu, 2001b).

Management

For asymptomatic women with aortic stenosis, no treatment except close observation is required. Management of a symptomatic

woman is undertaken in conjunction with a cardiologist and includes strict limitation of activity and cautious use of diuretics. If symptoms persist, surgical intervention or preterm delivery may be considered. Catheter-based valvuloplasty is associated with risks to both the mother and fetus and shows poor long-term efficacy (Pessel, 2014). Namely, the aortic valve can again narrow or new aortic regurgitation may develop. The alternative surgical approach—valve replacement—is associated with significant risk of fetal demise due to the hypotension associated with cardiac bypass. Transcatheter aortic valve replacement (TAVR) has been performed in low-risk nonpregnant women, but there is little experience with this procedure during pregnancy (Hodson, 2016; Mack, 2019). Accordingly, the American College of Cardiology, the American Heart Association, and the European Society of Cardiology recommend delaying conception until after surgical correction for severe aortic stenosis (Nishimura, 2014; Regitz-Zagrosek, 2018). For those with uncorrected severe symptomatic aortic stenosis, cesarean delivery is preferred. For asymptomatic women with severe stenosis, care is individualized. In nonsevere stenosis, vaginal delivery is preferred (Regitz-Zagrosek, 2018).

For women with critical aortic stenosis, intensive monitoring during labor is essential. Pulmonary artery catheterization may be helpful because of the narrow margin separating fluid overload from hypovolemia. Women with aortic stenosis are dependent on adequate end-diastolic ventricular filling pressures to maintain cardiac output and systemic perfusion. Abrupt drops in end-diastolic volume may result in hypotension, syncope, myocardial infarction, and sudden death. Thus, avoiding diminished ventricular preload and maintaining cardiac output are key. During labor and delivery, affected women are best managed on the "wet" side. This provides a margin of safety in intravascular volume in anticipation of possible hemorrhage. In women with a competent mitral valve, pulmonary edema is rare.

During labor, narcotic or low-dose, slow-infusion epidural analgesia seems ideal and avoids potentially hazardous hypotension. Easterling and coworkers (1988) studied the effects of epidural analgesia in five women with severe stenosis and demonstrated immediate and profound effects from decreased filling pressures. Xia and colleagues (2006) emphasize slow administration of dilute local anesthetic agents into the epidural space. In hemodynamically stable women, forceps or vacuum delivery is used only for standard obstetrical indications. In those experiencing dizziness, shortness of breath, or tachycardia with pushing, an operative vaginal delivery is preferred.

Aortic Insufficiency

Aortic valve regurgitation or insufficiency allows diastolic flow of blood from the aorta back into the left ventricle. Frequent causes of insufficiency are rheumatic fever, connective tissue abnormalities, and congenital lesions (Carabello, 2017). With Marfan syndrome, the aortic root may dilate and create regurgitation (p. 936). Acute insufficiency may also develop with bacterial endocarditis or aortic dissection. Last, aortic and mitral valve insufficiency have both been linked to the appetite suppressants fenfluramine and dexfenfluramine and to the ergot-derived dopamine agonists cabergoline and pergolide (Schade, 2007; Zanettini, 2007). With chronic insufficiency, left ventricular hypertrophy and dilation develop. Slow-onset fatigue, dyspnea, and pulmonary edema follows ventricular dilation with subsequent rapid deterioration (see Table 52-7).

Aortic insufficiency is generally well tolerated during pregnancy. Like mitral valve insufficiency, reduced vascular resistance is thought to improve hemodynamic function. If symptoms of heart failure develop, diuretics are given, and bed rest is encouraged.

Pulmonic Stenosis

This lesion is usually congenital and may be associated with Fallot tetralogy or Noonan syndrome (Chikwe, 2017). The greater hemodynamic burden of pregnancy can precipitate right-sided heart failure or atrial arrhythmias in women with severe stenosis. Surgical correction ideally is done before pregnancy, but if symptoms progress, a balloon valvuloplasty may be necessary antepartum (Galal, 2015; Siu, 2001a).

In studying pregnancy outcomes, Drenthen and associates (2006) found infrequent cardiac complications in 81 pregnancies in 51 Dutch women with pulmonic stenosis. The NYHA classification worsened in two women, and nine experienced palpitations or arrhythmias. No changes in pulmonary valvular function or other adverse cardiac events were reported. However, noncardiac complication rates were significant—17 percent had preterm delivery, 15 percent had hypertension, and 4 percent developed thromboembolism.

CONGENITAL HEART DISEASE

The incidence of congenital heart disease in the United States approximates 1.9 percent of live births, and half of these are moderate to severe forms (Lin, 2017). With modern surgeries, approximately 90 percent of those born with congenital heart disease survive to childbearing age, and it is now the most common type of heart disease encountered during pregnancy (Hopkins, 2018). Specifically, analysis from the United States Nationwide Inpatient Sample database showed a linear rise in the prevalence of congenital heart disease between 2000 and 2010—from 6.4 to 9.0 per 10,000 women admitted for delivery (Thompson, 2015).

The odds of obstetrical and perinatal complications are increased two- to threefold in women with congenital heart disease compared with unaffected women (Ramage, 2019). Also, the maternal mortality rate was higher for women with congenital heart disease at 178 per 100,000 deliveries compared with 7 per 100,000 deliveries in unaffected gravidas (Thompson, 2015).

Atrial Septal Defects

A patent foramen ovale (PFO) is a persisting incompetence of the fossa ovale, and this flap has the potential to open under increased hydrostatic pressure. Of all adults, approximately one fourth have this defect (Silvestry, 2015). The small risk of PFO-related stroke, discussed subsequently, is likely higher in

pregnant than in nonpregnant women and mainly attributed to normal pregnancy hypercoagulability (Chen, 2016). Preventive PFO repair is not recommended (Kernan, 2014).

An atrial septal defect (ASD) is a true hole in the septum. The secundum-type defect accounts for 70 percent, and associated mitral valve myxomatous abnormalities with prolapse are common. Most ASDs are typically asymptomatic until the third or fourth decade of life (Lin, 2017). If an ASD is discovered in adulthood, most recommend repair.

Pregnancy with an unrepaired ASD is well tolerated unless pulmonary hypertension has developed, but this is uncommon (Bredy, 2018). Medical treatment during pregnancy is indicated for congestive heart failure or an arrhythmia. The risk of endocarditis with an ASD is negligible.

With the potential to shunt blood from right to left, a *paradoxical embolism* is possible. A venous thrombus enters the systemic arterial circulation through the ASD, causing an embolic stroke (Bredy, 2018). For this reason, filters should be placed on intravenous access sites. In a gravida with an ASD but without current venous thromboembolism (VTE), the decision to add anticoagulant prophylaxis to counter this potential embolism risk is problematic. However, for a pregnant woman with an ASD who is immobile or has another risk factor for thromboembolism, compression stockings and prophylactic heparin are reasonable.

Ventricular Septal Defects

These lesions close spontaneously during childhood in 90 percent of cases. Of the four main ventricular septal defect (VSD) types, most defects are paramembranous. This location is well below the outlet valves yet above the ventricular musculature. The degree of associated left-to-right shunt and physiological derangements are related to lesion size. In general, if the defect measures <1.25 cm^2, pulmonary hypertension and heart failure do not develop. If the effective defect size exceeds that of the aortic valve orifice, symptoms rapidly develop. For these reasons, most children undergo surgical repair before pulmonary hypertension develops. Adults with unrepaired large defects develop left ventricular failure and pulmonary hypertension and have a high incidence of bacterial endocarditis (Brickner, 2014).

Pregnancy is well tolerated with small- to moderate-sized VSD shunts. However, if pulmonary arterial pressures reach systemic levels, flow is reversed or bidirectional—*Eisenmenger syndrome* (p. 929). If this cyanotic condition develops, the maternal and fetal mortality rates are significantly higher, and thus pregnancy is generally not advisable (Lin, 2017). Bacterial endocarditis is more common with unrepaired defects, and antimicrobial prophylaxis is often required (p. 934). As shown in Table 52-4, 16 percent of offspring born to these women also have a VSD.

Atrioventricular Septal Defects

An atrioventricular (AV) septal defect is characterized by a common, ovoid AV junction. These account for approximately 3 percent of all congenital cardiac malformations and are distinct from isolated ASDs or VSDs. This defect is associated with aneuploidy, Eisenmenger syndrome, and other malformations (Foeller, 2018). Compared with simple septal defects, complications are more frequent during pregnancy. In a review of 48 pregnancies in 29 affected women, complications included persistent deterioration of NYHA class in 23 percent, significant arrhythmias in 19 percent, and heart failure in 2 percent (Drenthen, 2005). Congenital heart disease was identified in 15 percent of the offspring.

Persistent (Patent) Ductus Arteriosus

The ductus connects the proximal left pulmonary artery to the descending aorta just distal to the left subclavian artery. Functional closure of the ductus from vasoconstriction occurs shortly after term birth. The physiological consequences with its persistence are related to its size. Most significant lesions are repaired in childhood. However, in women with an unrepaired ductus, pulmonary hypertension, heart failure, or cyanosis will develop if systemic blood pressure falls and blood flow reverses from the pulmonary artery into the aorta (Foeller, 2018). A sudden blood pressure decline at delivery—such as with regional analgesia or hemorrhage—may lead to fatal collapse. Therefore, hypotension is avoided but treated vigorously if it develops. Prophylaxis for bacterial endocarditis is indicated at delivery for unrepaired defects (p. 934). As shown in Table 52-4, the incidence of inheritance approximates 4 percent.

Cyanotic Heart Disease

Cyanosis develops when congenital heart lesions produce right-to-left shunting of blood past the pulmonary capillary bed. The classic and most commonly encountered lesion in adults and during pregnancy is the *Fallot tetralogy* (Foeller, 2018). This is characterized by a large VSD, pulmonary stenosis, right ventricular hypertrophy, and an overriding aorta that receives blood from both the right and left ventricles. The magnitude of the shunt varies inversely with systemic vascular resistance. Hence, during pregnancy, when peripheral resistance decreases, shunt flow increases and cyanosis worsens.

Generally, women with cyanotic heart disease do poorly during pregnancy. Those with concomitant Eisenmenger syndrome are at greatest risk (p. 929). With uncorrected Fallot tetralogy, maternal mortality rates approach 10 percent. For fetal outcome, there is a relationship between chronic hypoxemia, polycythemia, and complications such as miscarriage and perinatal morbidity. When hypoxemia is intense enough to stimulate a rise in hemoglobin concentration >20 g/dL, pregnancy wastage is virtually 100 percent (Lin, 2017).

Although not all cyanotic lesions are repairable, with satisfactory surgical correction before pregnancy, maternal and fetal outcomes are much improved. In a review of 197 pregnancies in 99 women with surgically corrected Fallot tetralogy, pregnancy was usually well tolerated, and no mothers died (Cauldwell, 2017). Still, almost 9 percent of pregnancies were complicated by adverse cardiac events including new-onset or worsening arrhythmias and heart failure (Balci, 2011; Kamiya, 2012).

Some women with *Ebstein anomaly*, characterized by a malpositioned and malformed tricuspid valve, may reach

reproductive age. The right ventricle is small and the right atrium is severely dilated. Right-sided heart failure is common. These women are very preload dependent, and pregnancy-induced hypervolemia can worsen the tricuspid regurgitation (Kanoh, 2018). Arrhythmias also are common, especially Wolff-Parkinson-White syndrome (p. 936). Vaginal delivery seems preferable in most cases. In the absence of cyanosis, heart failure, or significant arrhythmias, affected women usually tolerate pregnancy well (Safi, 2016).

■ Pregnancy after Surgical Repair

Transposition of the Great Vessels

Pregnancy following *arterial switch operation* for transposition is associated with good outcomes. A major concern is fatal arrhythmias that usually are precipitated by exercise (Lin, 2017). Earlier studies cited a relatively high rate of heart failure and arrhythmias, but more recent studies have favorable pregnancy outcomes (Trigas, 2014). In one study of 20 pregnancies, there were three cases of heart failure (Horiuchi, 2019). Stoll and coworkers (2018) reported no adverse cardiac events in 25 pregnancies.

Of other defects, repaired *truncus arteriosus* and *double-outlet right ventricle* with subsequent successful, although eventful, pregnancies have been described (Drenthen, 2008; Hoendermis, 2008). Ironically, preconceptional counseling did little to dissuade these women from childbearing (Cauldwell, 2016).

Single Functional Ventricle

With *hypoplastic left heart syndrome*, most affected women are now expected to survive into adulthood (Davis, 2018). Frequently, these women become pregnant, and those who have undergone a *Fontan repair* carry a particularly higher risk for complications. In brief, this procedure involves diverting blood via a surgical anastomosis from the vena cava to the pulmonary artery without passing through the right ventricle. Blood flows passively to the pulmonary vasculature. Preload drives circulation in the Fontan circuit, and thus patients are sensitive to volume changes (Moroney, 2018).

From their review of 255 pregnancies in 133 women, Garcia-Ropero and colleagues (2018) reported 115 miscarriages (45 percent) and 19 elective terminations (7 percent). Cardiac complications included arrhythmias in 8 percent and heart failure in 4 percent of pregnancies. Among 133 live births, there were 68 preterm births (59 percent) and 7 perinatal deaths (6 percent). Postpartum venous thromboembolism also is common (Moroney, 2020).

Similar complications attend a maternal *systemic right ventricle*, that is, one in which the right ventricle rather than the left pumps blood to the systemic circulation (Khan, 2015).

■ Eisenmenger Syndrome

This describes secondary pulmonary hypertension that arises from any cardiac lesion. The most common underlying defects are ASD, VSD, and persistent ductus arteriosus (Fig. 52-5).

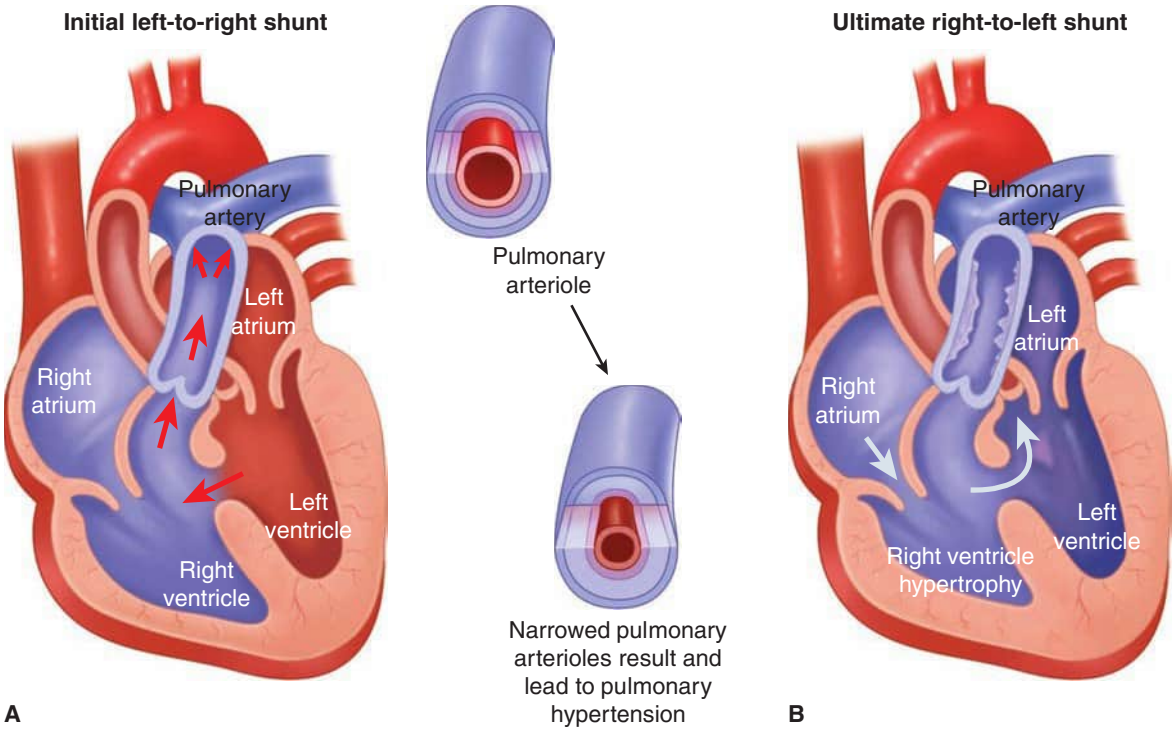

FIGURE 52-5 Eisenmenger syndrome due to a ventricular septal defect (VSD). **A.** Substantial left-to-right shunting through the VSD leads to morphological changes in the smaller pulmonary arteries and arterioles. Specifically, medial hypertrophy, intimal cellular proliferations, and fibrosis lead to narrowing or closure of the vessel lumen. These vascular changes create pulmonary hypertension and a resultant reversal of the intracardiac shunt **(B)**. With sustained pulmonary hypertension, extensive atherosclerosis and calcification often develop in the large pulmonary arteries. Although a VSD is shown here, Eisenmenger syndrome may also develop in association with a large atrial septal defect or persistent ductus arteriosus.

The syndrome develops when pulmonary vascular resistance exceeds systemic resistance and leads to concomitant right-to-left shunting. Patients are asymptomatic for years, but eventually pulmonary hypertension becomes severe enough to cause this shunting.

Pregnant women with Eisenmenger syndrome tolerate hypotension poorly, and death usually is caused by right ventricular failure with cardiogenic shock. In a review of 73 pregnancies, Weiss and associates (1998) cited a 36-percent maternal death rate. Three of 26 deaths were antepartum, and the remainder of women died intrapartum or within a month of delivery. In another study of 13 gravidas, one mother died 17 days after delivery, and there were five perinatal deaths (Wang, 2011). Last, in a series of 11 pregnancies in China, four mothers died (Duan, 2016). *Given such poor outcomes for both mother and fetus, Eisenmenger syndrome is considered to be an absolute contraindication to pregnancy* (American College of Obstetricians and Gynecologists, 2019; Foeller, 2018; Meng, 2017).

PULMONARY HYPERTENSION

Normal resting mean pulmonary artery pressure is 12 to 16 mm Hg. Most define *pulmonary hypertension* in nonpregnant individuals as a resting mean pulmonary pressure >25 mm Hg (Franco, 2019). Pulmonary vascular resistance in late normal pregnancy approximates 80 dyne/sec/cm^{-5}, which is 34-percent less than the nonpregnant value of 120 dyne/sec/cm^{-5} (Clark, 1989).

Physiologically, pregnancy is associated increased cardiac output, and in healthy gravidas, pulmonary vascular resistance decreases to help accommodate this (Clark, 1989). With pulmonary hypertension, the stiff pulmonary vasculature does not allow the normal fall in pulmonary vascular resistance. Thus, the normal increased cardiac output actually leads to further pulmonary artery pressure elevation and then eventually to right heart failure. With failure, the interventricular septum bulges leftward to impair left ventricular diastolic filling, which compromises cardiac output (Gei, 2014; Pieper, 2011).

The current clinical classification system, shown in Table 52-8, contains five groups of disorders that cause pulmonary hypertension (Galiè, 2016). Important prognostic and therapeutic distinctions separate group 1 pulmonary arterial hypertension and the other groups. Group 1, which is more common in nonpregnant women, indicates that a specific disease affects pulmonary arterioles. It includes idiopathic or primary pulmonary arterial hypertension as well as those cases secondary to a known cause such as connective tissue disease. For example, approximately a third of women with scleroderma and 10 percent with systemic lupus erythematosus have pulmonary arterial hypertension (Franco, 2019). Other causes in young women are human immunodeficiency virus (HIV) infection, sickle-cell disease, and thyrotoxicosis.

In pregnant women, group 2 disorders are the most common. These are secondary to pulmonary *venous* hypertension caused by left-sided atrial, ventricular, or valvular disorders. A typical example is mitral stenosis discussed earlier (p. 924). In contrast, groups 3 through 5 are seen infrequently in young otherwise healthy women.

Diagnosis and Prognosis

Symptoms may be vague, and dyspnea with exertion is the most frequent. With group 2 disorders, orthopnea and nocturnal dyspnea are also usually present. Angina and syncope occur when right ventricular output is fixed, and they suggest advanced disease. Chest radiography often shows enlarged pulmonary hilar arteries and attenuated peripheral markings. It may also disclose parenchymal causes of hypertension. Noninvasive echocardiography can provide an estimate of pulmonary artery pressures, although cardiac catheterization remains the standard for measurement. In studies of pregnant women who underwent both echocardiography and cardiac catheterization, pulmonary artery pressures were significantly overestimated by echocardiography in approximately a third of cases (Herrera, 2020; Wylie, 2007).

Regardless of the etiology, the final common pathway of pulmonary hypertension is right heart failure and death. The average survival length after diagnosis is <4 years (Krexi, 2015). That said, longevity depends on the severity and cause of pulmonary hypertension at discovery. As discussed later, some disorders respond to medical interventions, which may improve quality of life. Preconceptional and contraceptive counseling are imperative (American College of Obstetricians and Gynecologists, 2019).

Pregnancy

The maternal mortality rate is appreciable in affected women, and this is especially so with idiopathic pulmonary arterial hypertension (Martin, 2019). In the past, the ability to accurately identify causes and assess disease severity were often poor. Thus, although most severe cases of idiopathic pulmonary arterial hypertension had the worst prognosis, it was erroneously assumed that all types of pulmonary hypertension were equally dangerous. With widespread use of echocardiography, less-severe lesions with a better prognosis are now discernible. The maternal mortality rate for pulmonary hypertension has improved. In one study, it was 25 percent during the decade ending in 2007 compared with 38 percent for the decade ending in 1996 (Bédard, 2009). Importantly, almost 80 percent of the deaths were during the first month postpartum. Meng and associates (2017) reported mortality rates of 23 percent with group 1 and 5 percent with the other groups. Mortality risk correlates positively with advancing pulmonary hypertension severity, which is characterized by Eisenmenger syndrome, severe hypertension, and higher NYHA class (Keepanasseril, 2019; Sun, 2018). In an audit of 47 pregnancies in women with pulmonary hypertension at Parkland Hospital, the maternal mortality rate was 9 percent (Herrera, 2020). Of four deaths, three women had severe hypertension. A striking example of right ventricular hypertrophy in one of these women who died is shown in Figure 52-6.

Pregnancy is contraindicated with severe disease. This is especially true in women with pulmonary arterial changes, which develop in most group 1 cases. With milder disease from other causes—group 2 being the most common—the prognosis is better. With the more frequent use of echocardiography and pulmonary artery catheterization in young women with

TABLE 52-8. Comprehensive Clinical Classification of Pulmonary Hypertension of the European Society of Cardiology and the European Respiratory Society

1. Pulmonary arterial hypertension
- Idiopathic
- Heritable
- Drug and toxin induced
- Associated with connective tissue disease, HIV infections, portal hypertension, congenital heart diseases, schistosomiasis

1′ Pulmonary venoocclusive disease and/or pulmonary capillary hemangiomatosis
- Idiopathic
- Heritable
- Drugs, toxins and radiation induced
- Associated with connective tissue disease, HIV infection

1″ Persistent pulmonary hypertension of the newborn

2. Pulmonary hypertension due to left heart disease
- Left ventricular systolic dysfunction
- Left ventricular diastolic dysfunction
- Valvular disease
- Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies
- Congenital/acquired pulmonary vein stenosis

3. Pulmonary hypertension due to lung diseases and/or hypoxia
- Chronic obstructive pulmonary disease
- Interstitial lung disease
- Other pulmonary diseases with mixed restrictive and obstructive pattern
- Sleep-disoriented breathing
- Alveolar hypoventilation disorder
- Chronic exposure to high altitude
- Developmental lung diseases

4. Chronic thromboembolic pulmonary hypertension/other pulmonary artery obstructions
- Chronic thromboembolic pulmonary hypertension
- Other pulmonary artery obstructions, i.e., tumors, arteritis, pulmonary stenosis, parasites

5. Pulmonary hypertension with unclear and/or multifactorial mechanisms
- Hematological disorders: chronic hemolysis, myeloproliferative disorders, splenectomy
- Systemic disorders: sarcoidosis, pulmonary histiocytosis, neurofibromatosis
- Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
- Others: fibrosing mediastinitis, chronic renal failure

HIV = human immunodeficiency virus.
Adapted from Galiè, 2016.

FIGURE 52-6 Cross-sectional display of right cardiac dysmorphology in a pregnant woman who died from undiagnosed primary pulmonary hypertension. There is prominent dilation of the right ventricle with right ventricular hypertrophy (*arrow*).

heart disease, we have identified women with mild to moderate pulmonary hypertension who tolerate pregnancy, labor, and delivery well (Herrera, 2020).

■ Management

Treatment of symptomatic pregnant women includes limiting activity and avoiding supine position later in gestation. Diuretics, supplemental oxygen, and pulmonary vasodilator drugs are standard therapy for symptoms. Some recommend anticoagulation. Several reports describe the successful use of intravenous pulmonary artery vasodilators (Foeller, 2018; Franco, 2019). Prostacyclin analogues that can be administered parenterally include epoprostenol (Flolan) and treprostinil (Remodulin), whereas iloprost (Ventavis) is inhaled. Each has been used in pregnancy. Inhaled nitric oxide is an option that has been

employed in cases of acute cardiopulmonary decompensation. As reviewed by Običan and Cleary (2014), phosphodiesterase-5 inhibitors, such as sildenafil (Viagra), cause vasodilation of both the pulmonary and systemic vascular beds and have an inotropic effect on the hypertrophic right ventricle. This also has been used to advantage during pregnancy (Meng, 2017). Bosentan—an endothelin-receptor antagonist, and riociguat—a soluble guanylate cyclase stimulator, are teratogenic in mice and contraindicated in pregnancy (Franco, 2019).

During labor and delivery, supplemental oxygen is given to maintain >90 percent saturation. These women are at greatest risk when venous return and right ventricular filling are diminished. To avoid hypotension, assiduous attention is given to epidural analgesia induction, fluid therapy, and blood loss prevention and treatment at delivery (Martin, 2019; Meng, 2017).

CARDIOMYOPATHIES

The American Heart Association defines these as a heterogeneous group of myocardial diseases associated with mechanical and/or electrical dysfunction (Narula, 2017). Affected women usually have inappropriate ventricular hypertrophy or dilation. Cardiomyopathies stem from varied causes, and the most frequent is genetic. Of the two major divisions, *primary cardiomyopathies* are solely or predominantly confined to the heart muscle. Examples are hypertrophic cardiomyopathy, dilated cardiomyopathies, and peripartum cardiomyopathy. *Secondary cardiomyopathies* result from generalized systemic disorders that produce pathological myocardial involvement. Diabetes, systemic lupus erythematosus, chronic hypertension, and thyroid disorders are representative conditions.

Hypertrophic Cardiomyopathy

This disorder affects approximately 1 in 500 adults (Herrey, 2014). Characterized by cardiac hypertrophy, myocyte disarray, and interstitial fibrosis, the condition in up to 60 percent of affected patients is caused by mutations in genes that encode cardiac sarcomere proteins. In such cases, inheritance is autosomal dominant, and genetic screening is complex (Cirino, 2019; Elliott, 2014). Other genetic and nongenetic etiologies underlie 5 to 10 percent of cases, and the cause is unknown in approximately 25 percent. The resulting myocardial muscle abnormality is typified by left ventricular myocardial hypertrophy with a pressure gradient against left ventricular outflow. Diagnosis is established by echocardiographic identification of a hypertrophied and nondilated left ventricle in the absence of other cardiovascular conditions.

Most affected women are asymptomatic, but dyspnea, anginal or atypical chest pain, syncope, and arrhythmias may develop. Complex arrhythmias may progress to sudden death, which is the most frequent cause of death. Asymptomatic patients with runs of ventricular tachycardia are especially prone to sudden death. Symptoms usually worsen with exercise.

Studies that include more than 700 pregnancies in 500 women indicate an overall relatively good prognosis (Schaufelberger, 2019). In a systematic review with 237 women with hypertrophic cardiomyopathy who had a combined 408 pregnancies, the maternal mortality rate was 0.5 percent (Schinkel, 2014). Worsening of symptoms or other complications developed in 29 percent, and 26 percent delivered preterm.

Management is similar to that for aortic stenosis (p. 926). Controlling heart rate and avoiding preload and afterload reduction are therapy basics. Strenuous exercise is prohibited during pregnancy. Abrupt positional changes are avoided to prevent reflex vasodilation and decreased preload. If symptoms develop, especially angina, β-adrenergic or calcium-channel blocking drugs are given. Drugs that evoke diuresis or reduce vascular resistance are generally not used because they decrease preload. But if these are necessary, women should be closely monitored. The delivery route is determined by obstetrical indications. Choice of anesthesia is controversial, and some consider general anesthesia the safest. Regional analgesia can be used with carefully titrated, adequate intravascular volume to maintain left ventricular filling pressure. Neonates rarely demonstrate inherited lesions at birth.

Dilated Cardiomyopathy

This is characterized by left and/or right ventricular enlargement and reduced systolic function in the absence of coronary, valvular, congenital, or systemic disease known to cause myocardial dysfunction. Although there are many known inherited and acquired causes of dilated cardiomyopathy, the etiology remains undefined in approximately half of cases (Schaufelberger, 2019). Some result from viral infections, including myocarditis and HIV. Other causes, which are potentially reversible, include alcoholism, cocaine abuse, coronavirus disease 2019 (COVID-19), and thyroid disease.

In affected gravidas, the rate of major adverse cardiovascular events in pregnancy ranges from 25 to 40 percent (American College of Obstetricians and Gynecologists, 2019; Grewal, 2009). Heart failure and arrhythmias are the most common, and women with preexisting moderate or severe left ventricular dysfunction or NYHA functional class III or IV are at greatest risk. Dilated cardiomyopathy is managed with therapy for standard heart failure and for the specific underlying etiology (Bozkurt, 2016).

Peripartum Cardiomyopathy

This disorder is similar to other forms of nonischemic dilated cardiomyopathy except for its unique relationship with pregnancy. Peripartum cardiomyopathy shares a genetic predisposition with both familial and sporadic idiopathic dilated cardiomyopathy (Cunningham, 2019; Ware, 2016). It is a diagnosis of exclusion following a concurrent evaluation for peripartum heart failure.

Although the term *peripartum cardiomyopathy* has been used widely, until recently, little evidence supported a unique pregnancy-induced cardiomyopathy. Pearson (2000) reported findings of a workshop of the National Heart, Lung, and Blood Institute that established the following diagnostic criteria:

Development of cardiac failure in the last month of pregnancy or within 5 months after delivery (Fig. 52-7),

- Absence of an identifiable cause for the cardiac failure,
- Absence of recognizable heart disease prior to the last month of pregnancy, and

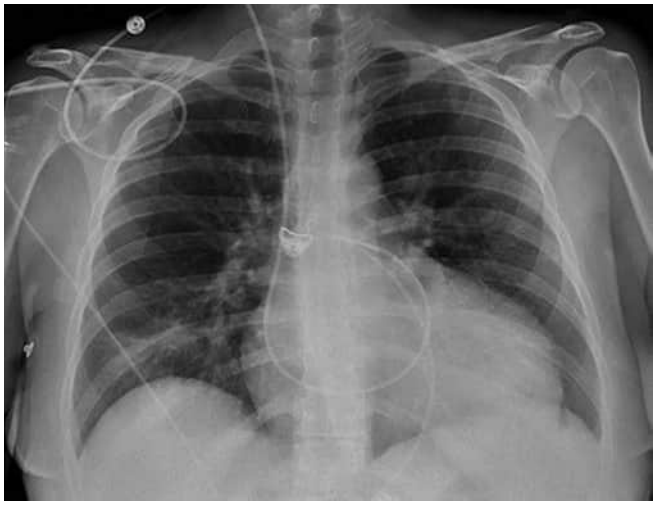

FIGURE 52-7 Peripartum cardiomyopathy with mild pulmonary edema. Chest radiograph of a woman with an abnormally enlarged heart and mild perihilar opacification consistent with dilated cardiomyopathy.

- Left ventricular systolic dysfunction demonstrated by classic echocardiographic criteria. These include depressed ejection fraction or fractional shortening along with a dilated left ventricle.

The incidence of peripartum cardiomyopathy varies considerably and depends on the population studied and the diligence of the search for a cause. The average frequency in the United States is 1 per 1000 to 4000 births (Cruz, 2018; Cunningham, 2019).

The etiology of peripartum cardiomyopathy remains unknown, and proposed causes include viral myocarditis, abnormal immune response to pregnancy, aberrant response to the greater hemodynamic burden of pregnancy, hormonal interactions, malnutrition, inflammation, and apoptosis. The current theory regarding pathophysiology is that of a "two-hit hypothesis" (Cruz, 2018; Ricke-Hoch, 2020). In this regard, peripartum cardiomyopathy affects genetically susceptible women who have one of several cardiac gene mutations to include *TTNC1*, *TTN*, and *STAT3*. Pregnancy at term is further characterized by prodigious secretion of prolactin by the maternal pituitary. At the same time, the placenta secretes high levels of the antiangiogenic molecule *soluble fms-like tyrosine kinase (sFlt-1)*. Although a number of putative triggering events have been hypothesized, a 16-kDa prolactin fragment—*vasoinhibin*—acts to cause myocardial damage with clinically apparent ventricular dysfunction. This is made worse by high levels of sFlt-1, which is superabundant in women with preeclampsia, multifetal pregnancy, or both. Bromocriptine therapy has been evaluated because it inhibits prolactin secretion, and preliminary studies support its use (Haghikia, 2019). For the same reason, it is also reasonable to proscribe breastfeeding.

Hypertensive disorders frequently coexist with peripartum cardiomyopathy, and another proposed mechanism links peripartum cardiomyopathy to preeclampsia (Cunningham, 2019). Antiangiogenic factors are known to be associated with preeclampsia and can induce peripartum cardiomyopathy in susceptible mice. Thus, cardiomyopathy may be precipitated by antiangiogenic factors in a genetically predisposed host because of insufficient proangiogenic factors.

Ntusi and coworkers (2015) analyzed the clinical features of women with peripartum cardiomyopathy compared with those with hypertensive heart failure. All women with peripartum cardiomyopathy became symptomatic in the postpartum period, whereas 85 percent of women with hypertensive heart failure developed symptoms antepartum. Peripartum cardiomyopathy was significantly linked with twin gestation, smoking, and echocardiographic abnormalities. In contrast, hypertensive heart failure patients more often had a family history of hypertension, hypertension and preeclampsia in a prior pregnancy, and left ventricular hypertrophy.

Management

Management of peripartum cardiomyopathy is the same as that of heart failure, and described earlier (p. 922). Therapy is aimed at volume overload, afterload reduction, rhythm control, and inotropic support (Davis, 2020). In addition, β-blocker therapy is used to decrease mortality rates. Anticoagulation with LMWH is considered when the ejection fraction reaches 30 to 35 percent because of the increased risk for left ventricular thrombi (Bauersachs, 2016; Bozkurt, 2016).

In one pilot study, bromocriptine resulted in higher rates of left ventricular recovery at 6 months and lower mortality rates (Sliwa, 2010). A larger study of 115 women showed no difference in full restoration of left ventricular function between those treated and untreated with bromocriptine (Haghikia, 2013). Another investigation of 63 women showed no difference in left ventricular function improvement with short-term versus long-term bromocriptine therapy (Hilfiker-Kleiner, 2017). The use of bromocriptine as adjuvant therapy is considered experimental at this time.

Prognosis

Approximately half of women suffering from peripartum cardiomyopathy recover baseline ventricular function within 6 months of delivery. This rate is lower in obese women (Davis, 2018). In a group of 100 women with newly diagnosed peripartum cardiomyopathy, 72 percent had a left ventricular ejection fraction ≥50 percent at 1 year postpartum (McNamara, 2015). Recovery to this level occurred in almost 90 percent of women whose baseline ejection fraction was at least 30 percent. This is compared with <40 percent in women whose baseline ventricular ejection fraction was <30 percent. Recovery was also related to the baseline left ventricular end-diastolic diameter. Event-free survival at 1 year occurred in 93 percent. Six women experienced nine major events that included four deaths, four left ventricular assist device implantations, and one heart transplantation. Li and colleagues (2016) also found that a baseline left ventricular ejection fraction <34 percent and a BNP level >1860 pg/mL were associated with an approximately threefold greater risk of persistent left ventricular systolic dysfunction. The mortality rate approaches 5 to 10 percent at 1 year in women with persistent cardiac failure (American College of Obstetricians and Gynecologists, 2019).

Long-term follow-up was reported in 28 women with a median surveillance of 91 months (Ersbøll, 2018). Although

most women were asymptomatic, compared with controls, they had lower ejection fractions, less maximal exercise capacity, and subtle diastolic dysfunction.

Subsequent Pregnancy

From the largest studies on the topic, approximately a third of women with a history of peripartum cardiomyopathy will suffer relapse with worsening of symptoms and deterioration of left ventricular function during another pregnancy (Elkayam, 2014a). The risk of relapse in women with persistent left ventricular dysfunction is substantially higher than in those who have recovered normal ventricular function before a subsequent pregnancy (Hilfiker-Kleiner, 2017). However, normalization of left ventricular function does not guarantee an uncomplicated pregnancy, because approximately 20 percent of these women are at risk for deterioration in that function (Codsi, 2018).

■ Other Cardiomyopathy Types

Arrhythmogenic right ventricular dysplasia is a unique cardiomyopathy defined histologically by progressive replacement of right ventricular myocardium with adipose and fibrous tissue. It has an estimated population prevalence of 1 in 5000, predisposes to ventricular tachyarrhythmias, and is a cause of sudden death, particularly in younger individuals (Agir, 2014). Studies of pregnancies in affected women reported symptoms, including heart failure, in 18 to 33 percent of pregnancies (Schaufelberger, 2019). Based on their systematic review, Krul and coworkers (2011) counsel against pregnancy.

Restrictive cardiomyopathy is probably the least common type. This inherited cardiomyopathy is characterized by a ventricular filling pattern in which worsening myocardial stiffness raises ventricular pressure precipitously and allows only a small filling volume (Elliott, 2008). Pregnancy is not advised because of the severe clinical course and poor prognosis in general.

Takotsubo cardiomyopathy is a rare form of acute reversible left ventricular apical wall ballooning (Kraft, 2017). It is considered to be "stress induced" and appears to be more common with preeclampsia and cesarean delivery. Myocardial infarction must be excluded (Oindi, 2019).

INFECTIVE ENDOCARDITIS

Persons at greatest risk for endocarditis are those with congenital heart lesions, intravenous drug use, degenerative valve disease, and intracardiac devices (Karchmer, 2018). *Subacute bacterial endocarditis* usually stems from a low-virulence bacterial infection superimposed on an underlying structural lesion. These are usually native valve infections. Organisms that cause indolent endocarditis are most often viridans-group streptococci or *Staphylococcus* or *Enterococcus* species. Among intravenous drug abusers and those with catheter-related infections, *Staphylococcus aureus* predominates. With prosthetic valve infections, *Staphylococcus epidermidis* is a frequent cause. *Streptococcus pneumoniae* and *Neisseria gonorrhoeae* may occasionally cause acute, fulminating disease. Others have reported other *Neisseria* species, group B streptococcus, and *Escherichia coli* endocarditis during pregnancy or peripartum.

■ Diagnosis and Management

Infective endocarditis symptoms vary and often develop insidiously. Fever, often with chills, is seen in 80 to 90 percent of cases; a murmur is heard in up to 85 percent; and anorexia, fatigue, and other constitutional symptoms are common (Karchmer, 2018). Clinical clues are anemia, proteinuria, and manifestations of embolic lesions that include petechiae, focal neurological changes, chest or abdominal pain, and extremity ischemia. In some cases, heart failure develops. Symptoms may persist for several weeks before the diagnosis is found, and a high index of suspicion is necessary.

Diagnosis is made using the *Duke-Li classification*, which combines microbiology and imaging criteria with five minor criteria (Iung, 2019). Echocardiography may be diagnostic, but lesions <2 mm or those on the tricuspid valve may be missed. If uncertain, transesophageal echocardiography is accurate and informative. Importantly, a negative echocardiographic study does not exclude endocarditis.

Treatment is primarily medical, and ascertainment of the infecting organism and its sensitivities is imperative for antimicrobial selection. Guidelines for appropriate antibiotic treatment are published by professional societies and updated regularly (Habib, 2015; Karchmer, 2018). Recalcitrant bacteremia and heart failure due to valvular dysfunction are a few reasons for which persistent infection may require valve replacement (Iung, 2019).

■ Pregnancy

Infective endocarditis is uncommon during pregnancy and the puerperium. In an earlier period, the incidence of endocarditis at Parkland Hospital approximated 1 in 16,000 births (Cox, 1988). With the current opioid use disorder epidemic, endocarditis may become more frequent (Prasad, 2019). Associated maternal and fetal mortality rates are from 25 to 35 percent (Dagher, 2021; Habib, 2015). In one review, risk factors were intravenous drug use (14 percent), congenital heart disease (12 percent), and rheumatic heart disease (12 percent). The most common pathogens were streptococcal (43 percent) and staphylococcal (26 percent) species. Among 51 pregnancies, the maternal mortality rate was 11 percent (Kebed, 2014).

■ Endocarditis Prophylaxis

For years, patients with any heart valve problem were given periprocedural antibiotics for endocarditis prophylaxis. Currently, however, recommendations are more stringent. The American Heart Association recommends prophylaxis for dental procedures in those with: (1) a prosthetic valve or prosthetic material used in a valve repair, (2) prior endocarditis, (3) unrepaired cyanotic heart defect or repaired lesion with residual defect at prosthetic sites, and (4) valvulopathy after heart transplantation (Nishimura, 2017). In the absence of pelvic infection, the American College of Obstetricians and Gynecologists (2018b) does not recommend endocarditis prophylaxis for either vaginal or cesarean delivery, except with the lesions cited above.

Pregnant women at highest risk for endocarditis are those with cyanotic cardiac disease, prosthetic valves, or both.

TABLE 52-9. Single-Dose Antibiotic Prophylaxis for Infective Endocarditis in High-Risk Patients

American College of Obstetricians and Gynecologists (2018b)
Standard (IV): ampicillin 2 g ***or*** cefazolin or ceftriaxone 1 g
Penicillin-allergic (IV): cefazolin or ceftriaxone 1 g ***or*** clindamycin 600 mg
Oral: amoxicillin 2 g
American Heart Association/European Society of Cardiology (Karchmer, 2018)
Standard: amoxicillin 2 g PO ***or*** ampicillin 2 g IV or IM
Penicillin-allergic: clarithromycin or azithromycin 500 mg PO; cephalexin 2 g PO; clindamycin 600 mg PO, IV, or IM; ***or*** cefazolin or ceftriaxone 1 g IV or IM

IM = intramuscularly; IV = intravenously; PO = per os (orally).
Cefazolin or ceftriaxone given 30 minutes, and all others given 1 hour prior to procedure.

Table 52-9 shows prophylactic regimens for women not already receiving intrapartum antimicrobial therapy for another indication that would also provide coverage against endocarditis. These are administered as close to 30 to 60 minutes before the anticipated delivery time as is feasible.

ARRHYTHMIAS

Both preexisting and new-onset cardiac arrhythmias are often encountered during pregnancy, labor, delivery, and the puerperium. They are usually benign and their incidence in pregnancy appears to be increasing (MacIntyre, 2018). The mechanism(s) responsible for the higher incidence are not clear. From some studies, estradiol and progesterone are proarrhythmic. Estrogen augments the number of adrenergic receptors in the myocardium, and adrenergic responsiveness seems to be greater in pregnancy (Enriquez, 2014). Perhaps the normal but mild hypokalemia of pregnancy and/or the physiological rise in heart rate serves to induce arrhythmias. Alternatively, detection of arrhythmias may be greater because of the frequent visits in routine prenatal care.

Bradyarrhythmias

Slow heart rhythms, including complete heart block, are compatible with a successful pregnancy outcome (Keepanasseril, 2015). Some women with complete heart block have syncope during labor and delivery, and occasionally temporary cardiac pacing is necessary. In our experiences and from others, women with permanent artificial pacemakers usually tolerate pregnancy well (Hidaka, 2011). With fixed-rate devices, cardiac output apparently is increased by augmented stroke volume.

Patients with pacemakers or other electrical implants require special precautions during surgery. Stray current may be interpreted as an intracardiac signal by the implanted device and lead to pacing changes. In addition, myocardial burns may result from conduction of electrosurgical current to the pacing electrode rather than to the grounding pad. With these devices, preventive steps include cardiology consultation; bipolar electrosurgery or Harmonic scalpel use rather than monopolar current; if needed, minimal monopolar settings; continuous cardiac and pulse oximetry monitoring; contingency plans for arrhythmias; and close proximity of active (electrosurgical pencil) and return (electrosurgical grounding pad) electrodes (Crossley, 2011).

Supraventricular Tachycardias

The most common arrhythmia seen in reproductive-aged women is *paroxysmal supraventricular tachycardia (SVT)*. The prevalence during pregnancy is 24 cases per 100,000 hospital admissions, and approximately 20 percent will experience symptomatic exacerbations during pregnancy (Enriquez, 2014). Interestingly, the mean heart rate of pregnant women with paroxysmal SVT is 184 bpm compared with 166 bpm in nonpregnant affected women (Yu, 2015). In one study, approximately half of women with paroxysmal SVT had an initial onset during pregnancy (Bánhidy, 2015). Notably, maternal paroxysmal SVT was associated with a twofold higher risk of septal cardiac defects, particularly secundum atrial septal defects, in their offspring.

For acute SVT treatment, vagal maneuvers, which include Valsalva maneuver, carotid sinus massage, bearing down, and immersion of the face in ice water, raise vagal tone and block the atrioventricular node. Intravenous adenosine is a short-acting endogenous nucleotide that also blocks AV nodal conduction. Our experiences are similar to those of others in that adenosine is safe and effective for cardioversion in hemodynamically stable gravidas (Page, 2015). Transient fetal bradycardia has been described with adenosine (Dunn, 2000).

If pharmacological therapy is ineffective or contraindicated, the American College of Cardiology and the American Heart Association recommend synchronized cardioversion in pregnant women with hemodynamically unstable SVT (Page, 2015). Although electrical cardioversion with standard energy settings is not contraindicated in pregnancy, vigilance is important. Barnes and colleagues (2002) described a case in which direct current cardioversion led to a sustained uterine contraction and fetal bradycardia. As an aside, pregnancy has no effect on the operation of implantable cardioverter-defibrillator devices (Boulé, 2014).

If cardioversion fails or is unsafe because of concurrent thrombus, then long-term anticoagulation and heart rate control with medication are necessary (DiCarlo-Meacham, 2011). Other treatment options recommended by the American College of Cardiology and the American Heart Association (Page, 2015) include:

- Intravenous metoprolol or propranolol when adenosine is ineffective or contraindicated,

- Intravenous verapamil when adenosine and β-blocking agents are ineffective or contraindicated,
- Intravenous procainamide,
- Intravenous amiodarone for potentially life-threatening SVT and when other therapies are ineffective or contraindicated.

Atrial fibrillation and *atrial flutter* rarely present for the first time during pregnancy. A new-onset atrial fibrillation should prompt a search for underlying etiologies that include cardiac anomalies, hyperthyroidism, pulmonary embolism, drug toxicity, and electrolyte disturbances (MacIntyre, 2018). Major complications include embolic stroke. When associated with mitral stenosis, pulmonary edema may develop in later pregnancy if the ventricular rate is increased. Unstable patients are treated with cardioversion and rate control.

Pregnancy may predispose otherwise asymptomatic women with *Wolff-Parkinson-White (WPW) syndrome* to exhibit arrhythmias. In a study of women with asymptomatic or mildly symptomatic disease, half developed SVT for the first time, and the other half experienced an increase in their attack rate (Kounis, 1995). In some patients, accessory pathway ablation may be indicated. Patients with Ebstein anomaly are prone to have WPW syndrome. Driver and associates (2015) have provided a review.

Ventricular Tachycardia

This form of arrhythmia is uncommon but potentially fatal in healthy young women without underlying heart disease. Brodsky and coworkers (1992) described seven pregnant women with new-onset ventricular tachycardia and reviewed 23 reports. Most of these women were not found to have structural heart disease. In 14 cases, tachycardia was precipitated by physical exercise or psychological stress. Abnormalities found included two cases of myocardial infarction, two of prolonged QT interval, and one of anesthesia-provoked tachycardia. They concluded that pregnancy events precipitated the tachycardia and recommended β-blocking agents for control. As previously discussed (p. 934), *arrhythmogenic right ventricular dysplasia* will result occasionally in ventricular tachyarrhythmias. If unstable, emergency cardioversion is indicated, and standard adult energy settings are adequate (Lin, 2015).

Prolonged QT-Interval

The *long QT syndrome* is the most frequent inherited channelopathy (MacIntyre, 2018). This conduction anomaly may predispose individuals to a potentially fatal ventricular arrhythmia known as *torsades de pointes*. Two studies comprised of 502 pregnant women with long QT syndrome both reported a significant rise in cardiac events postpartum but not during pregnancy (Rashba, 1998; Seth, 2007). The normal elevation in heart rate during pregnancy may be partially protective. Paradoxically, β-blocking agents—preferably propranolol—lower the risk of torsades de pointes in patients with long QT syndrome and should be continued throughout pregnancy and the puerperium (Ishibashi, 2017). Importantly, many medications, including some used during pregnancy, such as the erythromycins and many antiemetics, may predispose to QT prolongation. For opioid-addicted women, the use of methadone to treat withdrawal symptoms may be problematic (Bogen, 2017). Last, Cuneo and colleagues (2020) observed an eightfold risk for stillbirth in women with long QT syndrome (Chap. 35, p. 624).

DISEASES OF THE AORTA

Aortic Dissection

Marfan syndrome and coarctation are two aortic diseases that place the pregnant woman at greater risk for aortic dissection (Russo, 2017). Indeed, half of dissection cases in young women are related to pregnancy (O'Gara, 2004). Other risk factors are bicuspid aortic valve and Turner, Noonan, Loeys-Dietz, or Ehlers-Danlos syndrome (Cauldwell, 2019b; Russo, 2018). Pregnancy-related cardiac guidance for women with Turner syndrome is outlined in Chapter 3 (p. 37). Although the mechanism(s) involved are unclear, the initiating event is a tear in the intimal layer of the aorta, followed by hemorrhage into the media, and finally rupture.

In most cases, aortic dissection presents with severe chest pain described as ripping, tearing, or stabbing. Diminution or loss of peripheral pulses coupled with a recently acquired aortic insufficiency murmur is an important physical finding. The differential diagnosis of aortic dissection in pregnancy includes myocardial infarction, pulmonary embolism, pneumothorax, aortic valve rupture, and obstetrical catastrophes such as placental abruption and uterine rupture.

More than 90 percent of patients with aortic dissection have an abnormal chest radiograph. Aortic angiography is the most definitive method for diagnosis confirmation. However, sonography, computed tomography, and MR imaging are used more frequently depending on the clinical urgency.

Initial medical treatment is given to lower blood pressure. Proximal dissections most often need to be resected, and the aortic valve replaced if necessary. Distal dissections are more complex, and many may be treated medically. Among *nonpregnant* patients with abdominal aortic aneurysms <5.5 cm, survival is not improved by immediate elective repair compared with surveillance and delayed repair. Karthikesalingam and associates (2016) suggest that the size threshold for aneurysm repair should be revisited.

Marfan Syndrome

This autosomal dominant connective tissue disorder has an incidence of 1 per 3000 to 5000 individuals and is without racial or ethnic predilection (Azizad-Pinto, 2017). As discussed in Chapter 62 (p. 1121), Marfan syndrome is caused by any of more than 1000 mutations in the fibrillin (*FBN1*) gene. It is characterized by generalized tissue weakness that can result in dangerous cardiovascular complications. All tissues are involved, and other frequent defects include joint laxity and scoliosis. Progressive aortic dilation causes aortic valve insufficiency, and infective endocarditis or mitral valve prolapse with insufficiency may be comorbid. Aortic dilation and dissecting aneurysm are the most serious abnormalities. Early death is due to either a dissecting aneurysm or to valvular insufficiency and heart failure.

During pregnancy, the primary concern with Marfan syndrome is aortic dissection (Curry, 2014; Russo, 2017). A study using the Nationwide Inpatient Sample from 2003 to 2010 described 339 deliveries in women with Marfan syndrome. There was one maternal death and six (1.8 percent) aortic dissections (Hassan, 2015). From the United Kingdom, Cauldwell and colleagues (2019a) described 258 pregnancies in 151 affected women. Although no women died, 1.9 percent had an aortic dissection.

The aortic root usually measures approximately 2 cm, and during normal pregnancy, it expands slightly. With Marfan syndrome, aortic root repair is recommended at diameters of 4.0 to 4.5 cm (Azizad-Pinto, 2017). The guidelines of the American College of Cardiology, the American Heart Association, and the American Association of Thoracic Surgeons advise prophylactic aortic repair in women considering pregnancy if the diameter of the ascending aorta exceeds 4 cm (Hiratzka, 2010). The guidelines of the European Society of Cardiology advise repair of the aorta at diameters >4.5 cm (Regitz-Zagrosek, 2018). Surgical repair is also considered using a formula indexed to height because shorter patients have dissection at a smaller diameter (Bradley, 2014).

For pregnant women with known thoracic aortic root or ascending aortic dilation, monthly or bimonthly echocardiographic measurements of the ascending aortic dimensions are recommended to detect expansion (American College of Obstetricians and Gynecologists, 2019). Prophylactic β-blocking agents have become standard for gravidas with Marfan syndrome because they reduce hemodynamic stress on the ascending aorta and slow the dilation rate. Ideally, pregnant women with aortic aneurysms are delivered at facilities in which cardiothoracic surgery is available. Vaginal delivery with regional analgesia and an assisted second stage seem safe for women with an aortic root diameter <4 cm.

Cesarean delivery may be considered for values between 4.0 and 4.5 cm. When the aortic root measures >4.5 cm, elective cesarean delivery is recommended, and direct replacement of the proximal aorta with a prosthetic graft can be considered (Regitz-Zagrosek, 2018). Successful aortic root replacement during pregnancy has been described, but the surgery has also been associated with fetal hypoxic-ischemic encephalopathy (Seeburger, 2007). Several case reports describe emergency cesarean deliveries in women with acute type A dissections that were repaired successfully at the time of delivery (Guo, 2011; Haas, 2011; Papatsonis, 2009).

To evaluate obstetrical outcomes, investigators for one study of 63 women with Marfan syndrome analyzed their 142 pregnancies. Of 111 pregnancies progressing past 20 weeks' gestation, 15 percent delivered preterm, and 5 percent had preterm prematurely ruptured membranes (Meijboom, 2006). There were eight perinatal deaths, and half of the neonatal survivors were subsequently diagnosed with Marfan syndrome.

Aortic Coarctation

In this relatively rare lesion, the aorta is abnormally narrowed and is often accompanied by abnormalities of other large arteries. A fourth of affected patients have a bicuspid aortic valve, and another 10 percent have cerebral artery aneurysms. Other associated lesions are persistent ductus arteriosus, septal defects, and Turner syndrome. The collateral circulation arising above the coarctation remodels and expands, often strikingly, to cause localized erosion of rib margins by hypertrophied intercostal arteries. Typical findings include hypertension in the upper extremities but normal or decreased pressures in the lower extremities. Some have described diagnosis during pregnancy using MR imaging (Sherer, 2002; Zwiers, 2006). Jimenez-Juan and associates (2014) found that aortic diameter measured by MR imaging and the risk of adverse events during pregnancy were inversely correlated. Of note, no adverse outcomes occurred if the minimum diameter at the coarctation exceeded 15 mm.

Major complications with aortic coarctation include congestive heart failure after long-standing severe hypertension, bacterial endocarditis of an associated bicuspid aortic valve, and aortic rupture. Antihypertensive therapy using β-blocking drugs is usually required because hypertension may worsen in pregnancy. Aortic rupture is more likely late in pregnancy or early puerperium. Cerebral hemorrhage from *circle of Willis aneurysms* also may occur. According to the World Health Organization, severe coarctation should preclude pregnancy (Foeller, 2018).

In one study of outcomes from 188 pregnancies, a third of women had hypertension that was related to significant coarctation gradients, and one woman died from dissection at 36 weeks' gestation (Beauchesne, 2001). In 700 deliveries complicated with coarctation, hypertensive complications of pregnancy were increased three- to fourfold (Krieger, 2011). Importantly, almost 5 percent of women with coarctation had an adverse cardiovascular outcome—maternal death, heart failure, arrhythmia, cerebrovascular or other embolic event—compared with only 0.3 percent of controls. Of women with coarctation, 41 percent underwent cesarean delivery compared with 26 percent of controls.

Congestive heart failure demands vigorous efforts to improve cardiac function and may warrant pregnancy interruption. In this setting, some authors recommend that resection of the coarctation be undertaken to protect against the possibility of a dissecting aneurysm and aortic rupture. This poses significant perfusion risk, especially for the fetus, because all the arterial collaterals must be clamped for variable periods.

ISCHEMIC HEART DISEASE

Pregnant women with coronary artery disease commonly have the classic risk factors of family history, diabetes, smoking, hypertension, hyperlipidemia, and obesity (Tripathi, 2019). The rate of ischemic heart disease is estimated to be 10 cases per 100,000 pregnancy and postpartum hospitalizations (Smilowitz, 2018; Tripathi, 2019). Although relatively rare, the risk of acute myocardial infarction is approximately threefold higher in pregnant women compared with nonpregnant women of similar age (Elkayam, 2014b).

Acute Coronary Syndrome

Myocardial infarction (MI) is the end result of an acute coronary syndrome. It can result from coronary artery atherosclerosis,

dissection, embolism, spasm, or arteritis (American College of Obstetricians and Gynecologists, 2019; Cauldwell, 2020). The mortality rate with MI in pregnancy is higher compared with age-matched nonpregnant women. In a Nationwide Inpatient Sample study totaling 859 pregnancies complicated by acute MI, the death rate was 5.1 percent (James, 2006). Women who sustain an infarction <2 weeks before delivery are at especially high risk of death due to the greater myocardial demand of labor and delivery (Esplin, 1999).

In a systematic review of 150 cases, most women developed an acute MI during the third trimester or postpartum (Elkayam, 2014b). Approximately three fourths presented with ST segment-elevation MI (STEMI). The leading mechanisms of acute infarction included *spontaneous coronary dissection* (43 percent) and *atherosclerotic disease* (27 percent). Significant complications included heart failure (38 percent), recurrent angina or infarction (19 percent), and ventricular arrhythmias (12 percent). The maternal and fetal mortality rates were 7 and 5 percent, respectively.

Diagnosis of acute coronary syndrome during pregnancy does not differ from that in nonpregnant patients and is based on clinical presentation, characteristic ECG changes, and evidence of myocardial necrosis reflected by elevated serum high-sensitivity troponin I levels (Pacheco, 2014). Consider that troponin I levels are greater, however, in preeclamptic and hypertensive women compared with normotensive gravidas (Ravichandran, 2019).

With spontaneous coronary artery dissection, establishing the diagnosis requires an increased index of suspicion in the women presenting with chest pain (Codsi, 2016). For this condition, coronary angiography is considered the diagnostic gold standard and should be expeditiously performed if acute coronary syndrome—either MI or unstable angina—is present (Hayes, 2018).

Treatment of acute MI is similar to that for nonpregnant patients (Pacheco, 2014). Several reports describe successful percutaneous transluminal coronary angioplasty and stent placement during pregnancy (American College of Obstetricians and Gynecologists, 2019). Cardiopulmonary resuscitation may be required, as described in Chapter 50 (p. 897). If the infarct has healed sufficiently, cesarean delivery is reserved for obstetrical indications, and epidural analgesia is ideal for labor.

■ Pregnancy with Prior Ischemic Heart Disease

Ischemic heart disease is characteristically progressive, and because it is usually associated with hypertension or diabetes, pregnancy in most of these women seems inadvisable. In an earlier review of 30 pregnancies in women who had sustained an *infarction remote from pregnancy*, none of the women died, four had congestive heart failure, and four had worsening angina during pregnancy (Vinatier, 1994). Pombar and coworkers (1995) evaluated outcomes of women with diabetes-associated ischemic heart disease and infarction. Three had undergone coronary artery bypass grafting before pregnancy. Of 17 women, eight died during pregnancy. Certainly, pregnancy raises cardiac workload, and these investigators concluded that ventricular performance should be assessed using ventriculography, radionuclide studies, echocardiography, or coronary angiography before conception. Without significant ventricular dysfunction, pregnancy will likely be tolerated. For the woman who becomes pregnant before these studies are performed, echocardiography is done. Exercise tolerance testing may be indicated, and radionuclide ventriculography exposes the fetus to minimal radiation (Chap. 49, p. 875).

COMMON OBSTETRICAL MEDICATIONS

Common medications used in pregnancy require special consideration in women with cardiac conditions. Terbutaline causes vasodilation and tachycardia, which can be dangerous in patients with mitral and aortic stenosis. Nifedipine for hypertension control or tocolysis results in hypotension that can have negative consequences for patients with aortic stenosis, pulmonary hypertension, and Eisenmenger syndrome. Postpartum hemorrhage should be managed aggressively, and methylergonovine generally is a safe choice. Prostaglandin $F_{2\alpha}$ may cause pulmonary shunting and bronchospasm, which results in elevation of pulmonary artery pressure. Consideration is given to the vasodilatory effects of hydralazine in conditions such as hypertrophic cardiomyopathy. Hydralazine also causes tachycardia. The β-blocking agent labetalol is a safe choice unless there is ventricular failure. In general, oxytocin and magnesium sulfate have minimal cardiac effects.

CHAPTER 53

Chronic Hypertension

In reproductive-aged women, the prevalence of hypertension approximates 6 percent (Centers for Disease Control and Prevention, 2017). Thus, not surprisingly, chronic hypertension is one of the most common serious complications encountered during pregnancy. In one study of more than 56 million births, the incidence was 1.8 percent (Bateman, 2012). Chronic hypertension complicated 2.3 percent of pregnancies in data from the Medicaid Analytic Extract (Bateman, 2015). Despite an increasing prevalence from 1970 to 2010, optimal management has not been well studied (Ananth, 2019).

Chronic hypertension usually improves during early pregnancy. This is followed by variable behavior later in pregnancy and may include development of superimposed preeclampsia. The latter carries significant risks for maternal and perinatal morbidity and mortality.

GENERAL CONSIDERATIONS

Blood pressure is a polygenic biological variant that differs between populations. Numerous epigenetic factors also influence penetrance differences between individuals. Moreover, clinical features such as increasing age and weight correlate positively with rising pressures. Last, resting blood pressure measurements do not reflect daily activities. Therefore, adults have a broad range of normal blood pressure values, which makes defining hypertension difficult.

Definition and Classification

Chronic hypertension would logically be defined as some level of sustained resting blood pressure that is associated with acute or long-term adverse effects. Most consider 140/90 mm Hg as the upper limit of normal. In the United States, these values were derived primarily from life insurance actuarial tables constructed using data from white adult males. These "norms" disregard ethnicity, gender, and other covariants. The importance of race is emphasized by Kotchen (2018), who cites the incidence of hypertension—defined as blood pressure >140/90 mm Hg—to be 34 percent in blacks, 29 percent in whites, and 21 percent in Mexican Americans.

For many years, the Joint National Committee promulgated guidelines for diagnosis, classification, and management of chronic hypertension. Recently, a coalition led by the American College of Cardiology and the American Heart Association published criteria for the diagnosis of hypertension (Table 53-1) (Whelton, 2018).

TABLE 53-1. Criteria for Diagnosis of Hypertension

Blood Pressure (mm Hg)			Nonpregnant ACC/AHA	Pregnant ACOG
SBP		DBP		
<120	and	<80	Normal	Normal
120–129	and	<80	Elevated	Normal
130–139	or	80–89	Stage 1 HTN	Normal
140–159	or	≥90	Stage 2 HTN	Mild to moderate HTN
≥160	or	≥110	Stage 2 HTN	Severe HTN

ACC = American College of Cardiology; ACOG = American College of Obstetricians and Gynecologists; AHA = American Heart Association; DBP = diastolic blood pressure; HTN = hypertension; SBP = systolic blood pressure.

Treatment and Benefits for Nonpregnant Adults

Chronic hypertension accounts for nearly 15 percent of deaths worldwide (Kotchen, 2018). Long term, hypertension raises substantively the risk of cardiovascular disease, coronary heart disease, congestive heart failure, stroke, renal failure, peripheral arterial disease, and mortality. These risks decline with treatment of otherwise normal adults who have sustained hypertension.

Based on these benefits, current guidelines recommend antihypertensive therapy for stage 1 hypertension in nonpregnant adults with risk factors for current or future cardiovascular disease. However, given the different diagnostic criteria in pregnancy (see Table 53-1), the best management for women being treated and contemplating pregnancy, for those undergoing treatment who become pregnant, or for those first identified to have chronic hypertension during pregnancy is unknown (American College of Obstetricians and Gynecologists, 2018a; August, 2015). In these women, the benefits and safety of instituting antihypertensive therapy are less clear, as subsequently discussed.

Preconceptional Counseling

Women with chronic hypertension ideally undergo counseling before pregnancy (American College of Obstetricians and Gynecologists, 2018b). Initial questions ascertain hypertension duration, degree of blood pressure control, and current therapy. Home measurement devices are checked for accuracy. General health, daily activities, and dietary habits also are assessed (Table 53-2). Women who require multiple medications for control or who have poorly controlled pressures carry greater risk for adverse pregnancy outcomes. Patient counseling should disclose maternal and fetal risks, which are detailed in later sections (pp. 946 and 948).

For hypertensive women with disease exceeding 5 years or with comorbid diabetes, cardiovascular and renal function are assessed (August, 2015; Chahine, 2019). Renal function is evaluated by serum creatinine measurement and urine spot protein/creatinine ratio measurement. If the ratio is abnormally high (>0.3), proteinuria can be further quantified with a 24-hour urine collection (Kuper, 2016; Morgan, 2016a).

Women with evidence of organ dysfunction or those with prior adverse events such as a stroke, myocardial infarction, arrhythmias, or ventricular failure carry markedly higher risks for a recurrence or worsening dysfunction during pregnancy. Specific preconceptional guidance for these conditions is found in Chapters 63 (p. 1132) and 52 (p. 918), respectively. Although poorly controlled hypertension is considered a contraindication for pregnancy by some, there is no consensus. Women who maintain persistent systolic pressures ≥160 mm Hg or diastolic pressures ≥110 mm Hg despite therapy; require multiple antihypertensive agents; have a serum creatinine level >2 mg/dL; or have a history of prior stroke, myocardial infarction, or cardiac failure must be counseled regarding the marked risks to themselves and to their fetus. These are described in the next sections.

PREGNANCY CONSIDERATIONS

Diagnosis and Evaluation

Chronic hypertension is diagnosed if it precedes pregnancy or if it is identified before 20 weeks' gestation. Prior to this gestational age, preeclampsia is rarely seen (Chap 40, p. 690). The American College of Obstetricians and Gynecologists (2018a, 2020) defines hypertension as a systolic pressure ≥140 mm Hg or a diastolic pressure ≥90 mm Hg (see Table 53-1). In suspected

TABLE 53-2. Lifestyle Modifications for Hypertensive Patients

Weight reduction: BMI ≤25 kg/m^2
Consume a dietary pattern that emphasizes intake of vegetables, fruits, and whole grains; includes low-fat dairy products, poultry, fish, legumes, nontropical vegetable oils, and nuts; and limits sweets and red meats. Examples are DASH, USDA Food Pattern, or the AHA Diet
Lower sodium intake: consume no more than 2400 mg/d; 1500 mg/d desirable
Engage in aerobic physical activity three to four sessions per week, lasting on average 40 minutes per session, and involving moderate- to vigorous-intensity physical activity
Moderation of alcohol consumption: ≤1 drink daily (none when pregnant)

AHA = American Heart Association; DASH = Dietary Approaches to Stop Hypertension; USDA = United States Department of Agriculture.
Summarized from Kotchen, 2018; Whelton, 2018.

cases of "white-coat" hypertension, serial ambulatory monitoring can be considered. In some women without overt chronic hypertension, a history of repeated pregnancies complicated by gestational hypertension, with or without preeclampsia, may be elicited. Either is a risk factor for latent chronic hypertension. This is especially true for prior preeclampsia and particularly for early-onset preeclampsia (van Eerden, 2018). In many ways, gestational hypertension is analogous to gestational diabetes. Women with the former have a *chronic hypertensive diathesis*, in which heredity and epigenetics play a major role.

Although uncommon, secondary causes of hypertension are always a possibility in affected women. Thus, chronic renal disease, obstructive sleep apnea, connective tissue disease, primary aldosteronism, Cushing syndrome, pheochromocytoma, and myriad other causes are considered during evaluation (American College of Obstetricians and Gynecologists, 2018a). That said, most pregnant women with antecedent hypertension will have otherwise uncomplicated disease. The hypertensive disorders that uniquely complicate pregnancy are discussed in Chapter 40.

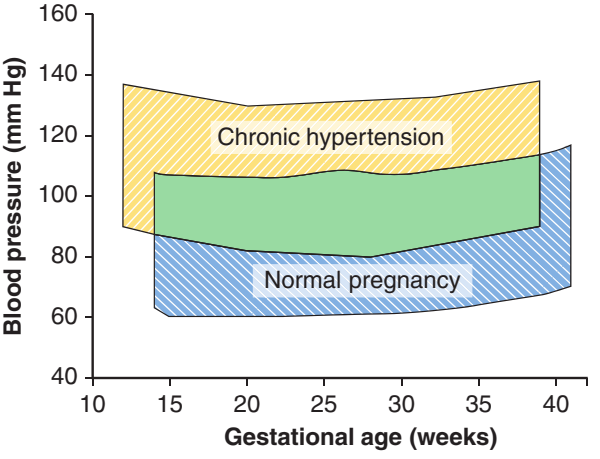

FIGURE 53-1 Mean systolic and diastolic blood pressures across pregnancy in 107 untreated chronically hypertensive women (*yellow*) compared with blood pressures across pregnancy in 4589 healthy nulliparas (*blue*). (Data from August, 2015; Levine, 1997; Sibai, 1990.)

■ Risk Factors

Several factors increase the likelihood that pregnant women will have chronic hypertension. Three of those most frequently cited are ethnicity, obesity, and diabetes. As previously noted, black women are more commonly affected. Related to this, hundreds of blood pressure–related phenotypes and genomic regions have been identified (Ward, 2015). Obesity may raise the prevalence of chronic hypertension tenfold (Chap. 51, p. 904). In addition, obese women are more likely to develop superimposed preeclampsia (Ornaghi, 2018).

The *metabolic syndrome* is a clinical cluster that includes hypertension, high blood sugar, excess fat at the waist, and abnormal cholesterol or triglyceride levels. This constellation is a risk marker for superimposed preeclampsia and for persistent postpartum hypertension (Jeyabalan, 2015). Diabetes is also prevalent in chronically hypertensive women, and its interplay with obesity and preeclampsia is prominent (Leon, 2016). The most frequent comorbidities associated with chronic hypertension are pregestational diabetes—6.6 percent, thyroid disorders—4.1 percent, and collagen vascular disease—0.6 percent (Bateman, 2012).

■ Physiological Effects of Chronic Hypertension

Blood pressure decreases in the first trimester due to a 30-percent drop in systemic vascular resistance. In most women with chronic hypertension, this decline is followed by a rise in blood pressure during the third trimester (Fig. 53-1). Women with chronic hypertension have persistently elevated vascular resistance and possibly reduced intravascular volume expansion (Tihtonen, 2007). Moreover, in women with superimposed preeclampsia, arterial mechanical properties are most marked (Hibbard, 2015).

ADVERSE PREGNANCY EFFECTS

Chronic hypertension is associated with adverse maternal and perinatal outcomes listed in Table 53-3. Rates of these complications positively correlate with the severity and duration of prepregnancy hypertension. Elevated blood pressure defined by criteria in Table 53-1 may herald adverse outcomes similar to those in women with chronic hypertension defined by criteria of the American College of Obstetricians and Gynecologists (Keene, 2019; Sutton, 2018). Development of superimposed preeclampsia, particularly early-onset disease, is especially dangerous.

■ Maternal Morbidity and Mortality

Most women with satisfactorily controlled hypertension and no end-organ damage will do well in pregnancy. Complications are more likely with severe baseline hypertension and documented end-organ damage, especially ventricular hypertrophy and hypertensive glomerulosclerosis (Ambia, 2018, 2019; Morgan, 2016b). Women with chronic hypertension have higher rates of stroke, pulmonary edema, and renal failure (Gilbert, 2007; Zofkie, 2018). These observations were verified in the report from the Nationwide Patient Sample (Bateman, 2012).

TABLE 53-3. Some Adverse Effects of Chronic Hypertension on Maternal and Perinatal Outcomes

Maternal	Perinatal
Superimposed preeclampsia	Stillbirth
HELLP syndrome	Fetal-growth restriction
Placental abruption	Preterm delivery
Pulmonary edema	Neonatal death
Stroke	Neonatal morbidity
Acute kidney injury	Congenital anomalies
Heart failure	
Hypertensive cardiomyopathy	
Myocardial infarction	
Maternal death	

HELLP = hemolysis, elevated liver enzyme levels, low platelet count.

In this study, hypertension complications included pulmonary edema—1.5 per 1000, stroke—2.7 per 1000, mechanical ventilation—3.8 per 1000, acute kidney injury—5.9 per 1000, and maternal mortality—0.4 per 1000. In another report, the maternal mortality rate was greater in women with severe hypertension (Akbar, 2019). Peripartum cardiomyopathy is another associated risk (Cunningham, 2019).

Dangerous blood pressure elevation can develop with chronic hypertension. Systolic pressure ≥160 mm Hg or diastolic pressure ≥110 mm Hg will rapidly cause renal or cardiopulmonary dysfunction or cerebral hemorrhage (Clark, 2012). In addition to hypertensive heart failure mentioned above, coronary artery and aortic dissection have been described (Faden, 2016; Weissman-Brenner, 2004). With superimposed preeclampsia or eclampsia, the maternal prognosis is poor unless the pregnancy is ended (Becker, 2018). Placental abruption is a common and serious complication (p. 946).

Chronic hypertension is associated with a fivefold higher risk for maternal death (Gilbert, 2007). In the United States from 2011 to 2013, hypertensive disorders, including chronic hypertension and preeclampsia syndrome, accounted for 7.4 percent of 2009 pregnancy-related deaths (Creanga, 2017). Undoubtedly related were other causes of death such as cardiovascular conditions—15.5 percent, cerebrovascular accidents—6.6 percent, and cardiomyopathy—11 percent. Moodley (2007) reported similar findings in 3406 maternal deaths from South Africa.

Superimposed Preeclampsia

The reported incidence of superimposed preeclampsia varies from 20 to 50 percent because it is not precisely defined (American College of Obstetricians and Gynecologists, 2018a, 2020; Bramham, 2016; Moussa, 2017). In a Maternal-Fetal Medicine Units Network trial, superimposed preeclampsia was diagnosed in 25 percent of hypertensive gravidas (Caritis, 1998). August and colleagues (2015) hypothesize that this predilection may stem from similar genetic, biochemical, and metabolic abnormalities.

The risk for superimposed preeclampsia positively correlates with the severity of baseline hypertension and the need for antihypertensive therapy (Ankumah, 2014; Morgan, 2016a). Preliminary observations indicate that pregnant women with initial blood pressures ≥130/80 mm Hg early in pregnancy have excessive rates of preeclampsia (Greiner, 2020; Keene, 2019; Roman, 2020). Moreover, compared with women who do not develop preeclampsia, these pressures nadir earlier in gestation (Fig. 53-2) (Morgan, 2016a). The preeclampsia risk is even greater if end-organ damage, such as baseline proteinuria, is present.

Prediction

Thus far, individual predictive tests for superimposed preeclampsia have been disappointing (Conde-Agudelo, 2015; Correa, 2016). First-trimester serum markers used for aneuploidy screening are one group (Chap. 17, p. 338). Of these, inhibin A levels are reduced in patients destined to develop preeclampsia, but its low sensitivity makes it clinically unuseful (Sibai, 2008; Zeeman, 2003). Similarly, maternal serum pregnancy-associated plasma protein-A (PAPP-A) levels are decreased in the first trimester of pregnancies that are later complicated by preeclampsia (Tan, 2018). Of angiogenic and antiangiogenic factors, low plasma levels of placental growth factor (PlGF) and high levels of soluble fms-like tyrosine kinase-1 (sFlt-1) have been associated with superimposed preeclampsia development (Binder 2020; Nzelu, 2020). Last, the umbilical artery pulsatility index appears to be elevated in the first trimester of these pregnancies (O'Gorman, 2016). Combining all these factors may be useful in predicting superimposed preeclampsia (O'Gorman, 2016; Stepan, 2020).

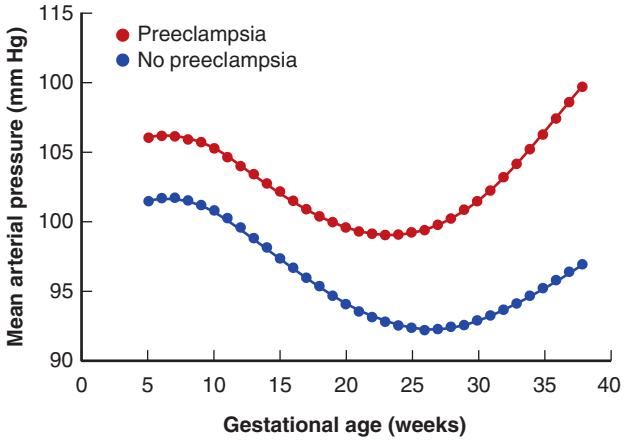

FIGURE 53-2 Blood pressure trends in treated, chronically hypertensive women with and without superimposed preeclampsia. Mean maternal pressures (MAPs) at entry ($p = 0.002$) and throughout gestation ($p < 0.001$) are significantly different for each group. MAP nadir at 23.3 weeks (95% CI, 22.5–24.1) for superimposed preeclampsia versus 26.4 weeks (95% CI, 22.5–27.6) for those without preeclampsia is significant (3.1 weeks, 95% CI, 2.3–4.3).

Prevention

Trials using various medications to prevent preeclampsia in women with chronic hypertension show little or no benefit. Low-dose aspirin has been evaluated most frequently (Mol, 2016; Staff, 2015). The U.S. Preventive Services Task Force concluded with "moderate certainty" that treatment with low-dose aspirin for chronically hypertensive women at high risk for preeclampsia is beneficial (Henderson, 2014). The American College of Obstetricians and Gynecologists (2018a) subsequently recommended initiating 81 mg between 12 and 28 weeks' gestation and continuing therapy until delivery for these at-risk gravidas.

Antioxidants to prevent preeclampsia have been studied. Spinnato and coworkers (2007) randomly assigned 311 women with chronic hypertension to treatment with vitamins C and E or with a placebo. A similar number in both groups developed preeclampsia—17 versus 20 percent, respectively.

Placental Abruption

Chronic hypertension increases the risk two- to threefold for premature placental separation. This event's harms are detailed in Chapter 43 (p. 753). The general obstetrical population risk is 1 abruption in 200 to 300 pregnancies, and in women with

chronic hypertension, this rises to 1 in 60 to 120 pregnancies (Ankumah, 2014; Cruz, 2011; Magee, 2015). Most abruptions affect women with worsening hypertension or superimposed preeclampsia. Vigil-De Gracia and associates (2004) reported an 8.4-percent risk in women with severe hypertension.

Perinatal Morbidity and Mortality

Rates of almost all adverse perinatal outcomes are greater in women with chronic hypertension than in normotensive gravidas. Those who develop preeclampsia have substantially higher adverse outcome rates. As shown in Figure 53-3, adverse outcome rates rise incrementally with increasing blood pressures (Ankumah, 2014). There is evidence to suggest that chronic hypertension—treated or untreated—is associated with congenital anomalies (Battarbee, 2020). Data from untreated women help tease away drug effects on organogenesis. Bateman and coworkers (2015) found an odds ratio of 1.5 for cardiac defects. A systematic review noted a comparable risk ratio of 1.4 (Ramakrishnan, 2015). From one large birth defect study, five cases of fetal esophageal atresia were found in those with untreated hypertension and yielded an adjusted odds ratio of 3.2 (van Gelder, 2015).

The stillbirth frequency with chronic hypertension is substantively greater, and common etiologies include superimposed severe preeclampsia, abruption, and fetal-growth restriction. Rates range from 15 to 24 deaths per 1000 births (Ahmad, 2012; Ankumah, 2014; Bateman, 2012). Low-birthweight neonates also are common and result from fetal-growth restriction, indicated preterm delivery, or both (see Fig. 53-3).

The incidence of fetal-growth restriction averages 20 percent. Zetterström and colleagues (2006) reported a 2.5-fold risk for fetal-growth restriction in 2754 chronically hypertensive Swedish women compared with the risk in normotensive gravidas. Another study of 1609 Dutch nulliparas showed a 1.3-fold greater risk (Broekhuijsen, 2012). As with other complications, fetal-growth dysfunction is more likely in those who develop superimposed preeclampsia. In one study, the incidence of growth-restricted fetuses born to women with superimposed preeclampsia was almost 50 percent compared with only 21 percent in chronically hypertensive women without preeclampsia

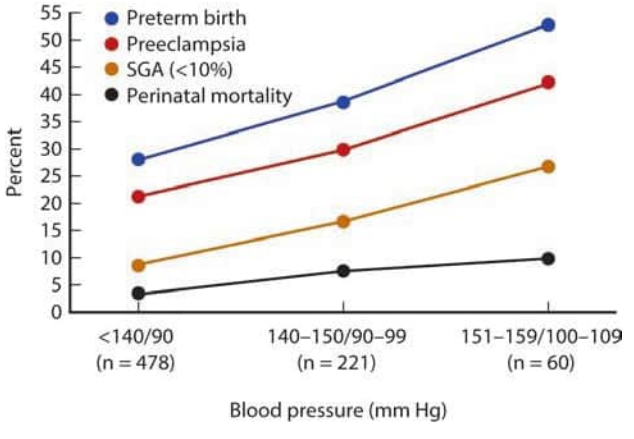

FIGURE 53-3 Frequency of selected adverse maternal and perinatal outcomes by blood pressure stratification in women with mild chronic hypertension. SGA = small for gestational age.

(Chappell, 2008). Last, women with chronic hypertension severe enough to warrant treatment had an 11-percent incidence of fetal-growth restriction sufficiently severe to yield birthweights ≤3rd percentile (Morgan, 2016a). Thus, neonates born to these women have a correspondingly high rate of intensive-care unit (ICU) admission.

All of these adverse perinatal effects of chronic hypertension contribute to the greater perinatal mortality rate, which is two- to fourfold higher than the rate in nonaffected gravidas (American College of Obstetricians and Gynecologists, 2018a). Stratified by severity, the perinatal death rate was 31 per 1000 births in those with mild hypertension, 72 per 1000 births with moderate disease, and 100 per 1000 births in women with severe chronic hypertension (Ankumah, 2014). In a study from Parkland Hospital, the perinatal mortality rate was 32 per 1000 births in women with hypertension severe enough to require treatment (Morgan, 2016a). As expected, the highest rates are in women who develop superimposed preeclampsia, for whom the risk doubles (Al Khalaf, 2021; Grover, 2021).

If diabetes coexists with chronic hypertension, preterm delivery, fetal-growth restriction, and perinatal mortality rates are increased even more (Yanit, 2012). Last, children born to women with chronic hypertension have long-term endocrine and metabolic morbidities, specifically obesity (Imterat, 2020). This epigenetic effect of hypertension and of other maternal chronic diseases is detailed in Chapter 47 (p. 831).

MANAGEMENT DURING PREGNANCY

Chronic hypertension management aims to prevent moderate or severe hypertension, to delay or dampen superimposed preeclampsia, and to reduce rates of adverse maternal or perinatal outcomes. Blood pressure self-monitoring is encouraged, but for accuracy, automated devices must be properly calibrated (Whelton, 2018). Dietary counseling and reduction of behaviors such as tobacco, alcohol, cocaine, or other substance use serve as early interventions. A low-sodium diet and low-dose aspirin are others (Battarbee, 2020; Chaemsaithong, 2020). Last, pharmacologic therapy is instituted to maintain blood pressures within suitable ranges, which are outlined later (p. 951).

Some women—especially those with long-term or untreated hypertension—have complications that raise the risk of adverse pregnancy events. Concentric ventricular hypertrophy and proteinuria are concerns in these women. (Ambia, 2017, 2019; Kim, 2016; Morgan, 2016a,b). Thus, early in prenatal care, cardiovascular and renal baseline functions are assessed with echocardiogram and a 24-hour urine collection for protein measurement.

Antihypertensive Drugs

Treatment of hypertension during pregnancy has included every drug class, but information is still limited regarding safety and efficacy (American College of Obstetricians and Gynecologists 2013, 2018a). Some commonly used drugs are listed in Table 53-4 and the following summary is abstracted from several sources, including the 2020 Prescribers' Digital Reference. Possible fetal effects of many of these drugs are also discussed in Chapter 8.

TABLE 53-4. Some Antihypertensive Drugs Used for Treatment of Chronic Hypertension During Pregnancy[a]

Drug	Comment
Adrenergic-receptor agents[b]	
β-blockers: propranolol, metoprolol	Avoid with asthma, decompensated heart function
α/β-blocker: labetalol	
α-agonist: methyldopa	Less effective for severe hypertension; sedative side effects
Calcium-channel blocking agents[b]	
Nifedipine, amlodipine, verapamil	Avoid with tachycardia
Diuretic[c]	
Hydrochlorothiazide	Begin before 20 weeks' gestation
Vasodilating agent[c]	
Hydralazine	Hypertension complicated by cardiac or renal dysfunction; less effective with severe hypertension

[a]Drugs compatible with pregnancy (Briggs, 2022).
[b]First-line agents.
[c]Second-line agents.

Adrenergic Receptor–Blocking Agents

Peripherally acting β-adrenergic-receptor blockers cause a generalized decline in sympathetic tone and lower cardiac output. Examples are propranolol (Inderal) and metoprolol (Lopressor, Toprol). Atenolol is not recommended because of its link with fetal-growth restriction (Bello, 2021). Labetalol (Normodyne) is an α/β-adrenergic blocker that is considered safe. Clonidine (Catapres) and α-methyldopa (Aldomet) act *centrally* by reducing sympathetic outflow to effect a generalized decreased vascular tone. Drugs in this class most frequently used in pregnancy are methyldopa and labetalol (American College of Obstetricians and Gynecologists, 2018a).

Calcium Channel–Blocking Agents

These drugs are divided into three subclasses based on their calcium-channel actions. Common agents include nifedipine (Procardia, Adalat)—a dihydropyridine—and verapamil (Calan)—a phenylalkyl amine derivative. These agents have negative inotropic effects and thus worsen ventricular dysfunction and congestive heart failure. Theoretically, they may potentiate the vasoactive actions of magnesium sulfate administered for eclampsia neuroprophylaxis. Webster and coworkers (2017) found nifedipine equally effective as labetalol for treatment of chronic hypertension in pregnancy. However, those treated with nifedipine advantageously had less blood pressure variation than those treated with labetalol (Shawkat, 2018). Although data are limited, calcium channel–blocking agents appear to be safe therapy for chronic hypertension during pregnancy (American College of Obstetricians and Gynecologists, 2018a; Briggs, 2022).

Diuretics

Thiazide diuretics are sulfonamides, and these were the first drug group used to successfully treat chronic hypertension. These agents and loop-acting diuretics such as furosemide (Lasix) are commonly used in nonpregnant patients. Short term, they provide sodium and water diuresis with volume depletion. Over time, there is *sodium escape,* and volume depletion partially corrects. Some aspect of lowered peripheral vascular resistance likely contributes to their effectiveness in reducing long-term morbidity (Umans, 2015).

Thiazide drugs may be mildly diabetogenic, and the normal expected volume expansion of pregnancy may be curtailed (Sibai, 1984). Although rates of adverse perinatal outcomes are not greater with diuretic use, concerns have curtailed diuretic use as first-line therapy for chronic hypertension in pregnancy and particularly after 20 weeks' gestation (Working Group Report, 2000). Overall, thiazide diuretics are considered safe in pregnancy (Briggs, 2022).

Vasodilators

Hydralazine (Apresoline) relaxes arterial smooth muscle and has been used parenterally for decades to safely treat severe peripartum hypertension (Chap. 41, p. 722). However, oral hydralazine monotherapy for chronic hypertension is not generally used because of its weak antihypertensive effects and resultant tachycardia. It is employed as an effective vasodilator adjunct for long-term use with other antihypertensives in women with chronic renal insufficiency or ventricular dysfunction.

Angiotensin-Converting Enzyme Inhibitors

These drugs inhibit the conversion of angiotensin-I to the potent vasoconstrictor angiotensin-II. They can cause severe fetal malformations when given in the second and third trimesters. These include oligohydramnios, hypocalvaria, and renal dysfunction (Chap. 8, p. 150). Some preliminary studies also suggest teratogenic effects (Hoeltzenbein, 2018). They are not recommended at any time during pregnancy (Briggs, 2022).

Angiotensin-receptor blockers act in a similar manner. However, instead of blocking the production of angiotensin-II, they inhibit binding to its receptor. They are presumed to have the same adverse fetal effects as angiotensin-converting enzyme inhibitors and also are contraindicated in pregnancy.

Antihypertensive Treatment in Pregnancy

Mild or Moderate Hypertension

Initiating or continuing prepregnancy antihypertensive treatment during pregnancy is debatable for women with mild or moderate hypertension (see Table 53-1). In older observational reports, most pregnancy outcomes were generally good in women with untreated mild to moderate hypertension. However, these studies were relatively small and had widely varying inclusion and outcome criteria. More recently, a Cochrane review of approximately 5000 women with mild to moderate hypertension reported that the risk for severe hypertension in these individuals with initially milder hypertension declined with therapy (Abalos, 2018). The frequencies of superimposed preeclampsia, preterm birth, small-for-gestational age newborns, and perinatal mortality, however, did not differ.

Lowering blood pressure can theoretically decrease uteroplacental perfusion and lead to small-for-gestational age neonates. von Dadelszen and coworkers (2000) found that the decline in mean arterial pressure associated with antihypertensive therapy was linked to a higher frequency of small-for-gestational age newborns. Other studies both confirm and refute these findings (Mitchell, 2019; Morgan, 2020). In two of the larger randomized trials, the incidence of growth restriction was not higher in women randomly assigned to treatment (Gruppo di Studio Ipertensione in Gravidanza, 1998; Sibai, 1990). Conversely, worsening blood pressure itself is associated with abnormal fetal growth. Also, some suggest that the drugs have a direct fetal action (Umans, 2015). Therefore, the question regarding treatment of mild to moderate chronic hypertension in pregnancy is yet to be resolved.

Severe Chronic Hypertension

As classified by the American College of Obstetricians and Gynecologists (2018a), severe hypertension includes a systolic pressure ≥160 mm Hg or a diastolic pressure ≥110 mm Hg. Treatment should be initiated for persistent severe hypertension to reduce maternal morbidity and mortality risks (Akbar, 2019). In women with cardiovascular or renal end-organ damage, treatment may be instituted at systolic pressures ≥140 to 150 mm Hg or diastolic pressures ≥90 to 100 mm Hg in an attempt to mitigate further damage.

Women whose hypertension is severe enough to require antihypertensive therapy or cause end-organ damage carry an increased risk for superimposed preeclampsia. In an older study, Sibai and coworkers (1986) described outcomes from 44 pregnancies in women whose blood pressure at 6 to 11 weeks' gestation was ≥170/110 mm Hg. All were given oral treatment with α-methyldopa and hydralazine to maintain pressures <160/110 mm Hg. Half of these women developed superimposed preeclampsia, and all adverse perinatal outcomes were in this group. Conversely, those women with severe chronic hypertension who did not develop superimposed preeclampsia had reasonably good outcomes. Morgan and colleagues (2016a) confirmed these findings in their study of 447 women requiring treatment for chronic hypertension prior to 20 weeks.

Cardiac abnormalities and renal insufficiency resulting from uncontrolled hypertension raise the risk for adverse pregnancy outcomes. Women with baseline proteinuria >300 mg/d have higher rates of superimposed preeclampsia, preterm birth, and small-for-gestational age neonates compared with those whose 24-hour protein excretion is <300 mg/d (Table 53-5) (Morgan, 2016b). Abnormal cardiac remodeling and left ventricular hypertrophy also are associated with superimposed preeclampsia, preterm birth, and neonatal ICU admission (Ambia, 2018, 2019).

"Tight Control"

During the past decade, the concept of *tight control* of blood pressure has been advocated to optimize maternal and perinatal outcomes. Such control is analogous to that of glycemic control for diabetes management. The observational study by

TABLE 53-5. Selected Pregnancy Outcomes in Women with Chronic Hypertension with and without Baseline Proteinuria[a] and Who Were Treated During Pregnancy

Outcome	Baseline Proteinuria[a]	No Proteinuria	*p* value
Superimposed preeclampsia	79%	49%	<0.001
Abruption	0	1%	0.45
EGA at delivery (mean)[b]	35.1 ± 4.3 wk	37.2 ± 3.3 wk	<0.001
≤30 weeks	18%	6%	0.001
≤34 weeks	34%	17%	0.005
≤37 weeks	48%	26%	0.002
Birthweight (mean)[b]	2379 ± 1028 g	2814 ± 807 g	<0.001
≤3rd percentile	20%	9%	0.01
≤10th percentile	41%	22%	<0.001
Perinatal mortality	36/1000	31/1000	0.47

[a]Defined as ≥300 mg/d protein excretion before 20 weeks' gestation.
[b]Mean ± standard deviations.
EGA = estimated gestational age.

Ankumah and colleagues (2014) noted earlier lends credence to tighter blood pressure control. They showed that the adverse pregnancy outcome risk was lower when blood pressures before 20 weeks' gestation were <140 mm Hg compared with higher-pressure categories and increasing blood pressures.

Unfortunately, those observations were not confirmed. Magee and associates (2015) randomized 987 women to either less-tight or tight control of hypertension. Except for a lower rate of severe hypertension in the tightly controlled group, other outcomes between these two groups did not differ (Table 53-6). Analyzing the same cohort, no gestational age was identified at which tight control was preferable (Pels, 2018). A systematic review reported similar results (Panaitesc, 2017). At this time, no proven benefits or risks are attributed to "tight"—target diastolic pressure <85 mm Hg—versus "less-tight"—target diastolic pressure <100 mm Hg—control of chronic hypertension during pregnancy (American College of Obstetricians and Gynecologists (2018a). A randomized trial—Project CHAP—is ongoing to help address this question (U.S. National Library of Medicine, 2020).

Recommendations for Therapy

Until the treatment of uncomplicated mild to moderate chronic hypertension in pregnancy is confirmed to have benefits, it seems reasonable to follow the guidelines of the American College of Obstetricians and Gynecologists (2018a) and the Society for Maternal-Fetal Medicine (2015). Thus, pregnant women with *severe hypertension* must be treated for maternal neuro-, cardio-, and renoprotection. Treatment is also mandatory for women with prior adverse outcomes such as a stroke, myocardial infarction, and evidence for cardiac or renal dysfunction.

Many find it reasonable to begin antihypertensive treatment in otherwise healthy pregnant women with persistent systolic pressures >150 mm Hg or diastolic pressures >95 to 100 mm Hg (August, 2015; Webster, 2017). Drugs commonly used are listed in Table 53-4. At Parkland Hospital, we initiate treatment with antihypertensive agents at blood pressures ≥150/100 mm Hg. Our preferred regimens include monotherapy with a β-blocking drug such as labetalol or a calcium channel–blocking agent such as nifedipine or amlodipine (Norvasc). Adjunct therapy with a thiazide diuretic seems reasonable for women in the first half of pregnancy. This is more beneficial in black women, in whom the prevalence of salt-sensitive chronic hypertension is high.

Controversy surrounds women who present early in pregnancy and who are already taking antihypertensive drugs (Rezk, 2016). According to the American College of Obstetricians and Gynecologists (2018a) and the Society for Maternal-Fetal Medicine (2015), for women with mild to moderate hypertension, it is *reasonable* to discontinue medications during the first trimester and to restart them if blood pressures approach the severe range. At Parkland Hospital, we continue treatment if the woman is already taking medications when she presents for prenatal care. As exceptions, angiotensin-converting enzyme inhibitors and angiotensin-receptor blockers are stopped.

Some women will have persistently worrisome hypertension despite usual therapy. In these women, development of superimposed preeclampsia becomes a primary concern and is detailed next. Other possibilities include inaccurate blood pressure measurements, suboptimal treatment, illicit drug use, and antagonizing substances such as chronic ingestion of nonsteroidal antiinflammatory drugs (NSAIDs) (Moser, 2006; Sowers, 2005).

TABLE 53-6. Selected Maternal and Perinatal Outcomes in Pregnant Women with Chronic Hypertension According to Less-Tight versus Tight Control

Outcome	Less-Tight Control	Tight Control
Maternal		
Placental abruption	2.2%	2.3%
Severe hypertension[a]	41%	28%
Preeclampsia	49%	46%
HELLP syndrome	1.8%	0.4%
Perinatal		
Deaths	28/1000	23/1000
Weight <10th percentile	16%	20%
Weight <3rd percentile	4.7%	5.3%
Respiratory problem	17%	14%

[a]p <0.001, all other comparisons p >0.05.
HELLP = hemolysis, elevated liver enzyme levels, low platelet count.

Superimposed Preeclampsia

As discussed in Chapter 40 (p. 690), conditions that support the diagnosis of superimposed preeclampsia include worsening hypertension, new-onset proteinuria, neurological symptoms such as severe headaches and visual disturbances, generalized edema, oliguria, and certainly, convulsions or pulmonary edema. These same criteria apply to women with chronic hypertension.

However, preeclampsia can be difficult to diagnose in a chronically hypertensive woman. First, blood pressures may increase during pregnancy in women with chronic hypertension alone and without superimposed preeclampsia. This is most commonly encountered near the end of the second trimester. In the absence of other supporting criteria for superimposed preeclampsia, this likely represents the higher end of the normal blood-pressure curve shown in Figure 53-1. In such women, if preeclampsia is excluded, it is reasonable to begin or to increase the dose of antihypertensive therapy.

As a second diagnostic obstacle, many chronically hypertensive patients have preexisting end-organ damage and laboratory values that mimic preeclampsia. New-onset proteinuria is consistent with the diagnosis of superimposed preeclampsia. However, this is not applicable to women who have underlying renal disease with chronic proteinuria (Cunningham, 1990; Morgan, 2016b). In these women, diagnosing superimposed preeclampsia based on worsening proteinuria is problematic. Laboratory abnormalities that support preeclampsia include rising serum creatinine or hepatic transaminase levels, thrombocytopenia, or any of the facets of HELLP (hemolysis, elevated liver enzyme levels, low platelet count) syndrome. For women with chronic

hypertension and superimposed preeclampsia with severe features, magnesium sulfate for maternal neuroprophylaxis is recommended (Chap. 41, p. 719).

Expectant Management of Early-Onset Preeclampsia

Given that 40 to 50 percent of cases of superimposed preeclampsia develop early and before 37 weeks, considerations for expectant management to allow fetal maturation may be reasonable (Harper, 2016). However, most maternal outcomes are better when women with superimposed preeclampsia are delivered, even when the fetus is markedly preterm. Increased risk for placental abruption, cerebral hemorrhage, and peripartum heart failure attend delivery delays (Cunningham, 1986, 2005; Martin, 2005). And prolonged expectant management is associated with an increased risk of maternal cardiac disease in the ensuing years (Rosenbloom, 2020). In a study from Magee-Women's Hospital, 42 of 68 carefully selected women with a median gestational age of 31.6 weeks were expectantly managed (Samuel, 2011). Despite liberal criteria to mandate delivery, 17 percent of these mothers developed either placental abruption or pulmonary edema. The latency period was extended by a mean of 10 days. There were no perinatal deaths, however, neonatal outcomes were no better than those in the group delivered immediately. Women with superimposed preeclampsia before 34 weeks' gestation may be candidates for expectant management at facilities with adequate maternal and neonatal ICU resources (American College of Obstetricians and Gynecologists, 2018a). At Parkland Hospital, we pursue delivery when superimposed preeclampsia is diagnosed.

Fetal Assessment

Because of greater stillbirth and fetal-growth restriction risks, antepartum fetal surveillance is recommended for women with chronic hypertension. However, data are limited regarding which subpopulations with chronic hypertension benefit most. The ideal test, testing interval, and gestational age of initiation are other unknowns (American College of Obstetricians and Gynecologists, 2018a; Freeman, 2008).

All women with chronic hypertension should undergo a sonographic fetal-growth assessment in the third trimester. Additionally, Chahine and colleagues (2019) recommend that women with low-risk disease undergo weekly antepartum testing. They defined low-risk by four criteria: (1) women ≤35 years of age, (2) mild- to moderate-range blood pressures not requiring medication, (3) no prior hypertension-related adverse pregnancy outcomes, and (4) no end-organ damage. For antepartum testing, a nonstress test or a biophysical profile is suitable (Chap. 20, p. 392).

Women with high-risk disease fail to meet these four criteria. For them, sonography and antepartum testing are considered earlier, and the value of these tools to assess fetal-growth restriction is detailed in Chapter 47 (p. 830). One surveillance algorithm for suspected fetal-growth restriction is outlined in Figure 47-6 (p. 829).

Delivery Timing

For women with mild to moderate chronic hypertension who have an otherwise uncomplicated pregnancy, the American College of Obstetricians and Gynecologists (2018a) recommends waiting for delivery until 37 to 38 weeks' gestation. Women taking antihypertensive drugs are not delivered before $37^{0/7}$ weeks, and those not receiving drug treatment are delivered no earlier than $38^{0/7}$ weeks. A nationally convened consensus committee recommended consideration for delivery at 38 to 39 weeks, that is, ≥37 completed weeks (Spong, 2011). A large population-based Canadian study showed similar results (Ram, 2018). Expectant management beyond 39 weeks' gestation is associated with an increasing incidence of severe preeclampsia, and planned delivery before 37 weeks was associated with a rise in rates of adverse neonatal outcomes (Harper, 206).

For women who have fetal-growth restriction, the decision to deliver incorporates clinical judgment. Maternal health is balanced against estimated fetal weight, gestational age, and chance of neonatal survival.

Intrapartum Considerations

For women with chronic hypertension, obstetrical factors dictate delivery route. Magnesium sulfate is not given unless there is superimposed severe preeclampsia. Epidural analgesia is ideal but does not substantively lower blood pressure. A trial of labor induction is preferable, and many of these women will deliver vaginally (Alexander, 1999; Atkinson, 1995). Similarly, for the growth-restricted fetus, delivery route is based on obstetrical factors. However, many fetuses with growth restriction exhibit nonreassuring fetal heart rate patterns and require cesarean delivery (McKinney, 2016).

For women with superimposed preeclampsia, intrapartum management mirrors that described in Chapter 41 (p. 719). These women may have a longer first-stage labor (Bregand-White, 2017). Epidural analgesia for labor and delivery is optimal, but it is not provided with the intent to treat hypertension (Lucas, 2001). That said, women with superimposed preeclampsia are more sensitive to the acute hypotensive effects of epidural analgesia (Vricella, 2012). Magnesium sulfate neuroprophylaxis is initiated for eclampsia prevention. Severe hypertension—diastolic blood pressure ≥110 mm Hg or systolic pressure ≥160 mm Hg—is treated with either intravenous hydralazine, intravenous labetalol, or oral nifedipine. Some prefer to treat women when the diastolic pressure reaches 100 to 105 mm Hg. Vigil-De Gracia and coworkers (2006) randomly assigned 200 gravidas to receive intravenous hydralazine or labetalol to acutely lower severe high blood pressure. Outcomes were similar except for significantly higher rates of maternal palpitations and tachycardia with hydralazine and significantly greater rates of neonatal hypotension and bradycardia with labetalol.

Postpartum Care

Prevention and management of adverse postpartum complications is similar in women with severe chronic hypertension and in those with severe preeclampsia–eclampsia. For persistent severe hypertension, consideration is given to causes such as pheochromocytoma or Cushing disease (Sibai, 2012). In women with chronic end-organ damage, certain complications

are more common. These include cerebral or pulmonary edema, heart failure, renal dysfunction, or cerebral hemorrhage, especially within the first 48 hours after delivery. These frequently are preceded by sudden elevations of mean arterial blood pressure, especially of the systolic component (Cunningham, 2000, 2005; Martin, 2005).

Following delivery, as maternal peripheral resistance rises, left ventricular workload also grows. This elevation is further aggravated by appreciable and pathological amounts of interstitial fluid that are mobilized to be excreted as endothelial disruption from preeclampsia resolves. In these women, sudden hypertension—either moderate or severe—may exacerbate diastolic dysfunction, cause systolic dysfunction, and lead to pulmonary edema (Cunningham, 1986; Gandhi, 2001). Prompt hypertension control, along with furosemide-evoked diuresis, usually quickly resolves pulmonary edema.

The antihypertensive regimen given antepartum may be continued in the puerperium. In untreated women, labetalol or nifedipine can also be used for persistent hypertension (Sharma, 2017). It also is possible in many women to forestall postpartum hypertension by administering intravenous or oral furosemide to augment normal postpartum diuresis. In one study, 20 mg oral furosemide given daily for 5 days to postpartum women with severe preeclampsia aided blood pressure control (Ascarelli, 2005). A recent randomized trial showed that daily furosemide decreased the need for antihypertensive therapy at hospital discharge (Perdigao, 2020). Daily weights are helpful in this regard. On average, a woman should weigh 15 pounds less immediately after delivery. Excessive extracellular fluid can then be estimated by comparing her last prenatal weight plus 15 pounds against the puerpera's current weight.

Some evidence supports that *chronic* ingestion of NSAIDs in the puerperium elevates blood pressure in women with severe preeclampsia (Vigil-De Gracia, 2017). This may not be problematic if these drugs are given only intermittently and as needed (Blue, 2018). Postpartum admission rates for severe hypertension approximate 1.5 percent (Chornock, 2021).

Discussion of postpartum contraception may begin prior to delivery. As described in Chapter 38 (p. 672), certain methods are less ideal or contraindicated for some women with chronic hypertension. Moreover, for puerpera at highest risk for future pregnancy complications, the Society for Maternal–Fetal Medicine (2019) encourages immediate postpartum long-acting reversible contraceptive (LARC) insertion for suitable candidates.

Long-Term Prognosis

Women with chronic hypertension are at high risk for lifetime cardiovascular complications, especially when accompanied by diabetes, obesity, and the metabolic syndrome. Persistent hypertension 3 years after severe preeclampsia was associated with a thicker left-ventricular septum compared with women who became normotensive (Vaught, 2019). The lifetime cardiovascular morbidity and mortality risks associated with hypertensive disorders of pregnancy are discussed in Chapter 41 (p. 726) (Wu, 2021).

CHAPTER 54

Pulmonary Disorders

During pregnancy, pulmonary disorders are frequently encountered. In one study, asthma and community-acquired pneumonia accounted for almost 10 percent of nonobstetrical antepartum hospitalizations (Gazmararian, 2002). Pregnant women, especially those in the last trimester, tolerate lung disease poorly because of important pregnancy-induced changes in ventilatory physiology (Han, 2018). Lung volumes and capacities are significantly altered. In turn, these shift gas concentrations and acid-base values in blood. These important and sometimes marked changes are reviewed in Chapter 4 (p. 66), and normal values for blood gas can be found in the Appendix (p. 1232). Some of these can be summarized as follows:

1. *Vital capacity* and *inspiratory capacity* increase by approximately 20 percent by late pregnancy.
2. *Expiratory reserve volume* declines from 1300 mL to approximately 1100 mL.
3. Progesterone-driven respiratory stimulation raises *tidal volume* approximately 40 percent.
4. *Minute ventilation* increases 30 to 40 percent due to higher tidal volume. As a result, arterial partial pressure of oxygen (Pao_2) rises from 100 to 105 mm Hg.
5. Expanded metabolic demands cause a 30-percent increase in *carbon dioxide (CO_2) production*. But, because of its concomitantly greater diffusion capacity and hyperventilation, the $Paco_2$ is reduced from 40 to 32 mm Hg.
6. *Residual volume* diminishes approximately 20 percent from 1500 mL to 1200 mL.
7. An expanding uterus and higher intraabdominal pressure lower *chest wall compliance* by one third. This causes a 10- to 25-percent reduction in *functional residual capacity*—the sum of expiratory reserve and residual volumes.

Beginning at 14 to 16 weeks' gestation *forced vital capacity* and *peak expiratory flow* progressively increase (Grindheim, 2012). The result of these pregnancy-induced changes is substantively greater ventilation due to deeper but not more frequent breathing. This is thought to be stimulated by basal oxygen consumption, which incrementally rises from 20 to 40 mL/min in the second half of pregnancy.

ASTHMA

Pathophysiology

Asthma is a chronic inflammatory airway syndrome with a major hereditary component. Polymorphism genes on chromosome 5q that include cytokine gene clusters, β-adrenergic and glucocorticoid receptor genes, and the T-cell antigen receptor gene are associated with greater airway responsiveness and persistent subacute inflammation (Barnes, 2018). Racial differences are seen, and morbidity rates are disproportionately higher in black compared with white women (Kodadhala,

2018). Asthma is etiologically and clinically heterogeneous, and an environmental allergic stimulant such as influenza or cigarette smoke serves as a promoter for susceptible individuals.

The hallmarks of asthma are reversible airway obstruction from bronchial smooth muscle contraction, vascular congestion, tenacious mucus, and mucosal edema. Stimuli cause acute infiltration of eosinophils, mast cells, and T lymphocytes. Inflammatory mediators produced by these and other cells include histamine, leukotrienes, prostaglandins, cytokines, immunoglobulin E (IgE), and many others. F-series prostaglandins and ergonovine exacerbate asthma, and these commonly used uterotonics are avoided if possible.

Clinical Course

Asthma manifestations range from mild wheezing to severe bronchoconstriction, which obstructs airways and decreases airflow. This lowers the forced expiratory volume in 1 second/forced vital capacity (FEV_1/FVC) ratio and the peak expiratory flow rate (PEFR). The work of breathing progressively increases, and patients note chest tightness, wheezing, or breathlessness. Subsequent worsening of oxygenation primarily reflects ventilation–perfusion mismatching. This results from an uneven distribution of airway narrowing.

Varied manifestations of asthma have led to a classification system that considers severity, onset, and duration of symptoms (Table 54-1). With persistent or worsening bronchial obstruction, clinical stages progress as shown in Figure 54-1. Hypoxia initially is mitigated by hyperventilation, which maintains the Pao_2 within a normal range but lowers $Paco_2$, creating respiratory alkalosis. As airway narrowing worsens, the degree of ventilation–perfusion defects is accentuated, and arterial hypoxemia ensues. With severe obstruction, fatigue causes early CO_2 retention and impairs ventilation. Because of hyperventilation, this may only be seen initially as the $Paco_2$ returning to the normal range. With continuing obstruction, respiratory failure follows.

These changes are generally reversible and well tolerated by the healthy nonpregnant individual. However, even early asthma stages may be dangerous for the pregnant woman and her fetus. This is because diminished functional residual capacity and greater pulmonary shunting render the gravida more susceptible to hypoxia and hypoxemia.

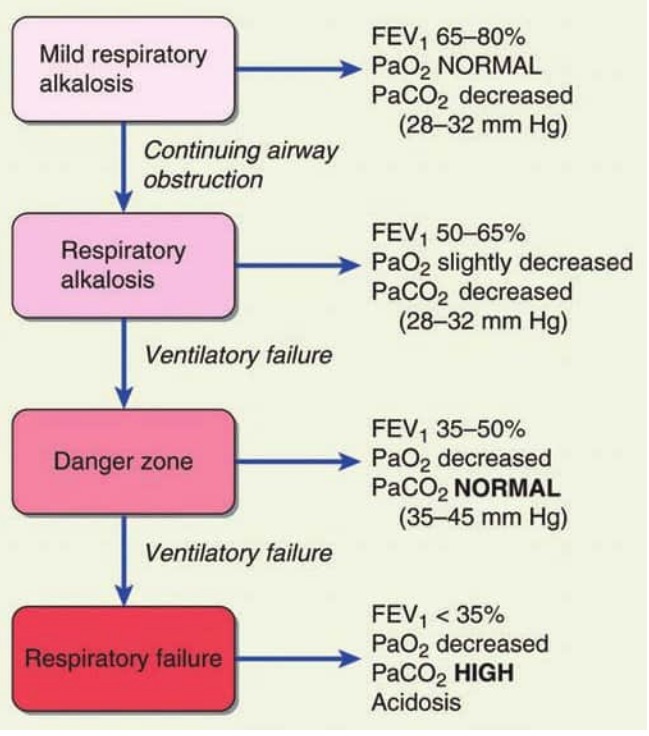

FIGURE 54-1 Clinical stages of asthma. FEV_1 = forced expiratory volume in 1 second.

Effects of Pregnancy on Asthma

Chronic asthma or an acute exacerbation affects up to 8 percent of gravidas (Baghlaf, 2019; Flores, 2020; Mazurek, 2018). Pulmonary function changes in pregnancy are more pronounced in asthmatics compared with healthy women (Zairina, 2015). Despite this, pregnancy has an unpredictable effect on underlying asthma. In a review of more than

TABLE 54-1. Classification of Asthma Severity

	Severity			
		Persistent		
Component	Intermittent	Mild	Moderate	Severe
Symptoms	≤2 d/wk	>2 d/wk, not daily	Daily	Throughout day
Nocturnal awakenings	≤2×/mo	3–4×/mo	>1×/wk, not nightly	Often 7×/wk
Short-acting β-agonist for symptoms	≤2 d/wk	≥2 d/wk, but not >1×/d	Daily	Several times daily
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Lung function	Normal between exacerbations			
FEV_1	>80% predicted	≥80% predicted	60–80% predicted	<60% predicted
FEV_1/FVC	Normal	Normal	Reduced 5%	Reduced >5%

FEV_1 = forced expiratory volume in 1 second; FVC = forced vital capacity.
From National Heart, Lung, and Blood Institute, 2007.

2000 gravidas, approximately a third each improved, remained unchanged, or clearly worsened (Gluck, 2006). Exacerbations are more common with severe disease (Ali, 2013). In a study by Schatz and associates (2003), baseline severity correlated with asthma morbidity during pregnancy. With mild disease, 13 percent of women had an exacerbation and 2.3 percent required admission; with moderate disease, these numbers were 26 and 7 percent; and for severe asthma, 52 and 27 percent. Others have reported similar findings (Charlton, 2013; Hendler, 2006).

Intrapartum exacerbation rates are controversial. In one study, 20 percent of women with mild or moderate asthma had an intrapartum exacerbation (Schatz, 2003). Mabie and coworkers (1992) reported an 18-fold greater exacerbation risk following cesarean versus vaginal delivery. Conversely, Wendel and colleagues (1996) reported exacerbations at the time of delivery in only 1 percent of asthmatics.

Pregnancy Outcome

Asthma remains a potential risk factor for worse pregnancy outcomes despite continued improvements in treatment. Data from two large studies are shown in Table 54-2. The incidences of small-for-gestational-age neonates and perinatal mortality also are significantly greater in women with asthma (Kemppainen, 2018). However, these findings are not consistent among all studies. A study of approximately 3000 pregnancies complicated by asthma showed higher rates of maternal pneumonia and cesarean delivery but not of perinatal mortality (Shaked, 2019). In a European report of 37,585 pregnancies of women with asthma, the risks for most obstetrical complications were not increased (Tata, 2007). Blais and associates (2013) noted that the incidence of spontaneous abortion may be slightly greater in women with asthma.

TABLE 54-2. Maternal and Perinatal Outcomes in Women with Asthma

Asthmatics[a]	Odds Ratio (95% CI)
Maternal outcomes	
Hemorrhage	1.09 (1.03–1.16)
Gestational diabetes	1.10 (1.03–1.19)
Chorioamnionitis	1.12 (1.09–1.15)
Preeclampsia	1.14 (1.06–1.22)
Placental abruption	1.22 (1.09–1.36)
Placenta previa	1.30 (1.08–1.56)
ICU admission	1.34 (1.04–1.72)
Pulmonary embolism	1.71 (1.05–2.79)
Perinatal outcomes	
SGA neonates	1.10 (1.05–1.16)
Preterm delivery	1.17 (1.12–1.23)
Preterm PROM	1.18 (1.07–1.30)
Anomalies	1.48 (1.04–2.09)

[a]Compared with outcomes in 206,468 nonasthmatic women.
CI = confidence interval; ICU = intensive care unit; PROM = premature rupture of membranes; SGA = small for gestational age.
Data from Baghlaf, 2019; Mendola, 2013, 2014.

Some evidence suggests that severe disease, poor control, or both is linked to higher morbidity rates. In a study by the Maternal-Fetal Medicine Units (MFMU) Network, delivery before 37 weeks' gestation was not more frequent in pregnancies of women with asthma compared with controls (Dombrowski, 2004). However, for women with severe asthma, the rate was approximately twofold higher. The MFMU Network study suggests also a direct relationship of baseline pregnancy FEV_1 with birthweight and an inverse relationship with rates of gestational hypertension and preterm delivery (Schatz, 2006). Kemppainen and coworkers (2018) found that women requiring treatment for asthma during pregnancy are at greater risk for adverse perinatal outcomes.

Maternal morbidity rises markedly with status asthmaticus and includes life-threatening complications such as muscle fatigue with respiratory arrest, pneumothorax, pneumomediastinum, acute cor pulmonale, and cardiac arrhythmias. Not surprisingly, maternal and perinatal mortality rates rise substantively when mechanical ventilation is required.

Fetal Effects

Animal and human studies suggest that development of maternal respiratory alkalosis leads to fetal hypoxemia well before the alkalosis compromises maternal oxygenation (Rolston, 1974). Theories hypothesize that the fetus is jeopardized by decreased uterine blood flow, reduced maternal venous return, and an alkaline-induced leftward shift of the oxyhemoglobin dissociation curve (Chap. 50, p. 886). The fetal response to maternal hypoxemia is lower umbilical blood flow, higher systemic and pulmonary vascular resistance, and decreased cardiac output. Several studies cited above confirm that fetal-growth restriction rates rise with asthma severity. Because the fetus may be seriously compromised, aggressive management is necessary. Monitoring the fetal response is, in effect, an indicator of maternal status. A return of moderate variability or accelerations in the fetal heart rate is an indicator of improving maternal oxygen status.

Possible teratogenic or adverse fetal effects of drugs given to control asthma are a concern. Several reports show a slightly greater risk for abnormalities such as cleft lip and palate and autism spectrum disorders, but further verification is necessary (Eltonsy, 2016; Gidaya, 2016; Murphy, 2013b; Wang, 2014). It is worrisome that up to half of women discontinue essential treatment between 5- and 13-weeks' gestation (Enriquez, 2006).

■ Clinical Evaluation

The subjective severity of asthma frequently does not correlate with objective measures of airway function or ventilation. Clinical examination also can be an inaccurate predictor, but useful signs include labored breathing, tachycardia, pulsus paradoxus, prolonged expiration, and use of accessory muscles. Signs of a potentially fatal exacerbation include central cyanosis and altered consciousness.

Pulmonary function testing should be routine in the management of asthma. Sequential measurement of the FEV_1 or of the PEFR is the best measure of severity (see Table 54-1).

An FEV_1 <1 L, or <20 percent of predicted value, correlates with severe disease defined by hypoxia, poor response to therapy, and a high relapse rate. The PEFR correlates well with the FEV_1, and it can be measured reliably with inexpensive portable meters. It is advantageous for each woman to determine her own baseline when asymptomatic to compare with values when symptomatic.

Management of Chronic Asthma

Asthma management by an experienced team produces better outcomes (Lim, 2014; Wendel, 1996). Management guidelines include:

1. Patient education about general asthma management and its effect on pregnancy (Bonham, 2018; Robijn, 2019).
2. Avoidance or control of precipitating environmental factors. Viral infections that include the common cold are frequent triggers (Ali, 2013; Murphy, 2013a). Influenza and pneumococcal vaccination is encouraged.
3. Objective assessment of pulmonary function with PEFR or FEV_1 and of fetal status with serial growth ultrasound and antepartum testing if indicated (Chap. 20, p. 392).
4. Pharmacological therapy with appropriate combinations and doses to provide baseline control and treat exacerbations. Periodic medication reviews are helpful to avoid noncompliance (Robijn, 2019).
5. Treatment of related disorders including smoking, depression, rhinitis, and gastroesophageal reflux (Bonham, 2018).

In general, women with moderate to severe asthma ideally measure and record either their FEV_1 or PEFR twice daily. The FEV_1 ideally is >80 percent of predicted. For PEFR, predicted values range from 380 to 550 L/min. Each woman has her own baseline value, and therapeutic adjustments can be made using this (American College of Obstetricians and Gynecologists, 2019). Another described method is a management algorithm using fractional exhaled nitric oxide (FeNO) as a noninvasive marker of airway inflammation (Powell, 2011). Asthma exacerbations were reduced by 50 percent with this approach (Clifton, 2019).

Agents for Chronic Treatment

Selection depends on disease severity. No therapeutic regimen for management of asthma in pregnancy is universally accepted (Bain, 2014). β-agonists help abate bronchospasm, and corticosteroids treat inflammation. Stepwise regimens recommended for outpatient management are listed in Figure 54-2.

For mild intermittent asthma, short-acting inhaled β-agonists as needed are usually sufficient. Table 54-3 lists suitable agents.

For persistent asthma, most inhaled corticosteroids (ICS) are administered twice daily. The goal is to reduce β-agonists use for symptomatic relief. Initial low-dose ICS may be augmented to medium-ranging dosing if the moderate or severe symptoms shown in Table 54-1 persist. A case-control study from Canada with a cohort of more than 15,600 nonpregnant women with asthma showed that ICS reduced hospitalizations by 80 percent (Blais, 1998). At Parkland Hospital, Wendel and colleagues (1996) achieved a 55-percent reduction in readmissions when severe exacerbations were treated with ICS. In one study of nonpregnant subjects with mild asthma, as-needed budesonide-formoterol, which is an aerosol ICS and β-agonist combination, was superior to albuterol alone to prevent exacerbations (Beasley, 2019). This is incorporated in new guidelines (Cloutier, 2020).

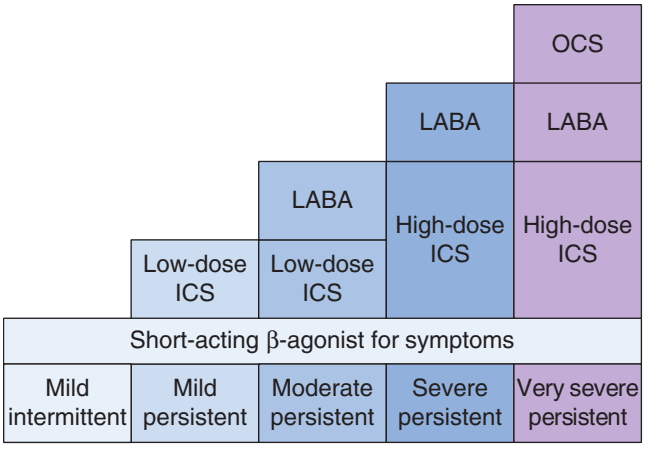

FIGURE 54-2 Stepwise approach to asthma treatment. ICS = inhaled corticosteroids; LABA = long-acting β-agonists; OCS = oral corticosteroids. (Barnes, 2018; National Heart, Lung, and Blood Institute, 2007.)

Theophylline has been used less frequently since ICS became available. Minimal benefit is gained with these compounds, and they have a high rate of side effects. However, some theophylline derivatives are considered useful for oral maintenance therapy if the initial response to ICS and β-agonists is not optimal (Barnes, 2018).

Of other agents, antileukotrienes inhibit leukotriene synthesis and include zileuton, zafirlukast, and montelukast. These drugs are given orally or by inhalation for prevention, but they are ineffective for acute disease (Barnes, 2018). For maintenance, they are used in conjunction with ICS to allow minimal corticosteroid dosing. Approximately half of individuals with asthma will improve with these drugs. However, they are less effective than ICS, and experience with their use in pregnancy is limited (Fanta, 2009). Last, cromones, which are mast cell degranulation inhibitors, are ineffective for acute asthma. They are used primarily to treat childhood asthma.

Vitamin D

Epidemiological data support an association between vitamin D insufficiency and asthma severity. The proposed mechanism is modulation of immunological pathways that diminish inflammatory responses (Pfeffer, 2018). Jensen and coworkers (2019) reported that pregnant women with asthma have low vitamin D levels. One systematic review suggested that increasing maternal vitamin D intake might prevent childhood asthma (Shi, 2021). Adams and colleagues (2021) reported an association between decreased maternal vitamin D levels and childhood wheezing. However, a randomized trial with antenatal vitamin D supplementation showed no lowering of childhood asthma risks at 6 years of age (Brustad, 2019).

TABLE 54-3. Chronic Asthma Treatment

Agent[a]	Brand Name	Available Doses per Puff	Dosage		
SABA Inhaler					
Albuterol	Proventil HFA, Ventolin HFA, ProAir HFA	90 μg	1-2 puffs every 4–6 hr		
Levalbuterol	Xopenex HFA	45 μg	1–2 puffs every 4–6 hr		
ICS Inhaler[b]			**Daily Corticosteroid Dosing**		
			Low	**Medium**	**High**
Beclomethasone HFA	QVAR	40, 80 μg	80–240 μg	>240–480 μg	>480 μg
Budesonide DPI	Pulmicort	90, 180, 200 μg	180–600 μg	>600–1200 μg	>1200 μg
Ciclesonide HFA	Alvesco	80, 160 μg	80–160 μg	>160–320 μg	>320 μg
Flunisolide HFA	Aerospan	80 μg	320 μg	>320–640 μg	>640 μg
Fluticasone furoate DPI	Arnuity Ellipta	100, 200 μg daily	100 μg	NA	200 μg
Fluticasone propionate DPI	Flovent Diskus	50, 100, 250 μg	100–300 μg	>300–500 μg	>500 μg
Fluticasone propionate HFA	Flovent HFA	44, 110, 220 μg	88–264 μg	>264–440 μg	>440 μg
Mometasone DPI	Asmanex	110, 220 μg	110–220 μg	330–440 μg	>440 μg
Mometasone HFA	Asmanex HFA	100, 200 μg	200 μg	400 μg	>400 μg
LABA /ICS Inhaler[b]					
Budesonide/formoterol	Symbicort	80/4.5, 160/4.5 μg	320/18 μg	>320/18–640/18 μg	>640/18 μg
Fluticasone/salmeterol DPI	Advair Diskus	100/50, 250/50, 500/50 μg	100/50–350/100 μg	350/100–500/100 μg	>500/50 μg
Fluticasone/salmeterol HFA	Advair HFA	45/21, 115/21, 230/21 μg	100/50–250/50 μg	300/50–500/50 μg	>500/50 μg
Fluticasone/salmeterol DPI	AirDuo Respiclick	55/14, 113/14, 232/14 μg	110/28 μg	226/28 μg	464/28 μg
Fluticasone/vilanterol	Breo Ellipta	100/25, 200/25 μg daily	100/25 μg	NA	200/25 μg
Mometasone/formoterol	Dulera	110/5, 200/5 μg	NA	400/20 μg	800/20 μg

[a]Agents in each group are arranged alphabetically.
[b]Twice daily dosing unless otherwise stated.
DPI = dry powder inhaler; HFA = hydrofluoroalkane (an aerosol propellant); hr = hour; ICS = inhaled corticosteroid; LABA = long-acting beta agonist; NA = not applicable; SABA = short-acting beta agonist.
American Academy of Allergy Asthma & Immunology, 2020; National Heart, Lung, and Blood Institute, 2007; Therapeutic Research Center, 2017.

Management of Acute Asthma

Early Treatment

Treatment of acute asthma during pregnancy is similar to that for the nonpregnant patient (Figure 54-3). Importantly, the threshold for hospitalization is significantly lower. Intravenous (IV) hydration may help clear pulmonary secretions, and supplemental oxygen is given by mask. The therapeutic aim is to maintain the Pao_2 >60 mm Hg, and preferably normal, along with 90- to 95-percent oxygen saturation. Baseline pulmonary function testing includes FEV_1 or PEFR. Continuous pulse oximetry and electronic fetal monitoring, depending on gestational age, may provide useful information. Arterial blood gas analysis aides in assessing the severity of an acute attack by providing objective assessment of maternal oxygenation, ventilation, and acid-base status (see Fig. 54-1). However, Wendel and associates (1996) found that *routine* arterial blood gas analysis did not help to manage most pregnant women who required admission for asthma control. If used, the results must be interpreted in relation to normal values for pregnancy. For example, a $Paco_2$ >35 mm Hg with a pH <7.35 is consistent with hyperventilation and CO_2 retention in a pregnant woman. Antibiotics are not given unless pneumonitis is comorbid (p. 962) (Terraneo, 2014).

First-line therapy for acute asthma includes a short-acting β-adrenergic agonist, such as terbutaline, albuterol, isoetharine, epinephrine, isoproterenol, or metaproterenol, which are given subcutaneously, taken orally, or inhaled. In severely ill women, these drugs can be given intravenously (Barnes, 2018).

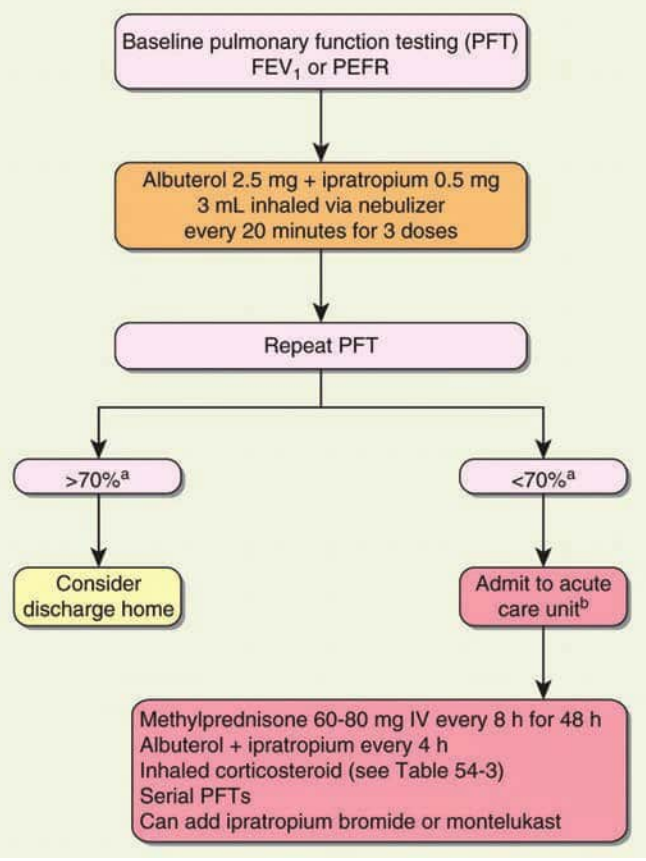

FIGURE 54-3 Protocol for management of acute asthma at Parkland Hospital. [a]Of predicted value. [b]Labor & delivery unit, recovery area, or intensive care unit. FEV_1 = forced expiratory volume at 1 second; PEFR = peak expiratory flow rate (liters per minute).

Systemic corticosteroids are given early to all patients with severe acute asthma. One regimen is oral prednisone or prednisolone or IV methylprednisolone in a dose of 30 to 45 mg daily for 5 to 10 days without tapering (Barnes, 2018). At Parkland Hospital, we use a higher daily IV dose (see Figure 54-3). Because their onset of action is several hours, corticosteroids are given initially along with β-agonists for severe acute asthma. If the response is unsatisfactory, a nebulized anticholinergic drug may be added. These drugs act to relax smooth muscle and diminish mucus. By nebulizer, a 0.5-mg dose of ipratropium bromide is provided every 20 minutes as needed for three consecutive doses. Additional doses every 6 to 8 hours can be used (National Heart, Lung, and Blood Institute, 2007). Also, for severe exacerbations, IV magnesium sulfate or theophylline may prove efficacious.

Further management depends on the severity and response to therapy. If initial therapy with a β-agonist is associated with FEV_1 or PEFR improvement to a level >70 percent of baseline, discharge can be considered. For the woman with obvious respiratory distress or with an FEV_1 or PEFR <70 percent of predicted after three doses of a β-agonist, admission is usually advisable (Lazarus, 2010). Intensive therapy is continued with short-acting inhaled β-agonists, IV corticosteroids, inhaled anticholinergics, and close observation for worsening respiratory distress or fatigue in breathing (Racusin, 2013). The woman is cared for in the delivery unit or an intermediate or intensive care unit (ICU) (Dombrowski, 2006; Zeeman, 2003).

Status Asthmaticus and Respiratory Failure

Severe asthma of any type not responding after 30 to 60 minutes of intensive therapy is termed *status asthmaticus*. Generally, management of nonpregnant patients with status asthmaticus in an intensive care setting results in a good outcome. In pregnant women, consideration should be given to early intubation when maternal respiratory status worsens despite aggressive treatment (see Fig. 54-1). Fatigue, CO_2 retention, and hypoxemia are indications for mechanical ventilation (Chan, 2015). In refractory cases, venovenous extracorporeal membrane oxygenation (ECMO) has been successfully used for status asthmaticus during pregnancy (Clifford, 2018; Steinack, 2017).

■ Labor and Delivery

For the laboring patient who has symptomatic asthma, the PEFR or FEV_1 is determined on admission, and serial measurements are taken. Maintenance medications are continued through delivery, and stress-dose corticosteroids are not necessary (Sylvester-Armstrong, 2020).

Oxytocin or prostaglandins E_1 or E_2 can be used for cervical ripening and induction. A non-histamine-releasing narcotic such as fentanyl may be preferable to meperidine for labor, and epidural analgesia is ideal. For surgical delivery, conduction analgesia is preferred because tracheal intubation can trigger severe bronchospasm. Postpartum hemorrhage is treated with oxytocin or prostaglandin E_1 (misoprostol) or E_2 (dinoprostone [Prostin]). Prostaglandin $F_{2\alpha}$ (Hemabate) is contraindicated because it may cause significant bronchospasm.

ACUTE BRONCHITIS

Large airway infection is manifest by cough without pneumonitis. It is common in adults, especially in winter months. Infections are usually caused by viruses, and of these, influenza A and B, parainfluenza, respiratory syncytial, coronavirus, adenovirus, and rhinovirus are frequent isolates (Irwin, 2018). Bacterial agents causing community-acquired pneumonia are rarely implicated. The cough of acute bronchitis persists for 10 to 20 days and occasionally lasts for a month or longer. Evidence supporting the benefits of antimicrobial therapy is limited (Smith, 2017). As supportive care, cough suppressants containing dextromethorphan and expectorants with guaifenesin appear safe in pregnancy (Briggs, 2022).

PNEUMONIA

Infection of the lungs is a leading cause of death in the United States (Heron, 2017). Current classification includes *community-acquired pneumonia (CAP),* which is typically encountered in healthy young women, including gravidas. Patients in outpatient care facilities develop an infection that more closely resembles *hospital-acquired pneumonia (HAP)* (Mandell, 2018).

In most cases of CAP, the offending pathogen is not identified. In a study from the Centers for Disease Control and Prevention (CDC), pathogens were identified in only 38 percent of nearly 2500 adults with pneumonia (Jain, 2015). These

included viruses in 23 percent, bacteria in 11 percent, both in 3 percent, and fungi or protozoa in 1 percent. These percentages changed in 2020 due to the COVID-19 pandemic (p. 964). Half of bacterial isolates were *Streptococcus pneumoniae*.

Pneumonia in pregnant women is relatively common (Brito, 2011; Sheffield, 2009). Gazmararian and coworkers (2002) reported that pneumonia accounts for 4.2 percent of antepartum admissions for nonobstetrical complications. Pneumonia is also a frequent indication for postpartum readmission (Belfort, 2010). Admission rates for respiratory illnesses during influenza season are higher than rates in the remaining months.

Regardless of etiology, mortality from pneumonia is infrequent in young women. However, during pregnancy, severe pneumonitis with appreciable loss of ventilatory capacity is less well tolerated (Callaghan, 2015; Rogers, 2010). Hypoxemia and acidosis are also poorly accommodated by the fetus, and they may stimulate preterm labor after midpregnancy. Because many cases of pneumonia follow viral upper respiratory illnesses, worsening or persistence of symptoms may represent developing pneumonia. Any gravida suspected of having pneumonia should undergo chest radiography.

Bacterial Pneumonia

Many bacteria that cause CAP, such as *S pneumoniae*, are part of the normal flora. Some factors that perturb the symbiotic relationship between colonizing bacteria and mucosal phagocytic defenses include acquisition of a virulent strain or bacterial infections following a viral infection. Cigarette smoking and chronic bronchitis favor colonization with *S pneumoniae*, *Haemophilus influenzae*, and *Legionella* species. Other risk factors include asthma, binge drinking, and human immunodeficiency virus (HIV) infection (Mandell, 2018).

Incidence and Causes

Pregnancy itself does not appear to predispose to pneumonia. Jin and associates (2003) reported the antepartum hospitalization rate for pneumonia to be 1.5 per 1000 deliveries—almost identical to the rate of 1.47 per 1000 for nonpregnant women. Similarly, among 75,000 pregnancies at Parkland Hospital, the incidence was 1.5 per 1000 (Yost, 2000). As discussed, at least half are caused by viruses—influenza A and B, metapneumovirus, adenovirus, and respiratory syncytial virus (Mandell, 2018). A fourth are bacterial, and *S pneumoniae* causes half of these. Community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) has emerged as a common pathogen that may cause necrotizing pneumonia (Moran, 2013). Occasionally, Legionnaires disease is encountered (Close, 2016).

Diagnosis

Typical symptoms of pneumonia include cough, dyspnea, sputum production, and pleuritic chest pain. Mild upper respiratory symptoms and malaise precede these symptoms, and mild leukocytosis is usually present. Chest radiography is essential for diagnosis (Fig. 54-4). Radiographical findings do not accurately predict the etiology, and as discussed, the responsible pathogen is often not identified. Tests to identify a specific agent are optional (Mandell, 2018). Sputum cultures, polymerase chain reaction (PCR) tests, serological testing, cold agglutinin identification, and tests for bacterial antigens are not routinely recommended. Exceptions are rapid PCR testing of nasal swab samples for influenza A and B and for COVID-19. An assay to screen for all three is available. Determination of serum procalcitonin levels did not improve diagnostic efficacy (Huang, 2018).

FIGURE 54-4 Chest radiograph in a pregnant woman with right middle lobe and left upper lobe pneumonia. Rounded right middle lobe and left apical infiltrates are consistent with the diagnosis.

Management

Many healthy young adults can be safely treated as outpatients, and the pneumonia severity index (PSI) and the CURB-65 scoring system are guides to admission (Mandell, 2018). Neither has been studied in pregnancy, and at Parkland Hospital, we hospitalize all gravidas with radiographically proven pneumonia. Outpatient therapy or 23-hour observation with optimal follow-up are reasonable options. Table 54-4 displays risk factors that should prompt consideration for hospitalization (Mandel, 2018).

With severe disease, admission to an ICU or intermediate care unit is advisable. Approximately 20 percent of pregnant women with pneumonia admitted to Parkland Hospital require this level of care (Zeeman, 2003). Severe pneumonia is a relatively common cause of acute respiratory distress syndrome (ARDS) during pregnancy, and mechanical ventilation may become necessary (Chap. 50, p. 885). In a review of 51 gravidas who required mechanical ventilation, 12 percent had pneumonia (Jenkins, 2003). Still, their mortality rate is lower than that for other causes of ARDS (Rush, 2017).

TABLE 54-4. Risk Factors for Early Deterioration in Community-Acquired Pneumonia

Respiratory rate ≥30/min
Arterial O_2 saturation <90%
Hypothermia: core temperature <36°C
Hypotension requiring aggressive fluid resuscitation
Multilobular infiltrates
Leukopenia: <4000/μL
Thrombocytopenia: <100,000/μL
Confusion/disorientation

TABLE 54-5. Empirical Inpatient Antimicrobial Treatment for Community-Acquired Pneumonia in Pregnancy[a]

Uncomplicated, otherwise healthy[b,c]

Macrolides[c]: clarithromycin, 500 mg twice daily or azithromycin, 500 mg daily. Both have IV and oral forms

Plus

Oseltamivir, 75 mg orally twice daily for 5 d for suspected influenza A infection

Severe pneumonia[d]

Respiratory fluoroquinolones: moxifloxacin, 400 mg daily or levofloxacin, 750 mg daily. Both have IV and oral forms

or

β-lactams: ampicillin/sulbactam, 3 g IV every 6 hr; ceftriaxone, 1–2 g daily; ceftaroline, 600 mg IV every 12 hr; or cefotaxime, 1–2 g every 8 hr. The β-lactam should be coupled with a macrolide above

Plus

Oseltamivir, as above, for suspected influenza A infection

[a]Antibiotics are discontinued after 5 to 7 days in those afebrile for 48 to 72 hours.
[b]Use as inpatient or outpatient regimen.
[c]Doxycycline may be given instead if postpartum.
[d]See Table 54-4 for criteria.
ER = extended release; IV = intravenous.

Initial antimicrobial and antiviral treatment is empirical (Mandell, 2018). In most otherwise healthy pregnant women, bacterial pneumonias are caused by pneumococci, *Mycoplasma*, or *Chlamydophila*. Monotherapy initially is with a macrolide (Table 54-5). Yost and colleagues (2000) reported that erythromycin monotherapy, given intravenously and then orally, was effective in all but one of 99 pregnant women with uncomplicated pneumonia. During influenza season, we routinely administer oseltamivir (Tamiflu) along with empirical therapy for bacterial pneumonia.

For women with more severe disease according to criteria in Table 54-4, Mandell and Wunderink (2018) recommend: (1) a respiratory fluoroquinolone or (2) a macrolide plus a preferred β-lactam (see Table 54-5). Resistance of pneumococcal isolates to macrolides will favor fluoroquinolone regimens. The teratogenicity risk of fluoroquinolones is low, and these should be given if indicated (Briggs, 2022). If MRSA is suspected, IV vancomycin, 15 mg/kg every 12 hours, or linezolid, 600 mg every 12 hours, is added (Metlay, 2019).

Clinical improvement is usually evident in 48 to 72 hours with resolution of fever in 2 to 4 days. With improvement, patients can be transitioned to oral forms. Treatment of uncomplicated pneumonia is recommended for 5 to 7 days total (Musher, 2014). Patients should be afebrile for 48 to 72 hours and demonstrate signs of clinical stability before therapy is discontinued. Radiographic abnormalities may take up to 6 weeks to completely resolve (Torres, 2008).

Worsening disease is a poor prognostic feature, and serial radiography is recommended if fever persists. Even with improvement, however, approximately 20 percent of women develop a pleural effusion. Treatment failure may occur in up to 15 percent of cases, and a wider antimicrobial regimen and more extensive diagnostic testing is warranted. For example, in some cases, computed tomography of the chest may be necessary to identify empyema that requires drainage.

Pregnancy Outcome

Maternal and perinatal morbidity and mortality rates from pneumonia remain formidable. In five studies with a total of 632 women published after 1990, almost 7 percent required intubation and mechanical ventilation, and the maternal mortality rate was 0.8 percent.

In up to a third of cases of acute lung infection, prematurely ruptured membranes and preterm delivery are frequent complications (Getahun, 2007; Shariatzadeh, 2006). Likely related to these, older studies report a twofold increase in rates of low-birthweight neonates (Sheffield, 2009). In one population-based study from Taiwan of nearly 219,000 births, incidences of preterm and growth-restricted newborns and of preeclampsia and cesarean delivery were significantly higher (Chen, 2012).

Prevention

Two pneumococcal vaccines are available—a 23-serotype preparation (PPSV23 [Pneumovax]) and a newer 13-serotype vaccine (PCV13 [Prevnar 13]). PPSV23 is 60- to 70-percent protective, and its use lowers emergence of drug-resistant pneumococci. Neither vaccine is recommended for healthy pregnant women. However, for gravidas with chronic diabetes mellitus or with chronic heart, lung, or liver disease, one lifetime dose of PPSV23 is suggested, if not previously provided. Moreover, for women with chronic immunocompromise, generalized malignancy, chronic renal disease, cochlear implant, or asplenia, such as with sickle-cell disease, one lifetime PCV13 dose is followed by one PPSV23 dose at least 8 weeks later and then again 5 years later if not provided previously (Freedman, 2021).

■ Influenza Pneumonia

Influenza A and B are RNA viruses that cause potentially epidemic respiratory infection, including pneumonitis, in the

winter months. The virus is spread by aerosolized droplets and quickly infects ciliated columnar epithelium, alveolar cells, mucus gland cells, and macrophages.

Clinical Presentation

Each year, 10 percent of pregnant women develop influenza (Cantu, 2013). Disease onset follows 1 to 4 days after exposure, and common symptoms include fever, cough, myalgia, and chills (Wright, 2018). In most healthy adults, infection is self-limited. Pneumonia is the most frequent complication and mimics bacterial pneumonia. According to the CDC, infected pregnant women are more likely to be hospitalized and admitted to an ICU (Lindley, 2019). Others have corroborated these observations (Mertz, 2019; Prasad, 2019). At Parkland Hospital during the 2003–2004 influenza season, pneumonia developed in 12 percent of pregnant women with influenza (Rogers, 2010).

The 2009–2010 pandemic with the influenza (A/H1N1) pdm09 strain was particularly severe (Rasmussen, 2014). In an MFMU Network study, 10 percent of pregnant or postpartum women admitted with H1N1 influenza were cared for in an ICU, and 11 percent of these patients died (Varner, 2011). Risk factors included advanced pregnancy, smoking, and chronic hypertension. Overall, influenza accounted for 12 percent of pregnancy-related deaths during the 2009–2010 pandemic (Callaghan, 2015). During the 2013–2014 influenza season, a fourth of pregnant women admitted to California ICUs died (Louie, 2015). ECMO may be lifesaving (Anselmi, 2015; Saad, 2016).

Rapid PCR testing of nasal swab samples for influenza A and B is available. Primary influenza pneumonitis is characterized by sparse sputum production and radiographic interstitial infiltrates (Wright, 2018). More commonly, secondary or mixed pneumonia develop from bacterial superinfection by streptococci or staphylococci after 2 to 3 days of initial clinical improvement. The CDC (2007) reported several cases in which CA-MRSA caused influenza-associated pneumonitis with a case-fatality rate of 25 percent.

Management

Supportive treatment is recommended for uncomplicated influenza, and early antiviral therapy is effective (Oboho, 2016; Wright, 2018). The American College of Obstetricians and Gynecologists (2018a) recommends treatment of all pregnant women with suspected or proven influenza. This is regardless of rapid influenza testing, which can have false-negative results (Datkhaeva, 2019). Hospitalization is considered for severely ill women and for those with pneumonia. Influenza hospitalization rates for those with advanced pregnancy are higher compared with nonpregnant women (Dodds, 2007; Schanzer, 2007).

Treatment is with neuraminidase inhibitors, which interfere with release of progeny virus from infected host cells and thus prevent infection of new host cells. The preferred agent is oseltamivir (Tamiflu), which is given orally, 75 mg twice daily. An alternative is zanamivir (Relenza), which is given by inhalation, 10 mg twice daily. Recommended treatment duration with either is 5 days. Last, peramivir (Rapivab) may be given as a 600-mg IV dose over 15 to 30 minutes. All shorten the course of illness by 1 to 2 days, and they probably reduce the risk for pneumonitis (Belgi, 2014; Muthuri, 2014). Few data guide use of these agents in pregnant women, but the drugs are not teratogenic in animal studies and are considered low risk (Briggs, 2022). Recently, the endonuclease inhibitor baloxavir marboxil (Xofluza) was approved for use in nonpregnant individuals but is not recommended for pregnant women.

Prevention

Vaccination against influenza A is recommended by the American College of Obstetricians and Gynecologists (2018b) and the Centers for Disease Control and Prevention (2019a). During the 2018–2019 flu season, the CDC reported that only half of pregnant women received the influenza vaccine (Lindley, 2019). In a recent survey, however, O'Leary and colleagues (2019) reported a 10-percent vaccine refusal rate in office practices.

Any inactivated influenza vaccines (IIV) or recombinant influenza vaccine (RIV) may be used and is given once each flu season. Live attenuated influenza vaccine (LAIV) should not be used in pregnancy (Freedman, 2021). Prenatal vaccination affords some temporary protection for infants (Madhi, 2014; Munoz, 2019; Tita, 2016). The vaccine has not been linked with birth defects or adverse childhood health effects at 5 years of age (Briggs, 2022; Conlin, 2018; Walsh, 2019). In one case-control study, an association with vaccination and miscarriage was found (Donahue, 2017). However, the observations were not definite and should not alter clinical practice (Rasmussen, 2019; Sperling, 2018). Effects on pregnancy outcomes are discussed in more detail in Chapter 67 (p. 1187).

A second coronavirus—Middle East Respiratory Syndrome (MERS-CoV)—originated in Saudi Arabia in 2013. Fortunately, the epidemic was contained and short lived.

Coronavirus

The first coronaviral infection in China in 2002 that caused severe acute respiratory syndrome (SARS) was termed SARS-CoV. It caused atypical pneumonitis with a case-fatality rate of approximately 10 percent (Dolin, 2012). SARS in pregnancy had a case-fatality rate of up to 40 percent (Maxwell, 2017). Ng and associates (2006) reported that the placentas from 7 of 19 cases showed abnormal intervillous or subchorionic fibrin deposition in three, and extensive fetal thrombotic vasculopathy in two.

In the winter of 2019–2020, a second worldwide outbreak of a genetically similar virus originated in China. This was Coronavirus 2 (SARS-CoV2) known as COVID-19. Illness severity ranges from mild common-cold symptoms to severe pneumonia or acute respiratory distress syndrome (Rasmussen, 2020). From 18 affected pregnancies, the clinical course of COVID-19 is similar to that seen in nonpregnant women. However, preterm labor appears to be an associated risk (Chen, 2020; Zhu, 2020).

To minimize transmission of COVID-19, inpatient guidelines recommend caring for an affected patient in a negative-pressure airborne infection isolation room (AIIR) or transfer to an equipped facility. The potential for vertical transmission (mother–to–newborn) transmission is currently unclear Breslin, 2020). Neonates are suspected to have infection. Thus, isolation of the newborn from other neonates is recommended.

A newborn may room in with its mother, who practices hand hygiene and wears a mask (American College of Obstetricians and Gynecologists, 2021; Centers for Disease Control and Prevention, 2020).

Varicella Pneumonia

Infection with varicella-zoster virus, the same agent responsible for chickenpox, results in pneumonitis in 5 percent of gravidas (Harger, 2002). Diagnosis and management are considered in Chapter 67 (p. 1186).

Pneumocystis Pneumonia

Fungal and yeast infections are usually of greatest consequence in immunocompromised hosts, especially in women with acquired immunodeficiency syndrome (AIDS). Of these, lung infection with *Pneumocystis jirovecii*, formerly called *Pneumocystis carinii*, is a common complication. The opportunistic yeast-like fungus causes interstitial pneumonia characterized by dry cough, tachypnea, dyspnea, and diffuse radiographic infiltrates. This organism is identified by polymerase chain reaction testing of bronchoalveolar lavage secretions or, when necessary, tissue staining of biopsy specimens (Morris, 2018). More common in HIV-infected persons, its incidence has risen in other immunocompromised groups (Rego de Figueiredo, 2019).

In a report from the AIDS Clinical Trials Centers, pneumocystis pneumonia was the most frequent HIV-related disorder in pregnant women (Stratton, 1992). Ahmad and associates (2001) reviewed 22 cases during pregnancy and cited a 50-percent mortality rate. Treatment is with trimethoprim-sulfamethoxazole for 14 to 21 days. Alternative agents include sulfadiazine plus pyrimethamine. Glucocorticoids also improve survival rates. Echinocandins have been used successfully in nonpregnant patients (Huang, 2019). Tracheal intubation and mechanical ventilation may be required in some cases.

For prophylaxis, several international health agencies recommend one double-strength trimethoprim-sulfamethoxazole tablet orally daily for certain groups of HIV-infected pregnant women. These include women with $CD4^+$ T-lymphocyte counts $<200/\mu L$, those whose $CD4^+$ T lymphocytes constitute <14 percent, or if there is an AIDS-defining illness, particularly oropharyngeal candidiasis (Centers for Disease Control and Prevention, 2021).

Fungal Pneumonia

Any of several fungi can cause pneumonia. In pregnancy, this is usually seen in women with HIV infection or other sources of immunocompromise. In uncompromised women, infection is usually mild and self-limited. It is characterized initially by cough and fever, and dissemination is infrequent (Mansour, 2015).

Histoplasmosis and *blastomycosis* do not appear to be more frequent or more severe during pregnancy (Youssef, 2013). Data concerning *coccidioidomycosis* are conflicting (Bercovitch, 2011; Patel, 2013). In a case-control study from an endemic area, pregnancy was a significant risk factor for disseminated disease (Rosenstein, 2001). In another study, however, Caldwell and coworkers (2000) identified 32 serologically confirmed cases during pregnancy and documented dissemination in only three. Women with associated erythema nodosum have a better prognosis, whereas mediastinal lymphadenopathy may more likely reflect disseminated disease (Mayer, 2013). Last, Crum and Ballon-Landa (2006) reviewed 80 cases of antepartum coccidioidomycosis and found that almost all women diagnosed in the third trimester had disseminated disease. Although the overall maternal mortality rate was 40 percent, it was 20 percent for 29 cases reported since 1973. Spinello (2007) and Bercovitch (2011) with their colleagues provide reviews of coccidioidomycosis in pregnancy.

Most cases of *cryptococcosis* reported during pregnancy manifest as meningitis. Otherwise healthy pregnant women occasionally have cryptococcal pneumonia (Asadi Gharabaghi, 2014). Diagnosis is difficult because clinical presentation is similar to that of other community-acquired pneumonias.

Itraconazole is the preferred therapy for most disseminated fungal infections (Edwards, 2018). Pregnant women have also been given IV amphotericin B or ketoconazole (Lewis, 2018; Paranyuk, 2006; Pilmis, 2015). Amphotericin B has been used extensively in pregnancy with no embryofetal effects. Early in pregnancy, fluconazole and ketoconazole may be embryotoxic in large doses. In the first trimester, these two and itraconazole are ideally avoided if possible (Briggs, 2022).

Three echinocandin derivatives—*caspofungin*, *micafungin*, and *anidulafungin*—are effective for invasive candidiasis (Edwards, 2018). They are embryotoxic and teratogenic in laboratory animals and use in human pregnancies has not been reported (Briggs, 2022).

TUBERCULOSIS

It is estimated that a third of the world population is infected with *Mycobacterium tuberculosis* (Getahun, 2015). In the United States, it is uncommon and is a disease of the elderly, the urban poor, minority groups, and patients with HIV infection (Raviglione, 2018). According to the CDC (2019b), the incidence of *active tuberculosis* in this country has plateaued since 2000, and immigrants account for more than half of active cases. Individuals born in the United States have newly acquired infection, whereas foreign-born persons usually have reactivation of latent infection.

Infection begins with inhalation of mycobacteria, which incites a granulomatous pulmonary reaction. In >90 percent of patients, infection is contained and is dormant for long periods (Getahun, 2015). In those who are immunocompromised, tuberculosis becomes reactivated to cause clinical disease. Active disease manifests usually as cough with minimal sputum production, low-grade fever, hemoptysis, and weight loss. Various infiltrative patterns are seen on chest radiograph, and cavitation or mediastinal lymphadenopathy may be associated. Stained smears of sputum reveal acid-fast bacilli (AFB) in approximately two thirds of culture-positive individuals. Forms of extrapulmonary tuberculosis include lymphadenitis, pleural, genitourinary, skeletal, meningeal, gastrointestinal, and miliary or disseminated (Raviglione, 2018). Silent endometrial tuberculosis can cause tubal infertility (Levison, 2010).

Tuberculosis and Pregnancy

The considerable influx of women into the United States from Asia, Africa, Mexico, and Central America has been accompanied by an increased frequency of tuberculosis in pregnancy. The prevalence of tuberculosis was 7.1 cases per 100,000 pregnancy-related hospitalizations (Dennis, 2018). Sackoff and associates (2006) reported positive tuberculin test results in half of 678 foreign-born women attending prenatal clinics in New York City. At Jackson Memorial Hospital in Miami, 21 percent of 207 pregnant women with HIV infection had a positive skin test result (Schulte, 2002).

One review of 3384 pregnant women showed that 72 percent of active disease is pulmonary (Sobhy, 2017). It also confirmed earlier studies that showed greater adverse maternal and perinatal outcomes (Table 54-6). Others have found similar untoward effects (Dennis, 2018; El-Messidi, 2016). From her review, Efferen (2007) cited twofold greater rates of low birthweight, preterm delivery, and preeclampsia. The perinatal mortality rate was almost tenfold higher. Conversely, treated tuberculosis is usually associated with good pregnancy outcomes (Moro, 2018; Taylor, 2013).

Extrapulmonary tuberculosis is less common, although its incidence appears to be rising (El-Messidi, 2016). Llewelyn and colleagues (2000) reported that 9 of 13 pregnant women with extrapulmonary disease had delayed diagnoses. In the review cited above, 5.8 percent of women had extrapulmonary infections, and they had worse outcomes (Sobhy, 2017). Jana and coworkers (1999) described outcomes in 33 pregnant women with renal, intestinal, and skeletal tuberculosis, and a third had low-birthweight newborns. Prevost and Fung Kee Fung (1999) reviewed 56 cases of tuberculous meningitis in which a third of mothers died. Spinal tuberculosis may cause paraplegia, but vertebral fusion may prevent it from becoming permanent (Badve, 2011). Psoas abscess develops in 5 percent of those with spinal infections (Nigam, 2013). Other presentations include widespread intraperitoneal tuberculosis simulating ovarian carcinomatosis or degenerating leiomyoma, and hyperemesis gravidarum stemming from tubercular meningitis (Kutlu, 2007; Moore, 2008; Sherer, 2005).

TABLE 54-6. Adverse Maternal and Perinatal Outcomes in 3384 Pregnancies Complicated by Active Tuberculosis

Outcomes	Odds Ratio[a](95% CI)
Maternal	
Cesarean delivery	2.1 (1.17–3.79)
ARDS	2.8 (1.35–6.10)
Anemia	3.8 (2.21–6.71)
Pneumonia	8.4 (5.8–12.3)
Miscarriage	9.0 (4.93–16.7)
Prenatal Admission	9.6 (2.3–40.6)
Perinatal	
Preterm birth	1.6 (1.2–2.4)
Low birthweight	1.7 (1.2–2.4)
Anomalies	1.8 (1.24–2.62)
Fetal distress	2.3 (1.2–4.5)
Mortality	4.2 (4.9–11.8)

[a]Compared with women without tuberculosis.
ARDS = acute respiratory distress syndrome.
Data from El-Messidi, 2016; Sobhy, 2017.

Diagnosis

For latent tuberculosis, two testing types are used. One is the time-honored *tuberculin skin test (TST),* and the others are *interferon-gamma release assays (IGRAs),* which are becoming preferred (Lewinsohn, 2017; Sosa, 2019). IGRAs are blood tests that measure interferon-gamma release in response to antigens present in *M tuberculosis* but not in *bacille Calmette-Guérin (BCG)* vaccine.

The alternative is skin testing, for which the preferred antigen is *purified protein derivative (PPD)* of intermediate strength of 5 tuberculin units. If the intracutaneously applied test result is negative, no further evaluation is needed. A positive skin test result measures ≥5 mm in diameter and requires evaluation for active disease, including a chest radiograph. For active infection, nucleic acid amplification testing and mycobacterial culture is recommended (Raviglione, 2018).

Clinicians should promptly contact their state health department for cases of suspected or confirmed active tuberculosis. Health departments can assist in providing patient and public health management. This often includes *directly observed therapy (DOT)* to ensure regimen compliance (Centers for Disease Control and Prevention, 2013a). Each state's control office can be found at www.cdc.gov/tb/links/tboffices.htm.

Treatment

Latent Infection

In nonpregnant, tuberculin-positive patients younger than 35 years with no evidence of active disease, treatment is given to substantially reduce the risk that their latent infection will progress to active disease. The preferred therapy is one of three rifamycin-based regimens with or without isoniazid for 3 to 4 months duration (Sterling, 2020). Alternatively, isoniazid, 300 mg orally daily, is given for 6 to 9 months. Isoniazid has been used for decades, and it is considered safe in pregnancy (Briggs, 2022; Moro, 2018). However, for gravidas with latent infection, most recommend that isoniazid therapy be delayed until after delivery (Hill, 2019). Some even recommend withholding treatment until 3 to 6 months after delivery because of a possibly increased isoniazid-induced hepatitis risk in postpartum women. Serum levels of hepatic transaminases should be monitored with isoniazid therapy.

Compliance is a major problem with postpartum therapy. Only 10 to 18 percent of postpartum patients complete treatment (Cruz, 2005; Sackoff, 2006). One obvious disconnect is that care for tuberculosis is given in health systems apart from prenatal care (Zenner, 2012). In a decision model, Boggess and colleagues (2000) reported fewer cases of tuberculosis if treatment for a positive tuberculin skin test result occurred antepartum.

There are exceptions to delayed treatment for latent infection in pregnancy. Recent skin test convertors are treated antepartum because the incidence of active infection is 5 percent in the first year (Zumla, 2013). Skin-test-positive women exposed to active infection are also treated because the incidence of infection is 0.5 percent per year. Last, women with HIV infection are treated because they have an approximate 10-percent annual risk of active disease.

Active Infection

Regimens. Resistance to antituberculosis drugs has led to emergence of *multidrug-resistant tuberculosis (MDR-TB)* strains. The World Health Organization (2017) recommends isoniazid, rifampin, ethambutol, and pyrazinamide together for 6 months for nonpregnant persons. These are used until susceptibility studies are performed (Nahid, 2016). Pyridoxine is added to help prevent isoniazid-associated neuropathy. A newer 4-month isoniazid, rifapentine, moxifloxacin, and pyrazinamide regimen was not inferior to the standard one (Dorman, 2021).

During pregnancy, in the first 2-month *bactericidal phase*, isoniazid, rifampin, and ethambutol are given. This is followed by a 7-month *continuation phase* with isoniazid and rifampin (Raviglione, 2018). A few reports describe MDR-TB during pregnancy, and treatment options have been reviewed (Esmail, 2018). Treatment should be undertaken in consultation with infectious disease and the local health department. Breastfeeding is not prohibited during antituberculous therapy. If neonatal therapy is indicated, medication levels in breast milk are inadequate for this.

Treatment of active disease is of special concern in HIV-infected women who are antiretroviral naïve. In these circumstances, beginning concomitant therapy with antituberculosis and antiretroviral therapy can cause the *immune reconstitution inflammatory syndrome (IRIS)* with toxic drug effects (Lai, 2016). That said, some studies support administration of antiretroviral therapy 2 to 4 weeks after beginning antituberculosis therapy (Blanc, 2011; Havlir, 2011). Also, rifampin or rifabutin may be contraindicated if certain protease inhibitors or nonnucleoside reverse transcriptase inhibitors are used. If there is resistance to rifabutin or rifampin, then pyrazinamide therapy is given. Of the second-line regimens, the aminoglycosides—streptomycin, kanamycin, amikacin, and capreomycin—are ototoxic to the fetus and are contraindicated (Briggs, 2022).

Transmission Prevention. Inpatient airborne precautions should be initiated for any patient with suspected active pulmonary tuberculosis or for patients who remain infectious despite treatment. Precautions include rooming in a negative-pressure room. Patients are encouraged to wear surgical masks during interactions, and health-care workers should don personally fitted N95 respirator masks. Patients undergoing treatment can be considered noninfectious: (1) after 2 weeks of DOT treatment compliance, (2) after three consecutive AFB-negative sputum smears, or (3) after clinical improvement evidenced by absent fever and resolving cough (Centers for Disease Control and Prevention, 2013b).

Neonatal Tuberculosis

Tuberculous bacillemia can infect the placenta, but the fetus infrequently becomes infected. *Congenital tuberculosis* applies also to newborns who are infected by aspiration of infected secretions at delivery. Each route constitutes approximately half of the cases. Neonatal tuberculosis simulates other congenital infections and manifests with hepatosplenomegaly, respiratory distress, fever, and lymphadenopathy (Yeh, 2019).

Cantwell and colleagues (1994) reviewed 29 cases of congenital tuberculosis. Only 12 of the mothers had active infection, and tuberculosis was frequently demonstrated by postpartum endometrial biopsy. Adhikari and associates (1997) described 11 South African postpartum women whose endometrial biopsy was culture-positive. Six of their neonates had congenital tuberculosis.

Neonatal infection is unlikely if the mother with active disease is treated before delivery or if her sputum culture is negative. Most experts recommend isolation of the susceptible newborn from the mother suspected of having active disease. If the mother is infectious, 3 to 6 months of isoniazid prophylaxis is given to the newborn. In an older study, the risk of disease in the untreated infant born to a woman with active infection was 50 percent in the first year (Jacobs, 1988).

SARCOIDOSIS

This is a chronic, multisystem inflammatory disease of unknown etiology characterized by an accumulation of T-helper lymphocytes and phagocytes within noncaseating granulomas (Baughman, 2018; Spagnolo, 2018). Predisposition to the disease is genetically determined and characterized by an exaggerated response of helper T lymphocytes to environmental triggers. Pulmonary involvement is most common, followed by skin, eyes, lymph nodes, and then all other organ systems. The prevalence of sarcoid in the United States is 20 to 60 cases per 100,000, with equal sex distribution. It is more than 10 times more common for blacks than for whites. Most patients are between 20 and 40 years at disease presentation.

Pulmonary symptoms are dominant, and more than 90 percent of patients have an abnormal chest radiograph at some point. *Interstitial pneumonitis* is the hallmark of pulmonary involvement, and half of affected patients develop permanent radiological changes. *Lymphadenopathy*, especially of the mediastinum, is present in 75 to 90 percent of cases. A third each have uveitis and skin involvement, the latter usually manifest as *erythema nodosum*. In women, sarcoid causes approximately 10 percent of cases of erythema nodosum (Mert, 2007). Importantly, any other organ system may be involved. Confirmation of the diagnosis is with biopsy—preferably a lymph node. However, because the lung may be the only obviously involved organ, tissue acquisition is often difficult.

The overall prognosis for sarcoidosis is good, and it resolves without treatment in 50 percent of patients. Still, quality of life is diminished, and in 20 percent chronic organ dysfunction, albeit mild and nonprogressive, persists (Spagnolo, 2018). Approximately 5 percent die because of their disease.

Glucocorticoids are the most widely used treatment for symptomatic disease. Permanent organ derangement is seldom reversed by their use (Spagnolo, 2018). Thus, the decision to treat is based on symptoms, physical findings, chest radiograph,

TABLE 54-7. Maternal and Perinatal Adverse Outcomes in 678 Women with Sarcoidosis

Outcomes	Odds Ratio[a] (95% CI)
Preeclampsia	1.62 (1.18–2.22)
Preterm delivery	1.73 (1.40–2.15)
Deep-vein thrombosis	4.92 (1.58–15.33)
Eclampsia	5.27 (1.69–16.40)
Pulmonary embolism	6.68 (3.99–11.21)

[a]Compared with 7,094,000 women without sarcoidosis.
CI = confidence interval.

and pulmonary function tests. Unless respiratory symptoms are prominent, therapy is usually withheld for a several-month observation period. If inflammation does not subside, prednisone, 20 to 40 mg/d, is given daily and tapered to <10 mg by 6 months (Baughman, 2018). For those with an inadequate response, immunosuppressive or cytotoxic agents and cytokine modulators can be used.

Sarcoidosis and Pregnancy

Because it is uncommon and frequently benign, sarcoidosis is not often diagnosed in pregnancy. In a study of the Nationwide Inpatient Sample, the incidence was 9.6 cases per 100,000 births (Hadid, 2015). Meningitis, heart failure, and neurosarcoidosis complicating pregnancy have been described (Cardonick, 2000; Maisel, 1996; Wallmüller, 2012). Many small studies report benign associations between sarcoidosis and pregnancy. However, Table 54-7 displays the increased incidences of both maternal and fetal adverse outcomes found in a Nationwide Inpatient Sample study of 678 cases (Hadid, 2015). Risks for preeclampsia and preterm delivery were approximately twofold greater. Risks for eclampsia, deep-vein thrombosis, and pulmonary embolism were five- to sevenfold higher.

Active sarcoidosis is treated using the same guidelines as for nongravid women. Severe disease warrants serial pulmonary function determination. Symptomatic uveitis, constitutional symptoms, and pulmonary symptoms are treated with prednisone.

CYSTIC FIBROSIS

Pathophysiology

Cystic fibrosis is an autosomal recessive exocrinopathy and is one of the most common fatal genetic disorders in Caucasians. Cystic fibrosis is caused by one of more than 2000 mutations in a 230-kb gene on the long arm of chromosome 7 (Sorscher, 2018). The normal peptide gene product functions as a chloride channel and is termed the *cystic fibrosis transmembrane conductance regulator (CFTR)*. Mutations in the chloride channel alters epithelial transport of electrolytes in CFTR-secretory cells. Affected sites include the sinuses, lung, pancreas, liver, and reproductive tract.

Exocrine gland ductal obstruction develops from thick, viscid secretions. In the lung, submucosal glandular ducts are affected. Eccrine sweat gland abnormalities are the basis for the diagnostic *sweat test*, characterized by elevated sodium, potassium, and chloride levels in sweat.

Lung involvement is commonplace and is usually the cause of death. Bronchial gland hypertrophy with mucous plugging and small-airway obstruction leads to subsequent infection that ultimately causes chronic bronchitis and bronchiectasis. For complex and not completely explicable reasons, chronic inflammation is caused by *Pseudomonas aeruginosa*, *S aureus*, *and H influenzae*. Acute and chronic parenchymal inflammation ultimately causes extensive fibrosis, and along with airway obstruction, ventilation–perfusion mismatch develops. Pulmonary insufficiency is the end result. Currently, the median predicted survival is 37 years, and nearly 80 percent of females with cystic fibrosis now survive to adulthood (Patel, 2015).

As discussed in Chapter 17 (p. 342), phenotypes vary widely, even among homozygotes for the common Phe508del (ΔF508) mutation. Disease severity depends on which two alleles are inherited, and approximately 10 percent are disease-causing mutations (Sorscher, 2018). Homozygosity for ΔF508 is one of the most severe, and 90 percent of individuals with clinical disease carry at least one F508 allele.

Preconceptional Counseling

Women with clinical cystic fibrosis are subfertile because of tenacious cervical mucus. Traxler and colleagues (2019) recommend in-depth preconceptional counseling regarding contraception. Males have oligospermia or aspermia from associated *congenital bilateral absence of the vas deferens (CBAVD)*, and 98 percent are infertile (Ahmad, 2013). Despite this, the North American Cystic Fibrosis Foundation estimated that 4 percent of affected women become pregnant every year (Edenborough, 1995). The endometrium and tubes express some CFTR but are functionally normal, and the ovaries do not express the *CFTR* gene. Both intrauterine insemination and in vitro fertilization can be successful for affected women. Important factors are the long-term prognosis for the parent(s) and mutation transmission to their offspring.

Screening

The American College of Obstetricians and Gynecologists (2020) recommends that carrier screening be offered to *all* women, affected by cystic fibrosis or not, who are currently pregnant or considering conception (Chap. 17, p. 342). The CDC also added cystic fibrosis to newborn screening programs (Chap. 32, p. 594). The CFTR2 website (www.cftr2.org) helps delineate which gene variants have a clear disease-causing role and which are benign mutations.

Prenatal Care

Pregnancy outcome is inversely related to severity of lung dysfunction. Advanced chronic lung disease, hypoxia, and frequent infections may prove deleterious. At least in the past, *cor pulmonale* was common, but even that does not preclude successful pregnancy (Cameron, 2005). In some women, *pancreatic dysfunction* may cause malnutrition. Approximately 10 percent have pregestational diabetes (Reynaud, 2017). Otherwise normal pregnancy-induced insulin resistance frequently

results in gestational diabetes after midpregnancy. In one study of 48 pregnancies, half had pancreatic insufficiency, and a third required insulin (Thorpe-Beeston, 2013).

Cystic fibrosis is not affected by pregnancy. Early reports of a deleterious effect on the course of cystic fibrosis were related to severe disease (Olson, 1997). When matched with nonpregnant women by disease severity, some reports indicate no deleterious effects on long-term survival (Schechter, 2013).

Management

Prepregnancy counseling is imperative. Women who choose to become pregnant require close surveillance for development of superimposed infection, diabetes, and heart failure. Serial pulmonary function testing assists management and estimates prognosis. If the FEV_1 is at least 50 percent, women usually tolerate pregnancy well (Reynaud, 2020). Emphasis is placed on postural drainage, bronchodilator therapy, and infection control.

β-Adrenergic bronchodilators help control airway constriction. Inhaled recombinant human deoxyribonuclease I improves lung function by reducing sputum viscosity (Sorscher, 2018). Inhaled 7-percent saline produces short- and long-term benefits. Nutritional status is assessed, and appropriate dietary counseling given. Calcium and vitamin D are given for poor bone mineralization. Pancreatic insufficiency requires replacement of oral pancreatic enzymes. Promising new therapy to correct CFTR protein dysfunction has been recently described. Using a combination of "CFTR correctors" (tezacaftor–ivacaftor congeners), patients homozygous for the Phe508del mutation significantly benefitted (Davies, 2018; Keating, 2018). No reports of these drugs are available regarding pregnant women.

Infection is heralded by increasing cough and mucus production. Oral semisynthetic penicillins or cephalosporins usually suffice to treat staphylococcal infections. *Pseudomonas* infection is problematic, and inhaled tobramycin and colistin have been used successfully to control this organism. Serious pulmonary infections are treated with immediate hospitalization and aggressive therapy. The threshold for hospitalization with other complications is low. For labor and delivery, epidural analgesia is recommended (Deighan, 2014).

Pregnancy Outcome

Earlier reports chronicled the poor maternal and perinatal outcomes in affected women (Cohen, 1980; Kent, 1993). More recent reports describe better outcomes, but there still are serious complications (Schlüter, 2019). Disease severity is now quantified by pulmonary function studies, which are the best predictor of pregnancy and long-term maternal outcome. One report of 69 pregnancies found that if prepregnancy FEV_1 was <60 percent of predicted, the risk for preterm delivery, respiratory complications, and death of the mother within a few years of childbirth was substantive (Edenborough, 2000). Others report similar findings (Fitzsimmons, 1996; Thorpe-Beeston, 2013).

Of 75 pregnancies from the French Cystic Fibrosis Registry, almost 20 percent of newborns were delivered preterm, and 30 percent had growth restriction (Gillet, 2002). The one maternal death was due to *Pseudomonas* sepsis in a woman whose prepregnancy FEV_1 was 60 percent. Long-term, however, 17 percent of women died, and four infants had confirmed cystic fibrosis. Meconium peritonitis is found in 10 to 20 percent of affected fetuses (Boczar, 2015; Terlizzi, 2016). In a more recent report from the French registry, women with pregestational diabetes had outcomes similar to those without diabetes (Reynaud, 2017).

TABLE 54-8. Odds Ratios for Maternal Complications in 1119 Pregnant Women with Cystic Fibrosis Compared with Controls

Complication	Odds Ratio
Asthma	5
Thrombophilia	6
Diabetes	14
Acute kidney injury	16
Respiratory failure	30
Mechanical ventilation	32
Pneumonia	69
Death	125

Patel and associates (2015) queried the National Inpatient Sample database and reported that the prevalence of cystic fibrosis in pregnancy had a significant linear rise from 2000 to 2010. They analyzed 1119 affected women and reported a litany of risks (Table 54-8). In contrast, perinatal outcomes were surprisingly good.

Lung Transplantation

Cystic fibrosis is a common antecedent disease leading to lung transplantation. Gyi and coworkers (2006) reviewed 10 pregnancies in women following transplantation and reported nine liveborn neonates. Maternal outcomes were less favorable. Of the three gravidas who developed rejection during pregnancy, all had progressively declining pulmonary function and died of chronic rejection by 38 months after delivery. More recent international data show a median survival of 10.5 years in patients living beyond the first year (Yusen, 2015).

CARBON MONOXIDE POISONING

Carbon monoxide is a ubiquitous gas, and most nonsmoking adults have a carbon monoxyhemoglobin saturation of 1 to 3 percent. In cigarette smokers, levels may be 5 to 15 percent, and polycythemia is comorbid. Carbon monoxide is the most frequent cause of poisoning worldwide (Stoller, 2007). Toxic levels are often encountered in inadequately ventilated areas warmed by space heaters.

Carbon monoxide is particularly toxic because it is odorless and tasteless and has a high affinity for hemoglobin binding. Thus, it displaces oxygen and impedes its transfer with resultant hypoxia. Besides acute sequelae including death and anoxic encephalopathy, cognitive defects develop in as many as half of patients following loss of consciousness or in those with carbon monoxide levels >25 percent (Weaver, 2002). Hypoxic brain

damage has a predilection for the cerebral cortex and white matter and for the basal ganglia (Lo, 2007; Prockop, 2007). A Parkinson syndrome sometimes follows after recovery.

Pregnancy and Carbon Monoxide Poisoning

Through several physiological alterations, the rate of endogenous carbon monoxide production almost doubles in normal pregnancy (Longo, 1977). Although the pregnant woman is not more susceptible to carbon monoxide poisoning, the fetus does not tolerate excessive exposure (Friedman, 2015; Nowadly, 2018). With chronic exposure, maternal symptoms usually appear when the carboxyhemoglobin concentration is 5 to 20 percent. Symptoms include headache, weakness, dizziness, physical and visual impairment, palpitations, and nausea and vomiting. With acute exposure, concentrations of 30 to 50 percent produce symptoms of impending cardiovascular collapse. Levels >50 percent may be fatal for the mother.

Because hemoglobin F has an even higher affinity for carbon monoxide, fetal carboxyhemoglobin levels are 10 to 15 percent higher than those in the mother. This may be due to facilitated diffusion (Longo, 1977). Importantly, the half-life of carboxyhemoglobin is 2 hours in the mother but 7 hours in the fetus. Carbon monoxide is bound so tightly to hemoglobin F, the fetus may be hypoxic even before maternal carbon monoxide levels are appreciably elevated. Several anomalies are associated with embryonic exposure, and anoxic encephalopathy is the primary sequela of later fetal exposure (Alehan, 2007; Nowadly, 2018).

Treatment

For all victims, treatment of carbon monoxide poisoning is supportive along with immediate administration of 100-percent inspired oxygen. Indications for hyperbaric oxygen treatment in nonpregnant individuals are unclear (Kao, 2005). Weaver and associates (2002) reported that hyperbaric oxygen treatment minimized the incidence of cognitive defects in adults at both 6 weeks and 1 year compared with normobaric oxygen. Hyperbaric oxygen is generally recommended in pregnancy if carbon monoxide exposure has been "significant" (Aubard, 2000; Ernst, 1998). The problem is how to define significant exposure (Friedman, 2015). Although maternal carbon monoxide levels are not accurately predictive of those in the fetus, some clinicians recommend hyperbaric therapy if maternal levels exceed 15 to 20 percent. Towers and Corcoran (2009) described affected fetuses to have an elevated baseline heart rate, diminished variability, and absent accelerations and decelerations with fetal monitoring. Treatment of the affected newborn with hyperbaric oxygen also is controversial (Bar, 2007).

Elkharrat and coworkers (1991) described successful hyperbaric treatments in 44 pregnant women. In another report, a woman's abnormal neurological and cardiopulmonary findings abated in a parallel fashion with resolution of associated fetal heart rate variable decelerations (Silverman, 1997). Greingor and coworkers (2001) used 2.5-atm hyperbaric 100-percent oxygen for 90 minutes in a 21-week-pregnant woman who was delivered of a healthy neonate at term. The Undersea and Hyperbaric Medical Society (2021) has a list of accredited facilities.

CHAPTER 55

Thromboembolic Disorders

During the past century, the frequency of venous thromboembolism (VTE) during the puerperium decreased remarkably as early ambulation became routine practice. Despite this and other advances in prevention and treatment, thromboembolism remains a leading cause of maternal morbidity and mortality (Abe, 2019). Thrombotic pulmonary embolism accounted for almost 10 percent of pregnancy-related deaths in the United States between 2011 and 2015 (Creanga, 2017; Petersen, 2019).

The absolute incidence of VTE during pregnancy is low—1 or 2 cases per 1000 pregnancies. However, the risk is approximately five times higher than that among women who are not pregnant (Greer, 2015). Approximately equal numbers of cases are identified antepartum and in the puerperium. But deep-vein thrombosis alone is more frequent antepartum, and pulmonary embolism is more common postpartum. During the first 6 weeks of the puerperium, the estimated incidence of a thromboembolic complication is 22 events per 100,000 deliveries. Although still elevated, the risk falls to approximately 3 cases per 100,000 deliveries during the second 6-week postpartum period (Kamei, 2014). As many as 2 percent of these women have postthrombotic syndrome (Govindappagari, 2020).

PATHOPHYSIOLOGY

Rudolf Virchow (1856) postulated that stasis, local trauma to the vessel wall, and hypercoagulability predisposed to venous thrombosis. During pregnancy, the risk for each of these rises. Compression of the pelvic veins and inferior vena cava by the enlarging uterus renders the lower extremity venous system particularly vulnerable to stasis. Marik and Plante (2008) cite a 50-percent reduction in venous flow velocity in the legs that lasts from the early third trimester until 6 weeks postpartum. This stasis is the most constant predisposing risk factor for venous thrombosis. Venous stasis, delivery, preeclampsia, and sepsis contribute to endothelial cell injury. Last, as listed in the Appendix (p. 1228), the synthesis of most clotting factors is markedly enhanced during pregnancy and favors coagulation.

Risk factors for developing VTE during pregnancy are shown in Table 55-1. The most important of these is a personal history of thrombosis. Specifically, 15 to 25 percent of all VTE cases during pregnancy are recurrent events (American College of Obstetricians and Gynecologists, 2020b). Another important individual risk factor is a genetically determined thrombophilia. An estimated 20 to 50 percent of women who develop a venous thrombosis during pregnancy or postpartum have an identifiable underlying procoagulant genetic disorder (American College of Obstetricians and Gynecologists, 2020a).

Calculated risks for thromboembolism are approximately doubled in women with multifetal gestation, anemia, hyperemesis, hemorrhage, cesarean delivery, obesity, preeclampsia, and postpartum infection (Waldman, 2013). Scheres and

TABLE 55-1. Some Risk Factors Associated with an Increased Risk for VTE

Obstetrical	General
Cesarean delivery	Age 35 years or older
Cesarean hysterectomy	Anatomical anomaly[a]
Diabetes mellitus	Antiphospholipid antibodies
Hemorrhage and anemia	Connective tissue disease
Hyperemesis	Dehydration
Immobility—prolonged bed rest	Hormonal contraceptives
Multifetal gestation	Hospitalization
Multiparity	Immobility
Preeclampsia	Infection and inflammatory disease
Puerperal infection	Inflammatory bowel disease
Stillbirth	Malignancy
	Nephrotic syndrome
	Obesity
	Orthopedic procedures
	Paraplegia
	Prior VTE
	Sickle-cell disease
	Smoking
	Surgery
	Thrombophilia

[a]Includes May-Thurner syndrome (iliac vein compression syndrome).
VTE = venous thromboembolism.

coworkers (2020) had similar observations for women with preeclampsia. Risks were significantly higher among women who had a stillbirth or who underwent peripartum hysterectomy. Last, as discussed in Chapter 57 (p. 1021), inflammatory bowel disease increases the risk two- to threefold (Kim, 2019).

THROMBOPHILIAS

Several important regulatory proteins act as inhibitors in the coagulation cascade (Fig. 55-1). Normal values for many of these proteins during pregnancy are found in the Appendix (p. 1228). Inherited or acquired deficiencies of these inhibitory proteins are collectively referred to as *thrombophilias*. These can lead to hypercoagulability and recurrent VTE (Connors, 2017). Although these disorders are collectively present in approximately 15 percent of white European populations, they are responsible for approximately 50 percent of all thromboembolic events during pregnancy (Pierangeli, 2011). Some aspects of the more common inherited thrombophilias related to VTE are summarized in Table 55-2.

Inherited Thrombophilias

Patients with inherited thrombophilic disorders often have a family history of thrombosis. These mutations are also found in up to half of all patients who present with VTE before the age of 45 years, particularly in those whose event occurred in the absence of well-recognized risk factors. Of greatest significance is a family history of sudden death due to pulmonary embolism or a history of multiple family members requiring long-term anticoagulation therapy because of recurrent thrombosis (Connors, 2017).

Antithrombin Deficiency

Synthesized in the liver, antithrombin is one of the most important inhibitors of thrombin and inactivates thrombin and factor Xa (Rhéaume, 2016). Notably, the rate of antithrombin interaction with its target is accelerated over 1000–fo1d by heparin. Antithrombin deficiency may result from hundreds of different mutations that are almost always autosomal dominant. Type I deficiency results from reduced synthesis of biologically normal antithrombin, and type II deficiency is characterized by normal levels of antithrombin with reduced functional activity.

Homozygous antithrombin deficiency is lethal. Heterozygous deficiency affects approximately 1 in 2500 individuals. It is the most thrombogenic of the heritable coagulopathies. The risk for thrombosis correlates with the degree of deficiency. Antithrombin deficiency is associated with a 25- to 50-fold higher relative risk of VTE in the general population and a sixfold increased risk of thromboembolic complications during pregnancy (Ilonczai, 2015). As shown in Table 55-2, those affected have an inordinately high risk of VTE during pregnancy.

Sabadell and associates (2010) studied the outcomes of 18 pregnancies complicated by antithrombin deficiency. Twelve of these women were treated with therapeutic doses of low-molecular-weight heparin (LMWH). Three of the untreated patients suffered a thromboembolic episode compared with none in the treated group. Untreated women also had a 50-percent risk of stillbirth and fetal-growth restriction. By comparison, none of the treated women had a stillbirth, but a fourth developed fetal-growth restriction. Abbattista and coworkers (2020) reported a 7-percent risk of VTE for women treated with LMWH during pregnancy and a 12-percent risk for those not treated. Similar results were reported by Ilonczai and colleagues (2015). Last, Garcia-Botella and associates (2016) described a mesenteric vein thrombosis in a pregnant woman with antithrombin deficiency.

Given such risk, affected women are managed during pregnancy with anticoagulation regardless of whether they have had a prior thrombosis (Abbattista, 2020; Bates, 2018). When anticoagulation is necessarily withheld, such as during surgery or delivery, or if VTE develops in an anticoagulated woman, treatment with recombinant human antithrombin may be protective (Paidas, 2016).

Protein C Deficiency

When thrombin is bound to thrombomodulin on endothelial cells of small vessels, its procoagulant activities are neutralized. This binding also activates protein C, a natural anticoagulant. It, in the presence of protein S, controls thrombin generation, in part, by inactivating factors Va and VIIIa (see Fig. 55-1). Protein C activity increases modestly but significantly throughout the first half of pregnancy, and some have speculated that this augmentation may play a role in maintaining early pregnancy through both anticoagulant and inflammatory regulatory pathways (Said, 2010).

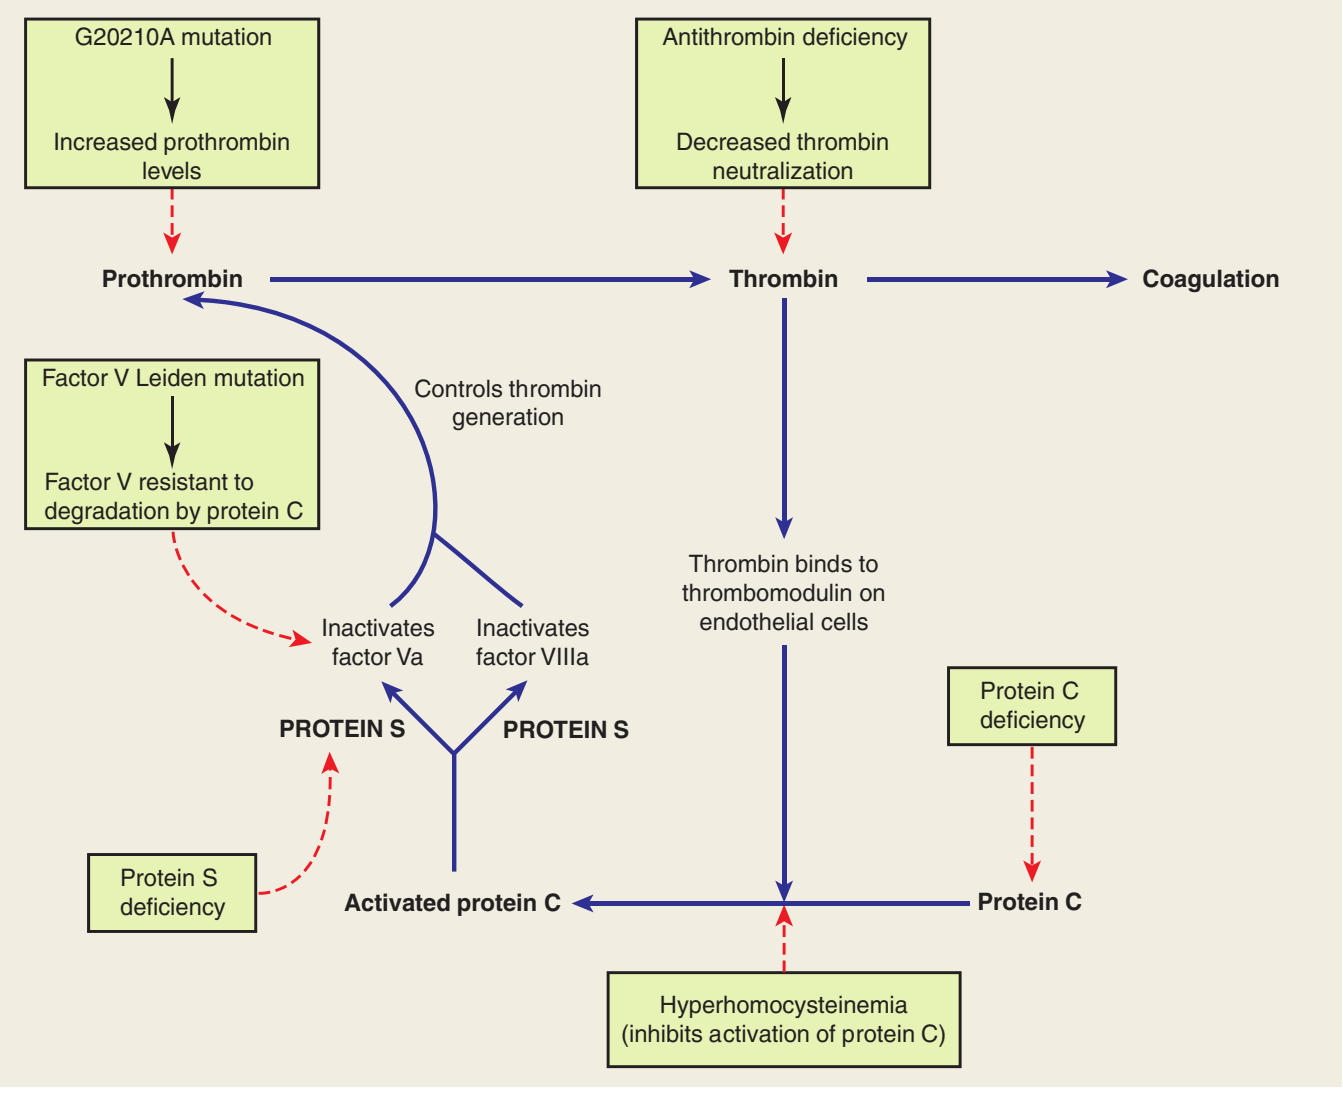

FIGURE 55-1 Inherited thrombophilias and their effect(s) on the coagulation cascade.

TABLE 55-2. Inherited Thrombophilias and Their Association with Venous Thromboembolism (VTE) in Pregnancy

	VTE Risk per Pregnancy (%)		
	No History	Prior VTE	Family History
Factor V Leiden heterozygote	0.5–3.1	10	0.06–1.2
Factor V Leiden homozygote	2.2–1.4	17	1–16
Prothrombin gene heterozygote	0.4–2.6	>10	0–0.73
Prothrombin gene homozygote	2–4	>17	1.6
Factor V Leiden/prothrombin double heterozygote	8.2	>20	0–2.4
Antithrombin deficiency	0.2–1.16	40	0–8
Protein C deficiency	0.1–5.4	4–17	0–5
Protein S deficiency	0.1–6.6	0–22	0–1.5
Hyperhomocysteinemia	0	0	<1

Data from Abbattista, 2020; American College of Obstetricians and Gynecologists, 2020a; Bates, 2018; Croles, 2017.

More than 160 different autosomal dominant mutations for the protein C gene have been described (Louis-Jacques, 2016). The prevalence of heterozygous protein C deficiency is 2 to 3 per 1000, but many of these individuals do not have a thrombosis history because the phenotypic expression is highly variable. These prevalence estimates correspond with functional activity threshold values of 50 to 60 percent, which are used by most laboratories. As shown in Table 55-2, these are associated with a six- to twelvefold higher risk for VTE (Lockwood, 2012). The rare cases of homozygous protein C deficiency may cause fatal neonatal purpura fulminans. Last, sepsis can result in purpura fulminans in the adult with heterozygous protein C deficiency (Bendapudi, 2021).

Protein S Deficiency

This circulating anticoagulant is activated by protein C, which enhances the capacity of protein S to inactivate factors Va and VIIIa (see Fig. 55-1). Protein S deficiency may be caused by more than 130 different mutations, with an aggregate heterozygous prevalence of approximately 0.3 to 1.3 per 1000 individuals (Louis-Jacques, 2016). Protein S deficiency may be measured by antigenically determined free, functional, and total S levels. All three decline substantively during normal gestation (Appendix, p. 1228). Thus, the diagnosis in pregnant women—as well as in those taking certain oral contraceptives—is difficult. If screening during pregnancy is necessary, threshold values for free protein S antigen levels in the second and third trimesters have been identified at <30 percent and <24 percent, respectively. The risk of VTE in pregnancy is increased severalfold (see Table 55-2). Among those with a positive family history, the VTE risk in pregnancy is 6 to 7 percent (American College of Obstetricians and Gynecologists, 2020a).

Conard and coworkers (1990) described thrombosis in five of 29 pregnant women with protein S deficiency. They, as well as Burneo and colleagues (2002), reported maternal cerebral vein thrombosis. Neonatal homozygous protein S deficiency is usually associated with purpura fulminans, the fatal clinical phenotype.

Factor V Leiden Mutation

This is the most prevalent of the known thrombophilia syndromes and is characterized by resistance of plasma to the anticoagulant effects of activated protein C. There are several mutations that create this resistance, but the most common is the factor V Leiden mutation. This missense mutation results from a substitution of glutamine for arginine at position 506 in the factor V polypeptide. As a result of this mutation, activated factor V is neutralized approximately tenfold more slowly by activated protein C (see Fig. 55-1). This leads to enhanced thrombin generation.

Heterozygous inheritance of factor V Leiden is the most common heritable thrombophilia. It is found in 3 to 15 percent of select European populations, 1.2 percent of African Americans, and 2.2 of Hispanic Americans, but is virtually absent in African blacks and Asians (American College of Obstetricians and Gynecologists, 2020a). Women who are heterozygous for factor V Leiden account for approximately 40 percent of VTE cases during pregnancy. However, the actual risk among pregnant women who are heterozygous and who do not have a personal history or a first-degree relative with a thrombotic episode before age 50 years is 5 to 12 events per 1000 births (see Table 55-2). In contrast, this risk is at least 10 percent among pregnant women with a personal or family history. Pregnant women who are homozygous without a personal or family history have a 1- to 4-percent risk for VTE, whereas those with such a history have an approximately 17-percent risk (American College of Obstetricians and Gynecologists, 2020a).

Diagnosis during pregnancy is performed by DNA analysis for the mutant factor V gene. Bioassay is not used because of the normal resistance that develops after early pregnancy from alterations in other coagulation protein concentrations. Of note, activated protein C resistance can also be caused by antiphospholipid syndrome, which is described on page 979 and also detailed in Chapter 62 (p. 1114).

To assess the prognostic significance of maternal factor V Leiden mutation during pregnancy, Kjellberg and associates (2010) compared the outcomes of 491 carriers with those of 1055 controls. All three of the thromboembolic events occurred among the carriers. But, preterm birth rates, birthweights, or hypertensive complication rates did not differ between the two groups. In a prospective observational study of almost 5000 women conducted by the Maternal-Fetal Medicine Units Network, the heterozygous mutant gene incidence was 2.7 percent (Dizon-Townson, 2005). Of three pulmonary emboli and one deep-vein thrombosis cases—a rate of 0.8 per 1000 pregnancies—none was among these carriers. Moreover, in the heterozygous women, the risks of preeclampsia, placental abruption, fetal-growth restriction, or pregnancy loss were not elevated. The investigators concluded that universal prenatal screening for the Leiden mutation and prophylaxis for carriers without a prior VTE is not indicated.

Prothrombin G20210A Mutation

This missense mutation in the prothrombin gene leads to excessive accumulation of prothrombin, which may be converted to thrombin. Prothrombin levels are increased approximately 30 percent in heterozygotes and 70 percent in homozygotes (MacCallum, 2014). As with factor V Leiden, a personal or family history of VTE in a first-degree relative before age 50 years raises the risk of VTE during pregnancy (see Table 55-2). For a heterozygous carrier with such a history, the risk exceeds 10 percent. Without such a history, heterozygous carriers of the mutation have less than a 1-percent risk of VTE during pregnancy (American College of Obstetricians and Gynecologists, 2020a).

Silver and coworkers (2010) tested nearly 4200 women for the prothrombin G20210A mutation. A total of 157—or 3.8 percent—of the women carried the mutation, and only one of these was homozygous. Carriers had similar rates of pregnancy loss, preeclampsia, fetal-growth restriction, and placental abruption compared with noncarriers. Three thromboembolic events occurred in women who tested negative for the mutation.

Homozygous patients, or those who are doubly heterozygous for a G20210A mutation with a factor V Leiden mutation, have a greater thromboembolism risk than heterozygous

carriers (Connors, 2017). Others have provided detailed information on pregnancy outcomes in women with such rare compound thrombophilias (Carroll, 2018; Lim, 2016).

Hyperhomocysteinemia

The most common cause of elevated homocysteine is the C667T thermolabile mutation of the 5, 10– methylene–tetrahydrofolate reductase (MTHFR) enzyme. Inheritance is autosomal recessive. Elevated homocysteine levels may also result from deficiency of one of several enzymes involved in methionine metabolism and from correctible nutritional deficiencies of folic acid, vitamin B_6, or vitamin B_{12}. During normal pregnancy, mean homocysteine plasma concentrations decline and make a diagnosis difficult (Lockwood, 2002).

A metaanalysis by den Heijer and associates (2005) reported an association between MTHFR polymorphisms and a slightly greater risk for thrombosis in international studies, but no such association was found in North American studies (den Heijer, 2005). The authors speculated that folic acid supplementation could explain the difference. Recall that folic acid serves as a cofactor in the remethylation reaction of homocysteine to methionine. Similarly, the American College of Chest Physicians posited that the lack of an association with thromboembolism could reflect the physiological reductions in homocysteine levels associated with pregnancy as well as the effects of widespread prenatal folic acid supplementation (Bates, 2012). The American College of Obstetricians and Gynecologists (2020a) has concluded that there is insufficient evidence to support assessment of MTHFR polymorphisms or measurement of fasting homocysteine levels in the evaluation for VTE.

Other Thrombophilia Mutations

Protein Z is a vitamin K–dependent protein that serves as a cofactor in factor Xa inactivation. Studies have found that low protein Z levels are associated with an elevated thromboembolism risk in nonpregnant patients and may be implicated in the pathogenesis of poor pregnancy outcomes (Almawi, 2013). Similarly, *plasminogen activator inhibitor type 1 (PAI-I)* is an important regulator of fibrinolysis. Certain polymorphisms in the gene promoter have been associated with slightly higher VTE risks. Although these thrombophilias may exacerbate risk among patients when coinherited with other thrombophilias, the American College of Obstetricians and Gynecologists (2020a) has concluded that evidence to recommend screening is insufficient.

Acquired Thrombophilias

Some examples of acquired hypercoagulable states include antiphospholipid syndrome (APS), heparin-induced thrombocytopenia, and cancer.

Antiphospholipid Syndrome

This prothrombotic disorder can affect both the venous and arterial circulations. The deeper veins of the lower limbs and the cerebral arterial circulation are the most frequent sites of venous and arterial thrombosis, respectively (Garcia, 2018; Konkle, 2018). Besides thrombosis, the other major clinical manifestations of APS are adverse obstetrical outcomes (Table 11-4, p. 205). Criteria for APS include (1) at least one otherwise unexplained fetal death at or beyond 10 weeks; (2) at least one preterm birth before 34 weeks' gestation because of eclampsia, severe preeclampsia, or placental insufficiency; or (3) at least three unexplained consecutive spontaneous abortions before 10 weeks. The syndrome is discussed in detail in Chapter 62 (p. 1114).

Testing for antiphospholipid antibodies should be performed in women with an unexplained arterial or venous thromboembolism or a history of one fetal loss or three or more recurrent embryonic or fetal losses (American College of Obstetricians and Gynecologists, 2020a). At this time, preterm severe preeclampsia and early-onset placental insufficiency do not support such testing. That said, there is evidence that antiphospholipid positivity confers a worse prognosis for pregnancies complicated by HELLP syndrome (Pécourt, 2021). These patients should be tested for the presence of three factors: (1) lupus anticoagulant, (2) anticardiolipin immunoglobulin G and M (IgG and IgM) antibodies, and (3) anti-β2 glycoprotein-I IgG and IgM antibodies. If any of these laboratory test results are positive, a confirmatory test is performed 12 weeks later (Connors, 2017).

Based on their study of 750 singleton pregnancies complicated by APS, Saccone and colleagues (2017) found that anticardiolipin antibody is the most common sole antiphospholipid antibody present. Women with APS have a 5- to 12-percent risk of thrombosis during pregnancy or the puerperium. Indeed, up to 25 percent of these thrombotic events occur during pregnancy or in the puerperium.

Thrombophilias and Pregnancy Complications

Contrary to past teaching, no definite causal link between inherited thrombophilias and adverse pregnancy outcomes exists (Ormesher, 2017). The confusion was caused by a number of observational studies that were later followed by large prospective cohort studies. Currently, the American College of Obstetricians and Gynecologists (2020a) does not recommend inherited thrombophilia screening for women with a history of fetal loss or adverse pregnancy outcomes such as fetal-growth restriction, placental abruption, and preeclampsia.

There are no convincing data that link inherited thrombophilias and fetal loss. It follows that there is no benefit to aspirin or heparin therapy as might accrue for recurrent pregnancy loss due to antiphospholipid antibodies (Chap. 62, p. 1116). Stillbirths also are not more common with heterozygous mutations, but there is a weak association with homozygous factor V Leiden mutation (Silver, 2016). Last, there is insufficient evidence to screen for inherited thrombophilias in women with a fetal death (Arachchillage, 2019).

Fetal-growth restriction also is not more common with inherited thrombophilias (American College of Obstetricians and Gynecologists, 2020a; Infante-Rivard, 2002). Likewise, there have been a number of prospective cohort studies that showed no association of inherited thrombophilias with *placental abruption* (Dizon-Townson, 2005; Silver, 2010). Conversely,

Alfirevic and coworkers (2002) reported an association with these and both heterozygosity and homozygosity for factor V Leiden mutations as well as heterozygous prothrombin G20210A mutation.

Studies showing an association of inherited thrombophilias and preeclampsia also are conflicting (American College of Obstetricians and Gynecologists, 2020a). One large systematic review and metaanalysis of nearly 22,000 women did not show an association between factor V Leiden or prothrombin gene mutations with preeclampsia (Rodger, 2010). Similarly, a more recent prospective study failed to show an association between preeclampsia and 12 hereditary thrombophilias (Fernandez Arias, 2019).

Thus, because of uncertainties in the magnitude of risk and in the benefits of prophylaxis given to prevent pregnancy complications in women with heritable thrombophilias, it remains unproven that universal screening is indicated (Louis-Jacques, 2016). In contrast, the association between APS and adverse pregnancy outcomes—including fetal loss, recurrent pregnancy loss, and preeclampsia—is much stronger (Liu, 2019).

Thrombophilia Screening

Given the relatively high incidence of thrombophilia in the population and the low incidence of VTE, universal screening during pregnancy is not cost-effective. Thus, a selective screening strategy is required. The American College of Obstetricians and Gynecologists (2020a) recommends that thrombophilia screening be considered in the following clinical circumstances: (1) a personal history of VTE with or without a recurrent risk factor such as fractures, surgery, or prolonged immobilization; and (2) a first-degree relative (parent or sibling) with a history of a high-risk inherited thrombophilia. As discussed previously, testing for inherited thrombophilias in women who have experienced recurrent fetal loss or adverse pregnancy outcomes is not recommended.

Methods of screening for the more common inherited thrombophilias are shown in Table 55-3. Whenever possible, laboratory testing is performed at least 6 weeks after the thrombotic event, while the patient is not pregnant, and when she is not receiving anticoagulation or hormonal therapy. Last, screening for hyperhomocysteinemia is not recommended (American College of Obstetricians and Gynecologists, 2020a).

DEEP-VEIN THROMBOSIS

Clinical Presentation

During pregnancy, most venous thromboses are confined to the deep veins of the lower extremity. Most of these are located in the iliofemoral and iliac veins without involvement of the calf veins (Chan, 2010). In contrast, in the general population, more than 80 percent of deep-vein thromboses involve calf veins (Huisman, 2015). The vast majority are left sided (Blanco-Molina, 2007). Greer (2003) hypothesizes that this results from compression of the left iliac vein by the right iliac and ovarian arteries, both of which cross the vein only on the left side. Yet, as described in Chapter 56 (p. 994), the ureter is compressed more on the right side.

Signs and symptoms vary depending on the degree of occlusion and the intensity of the inflammatory response. Classically, thrombosis involving the lower extremity is abrupt in onset, and there is pain and edema of the leg and thigh. The thrombus typically involves much of the deep-venous system to the iliofemoral region. Occasionally, reflex arterial spasm causes a pale, cool extremity with diminished pulsations. Calf measurements may identify a discordance in size. Alternatively, there may be appreciable clot, yet little pain, heat, or swelling. Importantly, calf pain, either spontaneous or in response to squeezing or to Achilles tendon stretching—*Homans sign*—may be caused by a strained muscle or contusion. *Importantly, 30 to 60 percent of women with a confirmed lower-extremity acute deep-vein thrombosis (DVT) have an asymptomatic pulmonary embolism* (p. 986).

Diagnosis

Clinical diagnosis of DVT is difficult without testing and is confirmed in only 10 percent of cases (Hull, 1990). Another

TABLE 55-3. How to Test for Thrombophilias

Thrombophilia	Testing Method	Is Testing Reliable During Pregnancy?	Is Testing Reliable During Acute Thrombosis?	Is Testing Reliable with Anticoagulation?
Factor V Leiden mutation	Activated protein C resistance assay (second generation)	Yes	Yes	No
	If abnormal: DNA analysis	Yes	Yes	Yes
Prothrombin gene mutation G20210A	DNA analysis	Yes	Yes	Yes
Protein C deficiency	Protein C activity (<65%)	Yes	No	No
Protein S deficiency	Functional assay (<55%)	No[a]	No	No
Antithrombin deficiency	Antithrombin activity (<60%)	Yes	No	No

[a]If screening in pregnancy is necessary, cutoff values for free protein S antigen levels in the second and third trimesters have been identified at less than 30% and less than 24%, respectively.

Reproduced with permission from American College of Obstetricians and Gynecologists' Committee on Practice Bulletins–Obstetrics. ACOG Practice Bulletin No. 197: Inherited Thrombophilias in Pregnancy, Obstet Gynecol 2018 Jul;132(1):e18-e34.

challenge is that many of the common diagnostic tests that have been investigated extensively in nonpregnant patients have not been validated appropriately in pregnancy (Huisman, 2015). Shown in Figure 55-2 is one diagnostic algorithm that can be used for evaluation of pregnant women. With a few modifications, we follow a similar evaluation at Parkland Hospital.

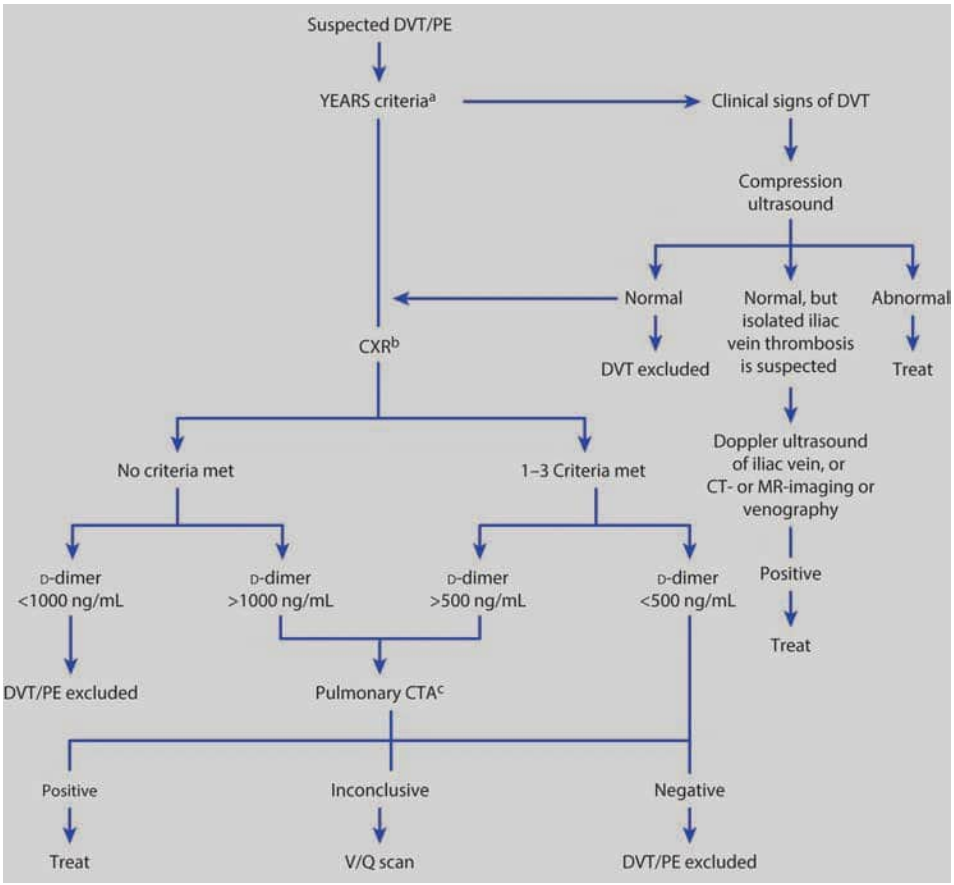

FIGURE 55-2 Algorithm to evalate suspected venous thromboembolism in pregnancy depending upon number of YEARS criteria met. Evidence of DVT should prompt compression ultrasound. [a]The three YEARS criteria are clinical signs of DVT, hemoptysis, and PE as the most likely diagnosis. [b]The American Thoracic Society and Society of Thoracic Radiology recommend CXR; [c]The American Society of Hematology recommends pulmonary V/Q scanning. CT = computed tomography; CTA = computed tomography angiography; CXR = chest x-ray; DVT = deep-vein thrombosis; MR = magnetic resonance; PE = pulmonary embolism; V/Q scan = ventilation perfusion scan. (From Bates, 2018; Guyatt, 2012; Leung, 2011; van der Hulle, 2019; van der Pol, 2019.)

Compression Ultrasonography

With suspected DVT, the initial diagnostic test recommended is compression ultrasonography of the proximal leg veins (American College of Obstetricians and Gynecologists, 2020b). The diagnosis is based on the noncompressibility and typical echoarchitecture of a thrombosed vein. For *nonpregnant* patients with suspected thrombosis, the safety of withholding anticoagulation for 1 week has been established in the setting of a normal compression ultrasound examination (Birdwell, 1998). Serial compression examinations are then performed because isolated undetected calf thromboses that ultimately extend into the proximal veins will do so within 1 to 2 weeks of presentation in approximately a fourth of patients. In *pregnant* women, however, normal findings with ultrasonography do not always exclude a pulmonary embolism. This is because the thrombosis may have already embolized or because it arose from iliac or other deep-pelvic veins, which are less accessible to ultrasound evaluation.

Two studies are helpful for evaluating whether serial examinations are necessary for pregnant women suspected of having a DVT. Chan and associates (2013) studied 221 pregnant and postpartum women presenting with a suspected DVT. The 205 women with a negative initial study result underwent serial testing, which was negative in all cases. Of these, one woman had a pulmonary embolism 7 weeks later. Le Gal and colleagues (2012) studied 210 pregnant and postpartum women with a suspected DVT. Of these, 177 women without a DVT were not anticoagulated and did not undergo serial testing. Two had an objectively confirmed thrombosis diagnosed within 3 months. In sum, these data suggest that a negative single complete compression ultrasonography study may safely exclude the diagnosis of DVT in most pregnant women.

Magnetic Resonance Imaging

This imaging technique allows excellent delineation of anatomical detail above the inguinal ligament. Thus, in many cases, magnetic resonance (MR) imaging is immensely useful for diagnosis of iliofemoral and pelvic vein thrombosis. The venous system can also be reconstructed using MR venography (Chap. 49, p. 875). MR imaging is 100-percent sensitive and 90-percent specific for detection of venographically proven DVT in nonpregnant patients (Erdman, 1990). Importantly, almost half of those without DVT were found to have nonthrombotic conditions that included cellulitis, myositis, edema, hematomas, and superficial phlebitis.

D-dimer Screening Tests

These specific fibrin degradation products are generated when fibrinolysin (plasminogen) degrades fibrin, as occurs in thromboembolism. Their measurement is usually incorporated into diagnostic algorithms for VTE in nonpregnant patients (Righini, 2018). This method was shown to be accurate in the YEARS study (van der Hulle, 2017). Screening with the D-dimer test in pregnancy, however, is problematic for several reasons. Depending

on assay sensitivity, D-dimer serum levels rise with gestational age along with substantively elevated plasma fibrinogen concentrations (Appendix, p. 1228) (Johnson, 2019). Levels are also affected by multifetal gestation and cesarean delivery (Hu, 2020; Miyamoto, 2020). Last, D-dimer concentrations can also be elevated in pregnancy complications such as placental abruption, preeclampsia, and sepsis (Cunningham, 2015).

Three large prospective studies have evaluated D-dimer testing in pregnant women to diagnose VTE. Righini and colleagues (2018) found that D-dimer measurement, bilateral leg ultrasound, and computed tomography-angiogram safely ruled out VTE. Subsequently, van der Pol and coworkers (2019) used a pregnancy-adapted YEARS algorithm to diagnose suspected pulmonary embolism. The algorithm used D-dimer measurements and clinical suspicion to confirm VTE. With none of the clinical criteria present, and with the D-dimer level <1000 ng/mL, or with one or more clinical criteria present and with the D-dimer level <500 ng/mL, pulmonary embolism was safely excluded (see Fig. 55-2). Last, the DiPEP study showed that neither clinical risk factors nor D-dimer levels were accurate in identifying pulmonary embolism in pregnant women (Goodacre, 2019). They concluded that pregnant women with suspected pulmonary embolism should all undergo imaging studies.

The findings of the YEARS study and subsequent others will no doubt guide care. However, currently the American College of Obstetricians and Gynecologists (2020b) recommends against the use of D-dimer assays to diagnose VTE in pregnant women. We agree, and in our view, these positive results need to be duplicated before adaptation of their widespread use in pregnant women. Still, a negative D-dimer assay should be reassuring, unless VTE is the most likely diagnosis (Viau-Lapointe, 2020).

Management of Venous Thromboembolism

Optimal management of VTE during pregnancy has not undergone major clinical study to provide evidence-based practices. There is, however, consensus for treatment with anticoagulation and limited activity. Thrombophilia testing does not change treatment (Connors, 2017). Anticoagulation is initiated with either unfractionated heparin (UFH) or LMWH (Table 55-4). Although either type is acceptable, most recommend one of the LMWHs (American College of Obstetricians and Gynecologists, 2020b; Kearon, 2016). The American Society of Hematology recommends preferential use of LMWH during pregnancy because of better bioavailability, longer plasma half-life, more predictable dose response, reduced risks of osteoporosis and thrombocytopenia, and less frequent dosing (Bates, 2018).

TABLE 55-4. Anticoagulation Regimen Definitions

Anticoagulation Regimen	Definition
Prophylactic LMWH[a]	Enoxaparin, 40 mg SC once daily Dalteparin, 5000 units SC once daily Nadroparin, 2850 units SC once daily Tinzaparin, 4500 units SC once daily
Therapeutic LMWH[b]	Enoxaparin, 1 mg/kg every 12 hours Dalteparin, 200 units/kg once daily Tinzaparin, 175 units/kg once daily Dalteparin, 100 units/kg every 12 hours Target an anti-Xa level in the therapeutic range of 0.6–1.0 units/mL 4 hours after last injection for twice daily regimen; slightly higher doses may be needed for a once-daily regimen.
Prophylactic UFH	UFH, 5000–7000 units SC every 12 hours in first trimester UFH 7500–10,000 units SC every 12 hours in the second trimester UFH, 10,000 units SC every 12 hours in the third trimester, unless the aPTT is elevated
Adjusted dose (therapeutic) UFH[b]	UFH, 10,000 units or more SC every 12 hours in doses adjusted to target aPTT in the therapeutic range (1.5–2.5 × control) 6 hours after injection
Postpartum anticoagulation	Prophylactic, intermediate, or adjusted-dose LMWH for 6–8 weeks as indicated. Oral anticoagulants may be considered postpartum based upon planned duration of therapy, lactation, and patient preference.
Surveillance	Clinical vigilance and appropriate objective investigation of women with symptoms suspicious of deep vein thrombosis or pulmonary embolism. VTE risk assessment should be performed prepregnancy or early in pregnancy and repeated if complications develop, particularly those necessitating hospitalization or prolonged immobility.

[a]Although at extremes of body weight, modification of dose may be required.
[b]Also referred to as weight adjusted, full treatment dose.
aPTT = activated partial thromboplastin time; INR = international normalized ratio; LMWH = low-molecular-weight heparin; SC = subcutaneously; UFH = unfractionated heparin.
Reproduced with permission from American College of Obstetricians and Gynecologists' Committee on Practice Bulletins–Obstetrics. ACOG Practice Bulletin No. 197: Inherited Thrombophilias in Pregnancy, Obstet Gynecol 2018 Jul;132(1):e18-e34.

The duration of full anticoagulation varies, and no studies have defined the optimal duration for pregnancy-related thromboembolism. In nonpregnant patients, evidence supports a minimum treatment duration of 3 months (Kearon, 2012). For pregnant patients, the American College of Obstetricians and Gynecologists (2020b) recommends therapeutic anticoagulation for 3 to 6 months followed by intermediate or prophylactic therapy for the duration of pregnancy and the postpartum period. If the woman is not breastfeeding, direct acting oral agents can be considered (p. 985).

Recall that pulmonary embolism develops in as many as 60 percent of patients with untreated venous thrombosis, and anticoagulation decreases this risk to less than 5 percent. In nonpregnant patients, the mortality rate with a pulmonary embolism approximates 1 percent (Douketis, 1998; Pollack, 2011).

With DVT, over several days, leg pain dissipates. After symptoms have abated, graded ambulation is begun. Elastic stockings are fitted, and anticoagulation is continued. Recovery to this stage usually takes 7 to 10 days. Graduated compression stockings can be continued for 2 years after the diagnosis to reduce the incidence of postthrombotic syndrome (Brandjes, 1997). Symptoms include chronic leg paresthesias or pain, intractable edema, skin changes, and leg ulcers. According to the American Society of Hematology, catheter-directed thrombolytic therapy does not mitigate against this complication (Bates, 2018).

Unfractionated Heparin

This agent should be considered for the initial treatment of thromboembolism and in situations in which delivery, surgery, or thrombolysis may be necessary (American College of Obstetricians and Gynecologists, 2020b). UFH can be administered by one of two alternatives: (1) initial intravenous therapy followed by adjusted-dose subcutaneous UFH given every 12 hours; or (2) twice-daily, adjusted-dose subcutaneous UFH with doses adjusted to prolong the activated partial thromboplastin time (aPTT) into the therapeutic range 6 hours post injection (Table 55-5).

For intravenous therapy, several protocols are acceptable. In general, if UFH is used, it is initiated with a bolus intravenous dose of 70 to 100 U/kg, which is 5000 to 10,000 U. This is followed by continuous intravenous infusions beginning at 1000 U/hr or 15 to 20 U/kg/hr. This infusion rate is titrated to achieve an aPTT 1.5 to 2.5 times control values (Linnemann, 2016). Intravenous anticoagulation is maintained for about 5 to 7 days, after which treatment is converted to subcutaneous heparin to maintain the aPTT to at least 1.5 to 2.5 times control throughout the dosing interval. For women with lupus anticoagulant, aPTT does not accurately assess heparin anticoagulation, and thus anti–factor Xa levels are preferred.

Low-molecular-weight Heparin

This is a family of derivatives of unfractionated heparin, and their molecular weights average 4000 to 5000 daltons compared with 12,000 to 16,000 daltons for conventional heparin. None of these heparins cross the placenta, and all exert their anticoagulant activity by activating antithrombin. UFH has equivalent activity against factor Xa and thrombin compared with LMWHs, which have greater activity against factor Xa than against thrombin. They also have a more predictable anticoagulant response and fewer bleeding complications than UFH because of their better bioavailability, longer half-life, dose-independent clearance, and decreased interference with platelets (American College of Obstetricians and Gynecologists, 2020b; Bates, 2018). Their longer half-life prohibits neuraxial analgesia in laboring women. LMWH compounds are cleared by the kidneys and must be used cautiously when there is renal dysfunction.

Several studies have shown that VTE is treated effectively with LMWH (Quinlan, 2004; Tapson, 2008). Using serial venograms, Breddin and associates (2001) observed that these compounds were more effective than UFH in reducing thrombus size without increasing mortality rates or major bleeding complications. Several different treatment regimens using LMWH for treatment of acute VTE are listed in Table 55-4 (American College of Obstetricians and Gynecologists, 2020b).

Whether LMWH requires adjustments during the course of pregnancy is controversial (Berresheim, 2014). The American College of Obstetricians and Gynecologists (2020b) recommends monitoring with an anti-Xa level 4 hours after an injection with dose adjustment to maintain a therapeutic level. Large studies using clinical end points that demonstrate an optimal therapeutic range or show that dose adjustments increase therapy, safety, or efficacy are lacking. Accordingly, the American Society of Hematology and others have concluded that routine monitoring with anti-Xa levels is difficult to justify (Bates, 2018; McDonnell, 2017).

In general, heparin pharmacokinetics includes more rapid clearance of heparins as pregnancy progresses. The peaks of anti-Xa activity of enoxaparin (Lovenox) across pregnancy are shown in Figure 55-3. Similarly, tinzaparin (Innohep) with a dosage of 75 to 175 U/kg/d was necessary to achieve peak anti–factor Xa levels of 0.1 to 1.0 U/mL (Smith, 2004). In studies

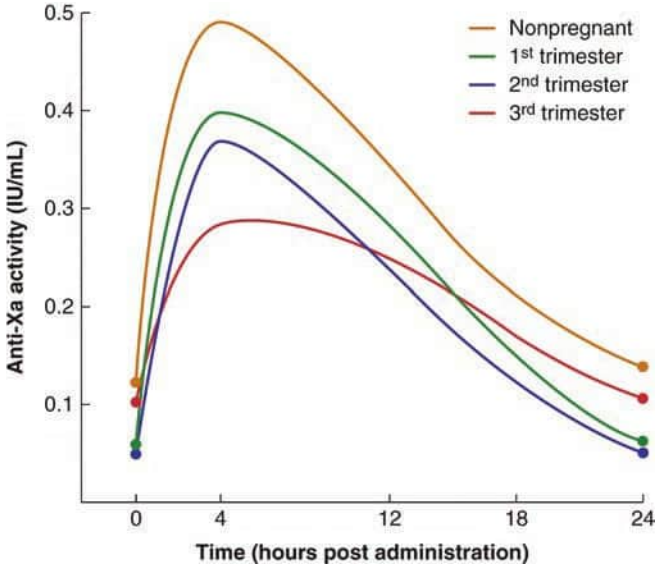

FIGURE 55-3 Anti–factor Xa activity with repeated daily administration of 40 mg enoxaparin subcutaneously in nonpregnant women and those from each trimester (Data from Lebaudy, 2008).

TABLE 55-5. Some Recommendations for Thromboprophylaxis During Pregnancy

Clinical Scenario	Pregnancy		Postpartum

[b]American Society of Hematology (Bates, 2018).
[c]Postpartum treatment levels should be ≥ antepartum treatment.
[d]Antithrombin deficiency; doubly heterozygous or homozygous for prothrombin 20210A and factor V Leiden.
[e]Heterozygous factor V Leiden or prothrombin 20210A; protein S or C deficiency.
[f]First-degree relative with VTE at <50 years; other major thrombotic risk factors, e.g., obesity, prolonged immobility.
[g]Women with antiphospholipid syndrome should not use estrogen-containing contraceptives.
[h]Treatment is recommended if the diagnosis of antiphospholipid syndrome is based on three or more prior pregnancy losses.
NSS = not specifically stated; VTE = venous thromboembolism.
Prophylactic, intermediate-, and adjusted-dose regimens are listed in Table 55-4.

of dalteparin (Fragmin) pharmacokinetics, conventional starting doses of dalteparin—100 U/kg every 12 hours—were likely insufficient to maintain full anticoagulation in pregnant women (Barbour, 2004; Jacobsen, 2003). Thus, slightly higher doses than that shown in Table 55-4 may be required.

Any concerns regarding teratogenicity of enoxaparin have been obviated (American College of Obstetricians and Gynecologists, 2020b; Bates, 2021). A comprehensive study of 1267 pregnant women treated with tinzaparin found no cases of heparin-induced thrombocytopenia, maternal deaths, or complications from regional analgesia (Nelson-Piercy, 2011). A total of 43 women (3.4 percent) required medical intervention for bleeding. Of 15 stillbirths, four were judged as possibly being related to tinzaparin use. LMWHs have been judged to be safe during breastfeeding (Bates, 2018).

Labor and Delivery

Women receiving either therapeutic or prophylactic anticoagulation should be converted from LMWH to the shorter-half-life UFH in the last month of pregnancy or sooner if delivery appears imminent. The purpose of conversion to UFH has less to do with any risk of maternal bleeding at the time of delivery, but rather with neuraxial blockade complicated by an epidural or spinal hematoma (Chap. 25, p. 478). The Society for Obstetric Anesthesia and Perinatology recommends that UFH low-dose thromboprophylaxis be withheld for 4 to 6 hours; UFH intermediate-dose thromboprophylaxis for 12 hours; and UFH therapeutic dose for 24 hours before neuraxial analgesia (Leffert, 2018). For LMWH, the Society recommends to withhold low doses for 12 hours; intermediate doses 12 to 24 hours; and therapeutic doses 24 hours.

If a woman begins labor while taking UFH, clearance can be verified by an aPTT. Reversal of heparin with protamine sulfate—1 mg per 100 units heparin with a maximum dose of 50 mg—is rarely required and is not indicated with a prophylactic dose of heparin. For women in whom anticoagulation therapy has temporarily been discontinued, pneumatic compression devices are recommended.

Warfarin Compounds

Vitamin K antagonists are generally contraindicated because they readily cross the placenta and cause fetal death and malformations from hemorrhages. This is discussed in detail in Chapter 8 (p. 156). Their sole antepartum use is in women with a mechanical heart valve (Daughety, 2020). These compounds do not accumulate in breast milk and are thus safe during breastfeeding.

Postpartum venous thrombosis is usually treated with intravenous heparin and oral warfarin initiated simultaneously. The initial dose of warfarin is 5 to 10 mg for the first 2 days. Subsequent doses are titrated to achieve an international normalized ratio (INR) of 2 to 3. To avoid paradoxical thrombosis and skin necrosis from the early antiprotein C effect of warfarin, these women are maintained on therapeutic doses of UFH or LMWH for 5 days and until the INR is in a therapeutic range for 2 consecutive days (American College of Obstetricians and Gynecologists, 2020b).

Treatment in the puerperium may require larger doses of anticoagulant. Brooks and colleagues (2002) compared anticoagulation in postpartum women with that of age-matched nonpregnant controls. The former required a significantly larger median total dose of warfarin—45 versus 24 mg—and a longer time—7 versus 4 days—to achieve the target INR.

Direct-acting Oral Anticoagulants

Of these newer oral anticoagulants, dabigatran (Pradaxa) inhibits thrombin and rivaroxaban (Xarelto) and apixaban (Eliquis) inhibit factor Xa. These agents are becoming the drugs of choice for nonpregnant subjects with thromboembolism (Kruger, 2019). Currently, very few reports address these newer agents during pregnancy and breastfeeding, and thus the human reproductive risks are essentially unknown (Lameijer, 2018; Rosenbloom, 2019). Despite this, the GARFIELD-VTE study reported that direct-acting oral anticoagulant use in pregnant women was gaining favor (Jerjes-Sanchez, 2021). Dabigatran crosses the placenta, however, it is unknown whether any of these agents are excreted in breast milk (Bapat, 2014). At this time, because of the potential for infant harm, a decision should be made to either avoid breastfeeding or use an alternative anticoagulant, such as warfarin, in breastfeeding women (Bates, 2021; Kruger, 2019).

■ Complications of Anticoagulation

Three significant complications associated with anticoagulation are hemorrhage, thrombocytopenia, and osteoporosis. The latter two are unique to heparin, and their risk may be reduced with LMWHs. The most serious complication is hemorrhage, which is more likely if there has been recent surgery or lacerations. Troublesome bleeding is also more likely if the heparin dosage is excessive. Unfortunately, management schemes using laboratory testing to identify when a heparin dosage is sufficient to inhibit further thrombosis, yet not cause serious hemorrhage, have been discouraging.

Heparin-induced Thrombocytopenia

There are two types—the most common is a nonimmune, benign, reversible thrombocytopenia that develops within the first few days of therapy and resolves in approximately 5 days without therapy cessation. The second is the severe form of heparin-induced thrombocytopenia, which results from an immune reaction involving IgG antibodies directed against complexes of platelet factor 4 and heparin. The diagnosis of heparin-induced thrombocytopenia (HIT) is based on a drop in the platelet count of more than 50 percent or thrombosis beginning 5 to 10 days after the start of heparin in association with the appearance of platelet-activating HIT antibodies. The fall in platelet count in HIT occurs rapidly—over a period of 1 to 3 days—and is assessed relative to the highest platelet count after the start of heparin. The typical nadir is 40,000 to 80,000 platelets per microliter (Greinacher, 2015).

Although the incidence of HIT is approximately 3 to 5 percent in nonpregnant individuals, it is <0.1 percent in obstetrical patients (American College of Obstetricians and Gynecologists, 2020b). Fausett and coworkers (2001) reported no cases among 244 heparin-treated gravidas compared with 10 among 244 nonpregnant patients. Accordingly, the American

College of Chest Physicians recommends against platelet count monitoring when the risk of HIT is considered to be <1 percent (Linkins, 2012). In others, they suggest monitoring every 2 or 3 days from day 4 until 14.

Women with a presumptive diagnosis of HIT should have laboratory testing for antiplatelet antibodies or by functional assays. However, these tests often require several days to return results, so initial management should be directed by clinical findings. Heparin therapy is stopped, and alternative anticoagulation initiated. LMWH may not be entirely safe because it has some cross reactivity with UFH. The American Society of Hematology recommends use of fondaparinux (Arixtra), which is a pentasaccharide factor Xa inhibitor (Bates, 2018). Successful use in pregnancy has been reported (De Carolis, 2015; Elsaigh, 2015). Last, platelet transfusions are avoided (Greinacher, 2015).

Heparin-induced Osteoporosis

Bone loss may develop with long-term heparin administration—usually 6 months or longer—and is more prevalent in cigarette smokers. UFH can cause osteopenia, and this is less likely with LMWHs. Women treated with any heparin should be encouraged to take an oral daily 1500-mg calcium supplement (Cunningham, 2005; Lockwood, 2012).

■ Anticoagulation and Abortion

The treatment of DVT with heparin does not preclude pregnancy termination by careful curettage. After the products are removed without trauma to the reproductive tract, full-dose heparin can be restarted in several hours.

■ Anticoagulation and Delivery

The effects of heparin on blood loss at delivery depend on several variables: (1) dose, route, and timing of administration; (2) number and depth of incisions and lacerations; (3) intensity of postpartum myometrial contractions; and (4) presence of other coagulation defects. Blood loss should not be greatly increased with vaginal delivery if there are no lacerations, and the uterus promptly contracts. Unfortunately, such ideal circumstances do not always prevail. Thus, heparin therapy generally is stopped during labor and delivery.

The American College of Obstetricians and Gynecologists (2020b) recommends restarting UFH or LMWH no sooner than 4 to 6 hours after vaginal delivery or 6 to 12 hours after cesarean delivery. From their review, Moriuchi and associates (2019) found that *thromboprophylaxis* started within 24 hours after cesarean delivery was safe. At Parkland Hospital, we wait at least 24 hours to restart therapeutic-dose heparin after cesarean delivery or after vaginal delivery with significant lacerations.

SUPERFICIAL VENOUS THROMBOPHLEBITIS

Thrombosis limited strictly to the superficial veins of the saphenous system is typically associated with varicosities or as a sequela of an indwelling intravenous catheter. It is treated with analgesia, elastic support, heat, and rest. Superficial vein thrombosis raises the risk of DVT four- to six-fold. In a metaanalysis of nonpregnant patients with thrombophlebitis, 18 percent had a concomitant DVT and 7 percent had a pulmonary embolism (Di Minno, 2016). Although controversial, the American Society of Hematology suggests LMWH therapy (Bates, 2018).

PULMONARY EMBOLISM

Although it causes approximately 10 percent of maternal deaths, pulmonary embolism is relatively uncommon during pregnancy and the puerperium. According to Marik and Plante (2008), 70 percent of gravidas presenting with a pulmonary embolism have associated clinical evidence of DVT. And recall that between 30 and 60 percent of women with a DVT will have a coexisting silent pulmonary embolism.

■ Clinical Presentation

In almost 2500 nonpregnant patients with a proven pulmonary embolism, symptoms included dyspnea in 82 percent, chest pain in 49 percent, cough in 20 percent, syncope in 14 percent, and hemoptysis in 7 percent (Goldhaber, 1999). Other predominant clinical findings typically include tachypnea, apprehension, and tachycardia. In some cases, an accentuated pulmonic closure sound, rales, and/or friction rub is heard.

Right axis deviation and T-wave inversion in the anterior chest leads may be evident on the electrocardiogram. In most cases, chest radiography results are normal. In others, nonspecific findings may include atelectasis, an infiltrate, cardiomegaly, or an effusion. Vascular markings in the lung region supplied by the obstructed artery can be lost. Although most women are hypoxemic, a normal arterial blood gas analysis does not exclude pulmonary embolism. Approximately a third of young patients have P_{O2} values >80 mm Hg. Thus, the alveolar- arterial oxygen tension difference is a more useful indicator of disease. More than 86 percent of patients with acute pulmonary embolism will have an alveolar-arterial difference >20 mm Hg (Lockwood, 2012). Even with massive pulmonary embolism, signs, symptoms, and laboratory data to support the diagnosis may be deceptively nonspecific.

■ Massive and Submassive Pulmonary Embolism

Defined as embolism causing hemodynamic instability, these account for 5 to 10 percent of cases (Handal-Örefice, 2019). Acute mechanical obstruction of the pulmonary vasculature causes increased vascular resistance and pulmonary hypertension followed by acute right ventricular dilation. In otherwise healthy patients, significant pulmonary hypertension does not develop until 60 to 75 percent of the pulmonary vascular tree is occluded (Guyton, 1954). Moreover, circulatory collapse requires 75- to 80-percent obstruction. This is depicted in Figure 55-4 and emphasizes that most acutely symptomatic emboli are large and likely a saddle embolism (Singhal, 1973). These are suspected when the pulmonary artery pressure is substantively increased as estimated by echocardiography.

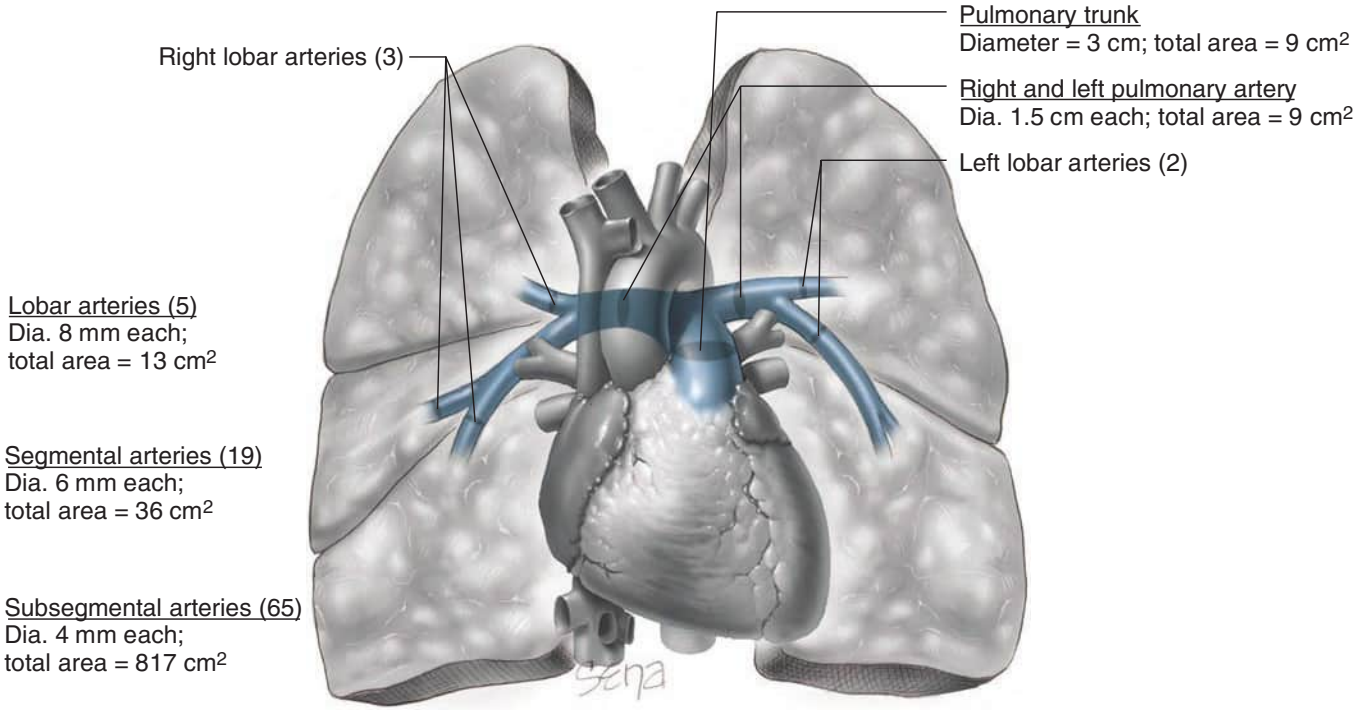

FIGURE 55-4 Schematic of pulmonary arterial circulation. Note that the cross-sectional area of the pulmonary trunk and the combined pulmonary arteries is 9 cm. A large saddle embolism could occlude 50 to 90 percent of the pulmonary tree, causing hemodynamic instability. As the arteries give off distal branches, the total surface area rapidly increases, that is, 13 cm for the combined five lobar arteries, 36 cm for the combined 19 segmental arteries, and more than 800 cm for the total 65 subsegmental arterial branches. Thus, hemodynamic instability is less likely with emboli past the lobar arteries.

Submassive embolism is diagnosed when there is evidence of right ventricular dysfunction (Handal-Örefice, 2019). The mortality rate approaches 25 percent, which compares with a 1-percent rate without such dysfunction (Kinane, 2008). It is important in these cases to infuse crystalloids carefully and to support blood pressure with vasopressors. Aggressive intravenous fluid infusion has been associated with worsening right-sided ventricular dysfunction (Konstantides, 2014). As discussed on page 988, oxygen treatment, tracheal intubation, and mechanical ventilation are completed preparatory to thrombolysis, filter placement, or embolectomy.

■ Diagnosis

In most cases, recognition of a pulmonary embolism requires a high index of suspicion that prompts objective evaluation. Exposure of the mother and fetus to ionizing radiation is a concern when investigating a suspected pulmonary embolism during pregnancy. However, this concern is largely overruled by the hazards of missing a potentially fatal diagnosis. Moreover, erroneously assigning a diagnosis of pulmonary embolism to a pregnant woman is also fraught with problems. It unnecessarily exposes the mother and fetus to the risks of anticoagulation treatment and will impact delivery plans, future contraception, and thromboprophylaxis during subsequent pregnancies. Therefore, investigations should aim for diagnostic certainty (Cohen, 2020).

Diagnosis of a pulmonary embolism follows the same algorithm as for DVT shown in Figure 55-2. In addition to compression ultrasound of the extremities, if a pulmonary embolism is suspected, chest x-ray and electrocardiogram may be revealing. Echocardiography is useful to detect other conditions that mimic pulmonary embolism—acute myocardial infarction, pericardial tamponade, and aortic dissection. Further imaging with computed tomography (CT) scanning, MR imaging, or ventilation-perfusion lung scanning confirms the diagnosis (American College of Obstetricians and Gynecologists, 2020b). As discussed later (p. 988), the American Society of Hematology recommends lung scanning as the first-line diagnostic tool (Bates, 2018). At Parkland Hospital we preferentially use CT-pulmonary angiography for suspected pulmonary embolism.

Computed Tomographic Pulmonary Angiography

Multidetector CT-pulmonary angiography (CTPA) is the most commonly employed technique to diagnose pulmonary embolism in nonpregnant patients. The technique is described further in Chapter 49 (p. 874), and an imaging example is shown in Figure 55-5. The estimated fetal radiation exposure averages 0.45 to 0.6 mGy. The estimated maternal breast dose is 10 to 70 mGy (Waksmonski, 2014).

CTPA has many advantages, but we find that the higher resolution allows detection of previously inaccessible smaller distal emboli that have uncertain clinical significance. Similar observations have been reported by others (Anderson, 2007; Hall, 2009). Bourjeily and colleagues (2012) performed a follow-up study of 318 pregnant women who had a negative CTPA performed for a suspected pulmonary embolism. All

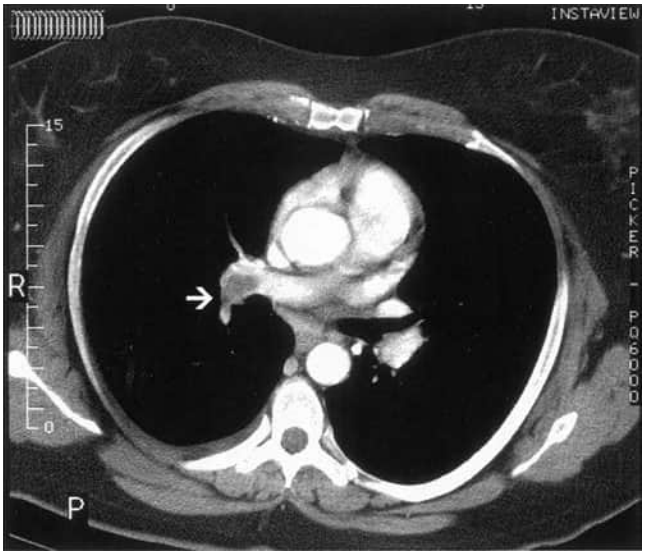

FIGURE 55-5 Axial image of the chest from a four-channel multidetector spiral computed tomographic scan performed after administration of intravenous contrast. There is enhancement of the pulmonary artery with a large thrombus on the right (*arrow*) consistent with pulmonary embolism. (Reproduced with permission from Dr. Michael Landay.)

were seen 3 months following their initial presentation or at 6 weeks postpartum. None of these women were subsequently diagnosed with a thromboembolism.

Ventilation-Perfusion Scintigraphy Lung Scan

This technique involves a small dose of radiotracer such as intravenously administered technetium-99m macroaggregated albumin. There is negligible fetal and maternal breast radiation exposure—0.1 to 0.4 mGy. The scan may not provide a definite diagnosis because many other conditions can cause perfusion defects. Examples are pneumonia or local bronchospasm. Chan and coworkers (2002) found that a fourth of ventilation-perfusion scans in pregnant women were nondiagnostic. In these instances, CTPA is preferred (Tromeur, 2017).

To compare the performance of lung scintigraphy and CTPA, Revel and associates (2011) evaluated 137 pregnant women with suspected pulmonary embolism. The two modalities performed comparably and had no significant differences between the proportions of positive, negative, or indeterminate results. Specifically, the proportion of indeterminate results for both approximated 20 percent, Similarly, one systematic review concluded that both CTPA and lung scintigraphy seem appropriate for exclusion of pulmonary embolism during pregnancy (van Mens, 2017).

Intravascular Pulmonary Angiography

This requires catheterization of the right side of the heart and is considered the reference test for pulmonary embolism. With newer-generation multidetector CT scanners, however, the role of invasive pulmonary angiography has been questioned. This is especially true given the higher radiation exposure for the fetus (Konstantinides, 2014). Other detractions are that it can be time consuming, uncomfortable, and associated with dye-induced allergy and renal failure. It is reserved for confirmation when less invasive tests are equivocal.

Management

Immediate treatment for pulmonary embolism is full anticoagulation similar to that for DVT as discussed on page 982 and shown in Table 55-4. There are several complementary procedures that may be indicated.

Vena Caval Filters

The woman who has very recently suffered a pulmonary embolism and who must undergo cesarean delivery presents a particularly serious problem. Reversal of anticoagulation may be followed by another embolus, and surgery while fully anticoagulated frequently results in life-threatening hemorrhage or troublesome hematomas. In these cases, placement of a vena caval filter should be considered before surgery (Marik, 2008). Moreover, in the very infrequent circumstances in which heparin therapy fails to prevent recurrent pulmonary embolism from the pelvis or legs or in which embolism develops from these sites despite heparin treatment, a vena caval filter may also be indicated. Such filters can also be used following massive emboli in patients who are not candidates for thrombolysis.

The device is inserted through either the jugular or femoral vein and can be inserted during labor (Jamjute, 2006). Routine filter placement has no added advantage to heparin given alone (Decousus, 1998). Retrievable filters may be used as short-term protection and then removed 1 to 2 weeks later (Liu, 2012). From their systematic review, Harris and colleagues (2016) found that complication rates in pregnant women with vena caval filters are comparable to those in nonpregnant patients. In another series of 24 filters placed in obstetrical patients, 29 percent had complications including removal failure (Rottenstreich, 2019).

Thrombolysis

Compared with heparin, thrombolytic agents provide more rapid lysis of pulmonary clots and improvement of pulmonary hypertension in life-threatening cases (Bates, 2021; Goldhaber, 2018). In one study of nonpregnant patients receiving heparin for an acute submassive pulmonary embolism, those receiving the recombinant tissue plasminogen activator *alteplase* had a lower risk of death or treatment escalation (Konstantinides, 2002). One metaanalysis of trials involving nonpregnant patients reported that the risk of recurrence or death was significantly lower in patients given thrombolytic agents and heparin compared with those given heparin alone—10 versus 17 percent (Agnelli, 2002). Importantly, however, there were five—2 percent—fatal bleeding episodes in the thrombolysis group and none in the heparin-only group.

There have been several case reports and reviews of thrombolysis in pregnant women. Leonhardt and coworkers (2006) identified 28 reports of tissue plasminogen activator use during pregnancy. Ten cases were for thromboembolism. Complication rates were similar to those in nonpregnant patients, and the authors concluded that such therapy should not be withheld during pregnancy if indicated. Akazawa and Nishida

(2017) reviewed 13 cases of systemic thrombolytic therapy administered during the first 48 hours after delivery. Blood transfusion was required in five of the eight cesarean deliveries, including three cases of hysterectomy and two cases of hematoma drainage. Sousa-Gomes and associates (2019) reviewed outcomes in 141 pregnant women undergoing thrombolysis for VTE or stroke. Maternal death complicated 3 percent of cases, and major bleeding occurred in 9 percent.

Embolectomy

Given the efficacy of thrombolysis and filters, surgical embolectomy is uncommonly indicated. Published experience with emergency embolectomy during pregnancy is limited to case reports (Colombier, 2015; Saeed, 2014). From their review, Ahearn and colleagues (2002) found that although the operative risk to the mother is reasonable, the stillbirth rate is 20 to 40 percent.

THROMBOPROPHYLAXIS

A Cochrane review of guidelines for thromboprophylaxis in pregnancy concluded that there is a lack of overall agreement about which women should be offered thromboprophylaxis (Middleton, 2021). The American Society of Hematology summarized that evidence-based recommendations rely largely on observational studies and on data extrapolated from nonpregnant patients. In many cases, this led them to *suggest*—rather than *recommend*—various schemes for thromboprophylaxis (Bates, 2018). In an earlier study, Cleary-Goldman and coworkers (2007) surveyed 151 fellows of the American College of Obstetricians and Gynecologists and reported that intervention without a clear indication is common. Table 55-5 lists several consensus recommendations for thromboprophylaxis. In some cases, more than one option is listed, thus illustrating the confusion that currently reigns. It is important to emphasize that the decision to treat with anticoagulation in pregnancy is influenced by personal VTE history, family history of VTE, severity of thrombophilias, and additional risk factors such as obesity, cesarean delivery, or prolonged immobility (American College of Obstetricians and Gynecologists, 2020a).

■ Prior Venous Thromboembolism

In general, either antepartum surveillance or heparin prophylaxis is recommended for women with prior VTE but without a recurrent risk factor. Tengborn and associates (1989), however, suggested that such management may not be effective. They reported outcomes in 87 pregnant Swedish women who had prior thromboembolic disease and were not tested for thrombophilias. Despite unfractionated heparin prophylaxis, which was usually 5000 U twice daily, 15 percent developed antepartum VTE recurrence. This compared with 12 percent not given heparin.

Brill-Edwards and colleagues (2000) prospectively studied 125 pregnant women with a single prior VTE. Antepartum heparin was not given, but anticoagulant therapy was given for 4 to 6 weeks postpartum. Six women had a recurrent venous thrombosis, but there were no recurrences in women without a known thrombophilia or whose prior thrombosis was associated with a temporary risk factor. A study of 88 women without antiphospholipid antibodies and who were not given antithrombotic prophylaxis reported a subsequent pregnancy- or puerperium-related VTE in 22 percent (De Stefano, 2006). Of 20 women whose original thrombosis was associated with a transient risk factor—not including pregnancy or oral contraceptive use—there were no recurrences during pregnancy, but two during the puerperium. These findings imply that women with a prior thrombosis in association with a thrombophilia or in the absence of a temporary risk factor generally should be given both antepartum and postpartum prophylaxis (Connors, 2017). These data also suggest that for women with a prior VTE, antithrombotic prophylaxis during pregnancy could be tailored according to the circumstances of the original event.

It is important to emphasize that VTE may recur despite antithrombotic prophylaxis. A study of 270 women who had at least one previous VTE found that 10 percent suffered a recurrent VTE (Galambosi, 2014). Twelve of these recurrences occurred early in pregnancy before the initiation of antithrombotic prophylaxis, and 16 occurred despite prophylactic use of LMWH.

Our practice at Parkland Hospital for many years for women with a history of prior VTE was to administer subcutaneous UFH, 5000 to 7500 units two to three times daily. More recently, we have used 40 mg of enoxaparin given subcutaneously daily with transition to UFH near delivery. With either regimen, the recurrence of documented DVT embolization has been uncommon.

■ Cesarean Delivery

The risk for DVT and especially for fatal thromboembolism rises many fold following cesarean delivery compared with that after vaginal delivery. When considering that a third of women giving birth in the United States yearly undergo cesarean delivery, pulmonary embolism is understandably a major cause of maternal mortality (Creanga, 2017; Petersen, 2019). That said, the lack of consensus described earlier by Middleton and coworkers (2021) creates considerable variation in the current recommendations promulgated by the American College of Obstetricians and Gynecologists, the Royal College of Obstetricians and Gynaecologists, and the American College of Chest Physicians (Palmerola, 2016).

Adherence to individual society guidelines following cesarean delivery confers a greater risk in some instances. According to the Society for Maternal-Fetal Medicine (2020), if American College guidelines were followed, only 1 percent of these women would be candidates for thromboprophylaxis. Almost 85 percent of the same cohort would be given thromboprophylaxis following Royal College guidelines and about 35 percent if American College of Chest Physician guidelines were followed. Some comparisons of these thromboprophylaxis guidelines are shown in Table 55-6.

Since 2011, the American College of Obstetricians and Gynecologists (2020b) recommends placement of pneumatic compression devices before cesarean delivery for all women not already receiving thromboprophylaxis. This recommendation was based primarily on consensus and expert opinion. For patients

TABLE 55-6. Thromboprophylaxis Guidelines for Women Undergoing Cesarean Delivery

Organization	Recommendations	Risk Factors
ACOG[a]	Pneumatic compression devices for all Pharmacological prophylaxis for risk factors	Risk factors not defined; individualize therapy
SMFM[b]	Pneumatic compression devices for all Prophylactic LMWH Intermediate-dose LMWH Individualized therapy	History of VTE Thrombophilia without history of a VTE Class III obesity with a thrombophilia or history of a VTE Combination of the above factors
RCOG[c]	Prophylactic LMWH for 10 days	Cesarean during labor BMI >40 kg/m^2 Medical comorbidities *or* 2 or more of the following: age >35, parity >3, obesity, smoker, varicose veins, systemic infection, preeclampsia, preterm delivery, stillbirth, operative vaginal delivery, PPH, prolonged admission
	Prophylactic LMWH for 6 weeks	Prior VTE High-risk thrombophilia Low-risk thrombophilia and family history of VTE Antenatal LMWH therapy

[a]ACOG = American College of Obstetricians and Gynecologists, 2020b.
[b]SMFM = Society for Maternal-Fetal Medicine, 2020.
[c]RCOG = Royal College of Obstetricians and Gynaecologists, 2015.
BMI = body mass index; CHF = congestive heart failure; DM = diabetes mellitus; IBD = inflammatory bowel disease; LMWH = low-molecular-weight heparin; PPH = postpartum hemorrhage; VTE = venous thromboembolism

undergoing cesarean delivery with additional risk factors for thromboembolism, both pneumatic compression devices and UFH or LMWH may be recommended. The College stipulated that cesarean delivery in an emergency setting should not be delayed because of the time necessary to begin thromboprophylaxis.

Implementation of this strategy by the Hospital Corporation of America, the largest for-profit obstetrical health care delivery system in the United States, was associated with a reduction in deaths from pulmonary embolism from 7 of 458,097 cesarean births to 1 of 465,880 cesarean births (Clark, 2011, 2014).

In 2016, the National Partnership for Maternal Safety published several consensus recommendations for the prevention of maternal VTE (D'Alton, 2016). These recommendations included expanded use of antenatal thromboprophylaxis for women hospitalized 3 days or longer, expanded use of prophylaxis during and after vaginal delivery, and expanded use of pharmacological prophylaxis to most women after cesarean delivery. In response, Sibai and Rouse (2016) expressed concern that these new recommendations derive from sparse data of questionable applicability to obstetrical patients. They called for better quality evidence to measure the benefits, harms, and costs of increased pharmacological thromboprophylaxis. As aptly expressed by Macones (2017), "an intervention, such as increased postcesarean pharmacologic thromboprophylaxis, where there are legitimate concerns about efficacy and safety, requires a much higher degree of evidence before a national guideline is implemented." We agree with these sentiments.

CHAPTER 56

Renal and Urinary Tract Disorders

Disorders of the kidneys and urinary tract are commonly encountered in pregnancy. Some precede pregnancy—one example is nephrolithiasis. Pregnancy-induced changes may predispose to the development or worsening of urinary tract disorders—an example is the markedly increased risk for pyelonephritis. Last, renal pathology unique to pregnancy, such as preeclampsia, can develop. In one Australian study, kidney disorders had an incidence of 0.3 percent in 407,580 births (Fitzpatrick, 2019).

PREGNANCY-INDUCED URINARY TRACT CHANGES

During normal pregnancy, significant changes in both structure and function take place in the urinary tract (Chap. 4, p. 67). The kidneys become larger, and dilation of the renal calyces and ureters can be striking. Some dilation develops before 14 weeks and likely is due to progesterone-induced relaxation of the muscularis. More marked dilation is apparent beginning in midpregnancy and stems from ureteral compression, especially on the right side. *Vesicoureteral reflux* also occurs during pregnancy. Important consequences of these physiological changes are an increased risk of upper urinary infection and erroneous interpretation of studies.

Evidence of functional renal hypertrophy becomes apparent very soon after conception. Glomeruli are larger, although cell numbers are not greater (Strevens, 2003). Intrarenal vasodilation lowers resistance of both afferent and efferent arterioles, and leads to higher effective renal plasma flow and glomerular filtration (Helal, 2012; Hussein, 2014). By 12 weeks' gestation, the glomerular filtration rate (GFR) is already 20 percent above nonpregnant values (Hladunewich, 2004). Ultimately, renal plasma flow rises by 40 percent and GFR by 65 percent. Consequently, serum concentrations of creatinine and urea decline substantively across pregnancy. Thus, values within a nonpregnant normal range may be abnormal for pregnancy (Appendix, p. 1232). Other alterations include those related to acid–base homeostasis and osmoregulation.

Assessment of Renal Function During Pregnancy

Urinalysis results are essentially unchanged during normal pregnancy, except for occasional glucosuria. In nondiabetic gravidas, glucosuria is thought to stem from a pregnancy-related reduced rate of renal tubular glucose reabsorption (Welsh, 1960). This normal physiological change may add confusion and concerns for a gestational diabetes mellitus (GDM) diagnosis. Indeed, 1+ or greater urine dipstick readings have been associated with subsequent GDM diagnosis later in pregnancy. Despite this association, urine dipstick testing alone shows poor sensitivity

to diagnose GDM (Buhlin, 2004; Olagbuji, 2015). For women with glucosuria, no guidelines in the United States direct practice, but in the United Kingdom, early oral glucose testing is considered for those with an isolated 2+ or repetitive 1+ urine dipstick readings (National Institute for Health And Clinical Excellence, 2015). This seems to be a reasonable approach.

Protein excretion is slightly elevated, but it seldom reaches levels that are detected by usual screening methods. Higby and colleagues (1994) reported 24-hour protein excretion in normal pregnancy to be 115 mg, with a 95-percent confidence level of 260 mg/d (Chap. 4, p. 68). This value did not significantly differ by trimester. Albumin constitutes only a small part of total protein excretion, and amounts range from 5 to 30 mg/d. From their review, Airoldi and Weinstein (2007) concluded that proteinuria must exceed 300 mg/d to be considered abnormal. Many consider 500 mg/d to be important with gestational hypertension. As an initial surrogate for 24-hour collections, quantification of the urinary protein-to-creatinine ratio in a spot urine sample is helpful in estimating a 24-hour protein excretion rate. The ratio is nearly the same numerically as the number of grams of protein excreted in urine per day. This measurement is best obtained from a first morning void. Surprisingly, women with lower urinary tract infections do not have more proteinuria (Stephens, 2019).

Blood is another urinalysis marker. In one study, 3 percent of 4307 nulliparas who were screened before 20 weeks' gestation had *idiopathic hematuria*, defined as 1+ or greater blood on urine dipstick (Stehman-Breen, 2002). These women had a twofold higher risk of developing preeclampsia. However, the link between preeclampsia and hematuria has not been found by all (Brown, 2005; Shahriaki, 2016). In another study of 1000 women screened during pregnancy, Brown and coworkers (2005) reported a 15-percent incidence of dipstick microscopic hematuria. Most women had trace levels of hematuria, and the false-positive rate with this tool was 40 percent. Notably, other elements such as vitamin C, povidone-iodine, myoglobin, free hemoglobin can produce false-positive results. Thus, positive dipstick results should prompt formal urinalysis. Microscopic hematuria is defined as >3 red blood cells (RBCs) per high-powered field (HPF).

For verified asymptomatic microscopic hematuria, few guidelines direct the best evaluation. History and physical often point to benign causes. If not, initial exclusion of infection by urinalysis or culture is reasonable. For early glomerular disease, serum creatinine and blood urea nitrogen levels, a spot protein-to-creatinine ratio or 24-hour urine collection, and urinalysis with examination of urine sediment can aid diagnosis. With this last step, proteinuria, dysmorphic RBCs, and cellular casts are characteristics. To help exclude neoplastic or stone disease, magnetic resonance urography (MRU) of the upper and lower urinary tract and cystoscopy is suitable in pregnancy (Davis, 2012). However, the American College of Obstetricians and Gynecologists (2017) recommends against the last steps to exclude cancer for asymptomatic, low-risk, never-smoking women younger than 50 years who have ≤25 RBCs seen per HPF.

If the serum creatinine level in pregnancy persistently exceeds 0.9 mg/dL (75 µmol/L), intrinsic renal disease should be suspected (Wiles, 2019a). In these cases, some determine the creatinine clearance as an estimate of the GFR.

Of imaging tools, *sonography* informs on renal size, relative consistency, and elements of obstruction. Full-sequence *intravenous pyelography* is not done routinely. However, the clinical situation may warrant *one-shot pyelography*, in which contrast medium injection is followed after 30 minutes by one or two abdominal radiographs (Chap. 49, p. 873). Magnetic resonance (MR) imaging of renal masses provides excellent results due to its excellent resolution at soft-tissue interfaces (Putra, 2009). *Cystoscopy* is performed for the same indications as in the nonpregnant population. *Ureteroscopy* similarly may be indicated and carries an approximate 5-percent complication rate during stone removal during pregnancy (Johnson, 2012).

Although relatively safe during pregnancy, *renal biopsy* usually is postponed unless results may change therapy. From a review of 243 biopsies in pregnant women, the incidence of complications was 7 percent compared with 1 percent in postpartum women (Piccoli, 2013). Lindheimer and colleagues (2013) recommend its consideration for those with rapid deterioration of renal function of unclear etiology or with symptomatic nephrotic syndrome. We have found biopsy helpful in selected cases to direct management. Renal biopsy performed in *normal* pregnant volunteers showed that approximately 50 percent had slight to moderate glomerular endotheliosis (Strevens, 2003). In contrast, all 27 women with proteinuric hypertension had moderate to severe endotheliosis.

Pregnancy After Unilateral Nephrectomy

After removal of one kidney, a remaining normal kidney provides augmented compensatory renal function. With pregnancy, this is further amplified. Functional evaluation of the remaining kidney is essential, even though most women have no difficulty in pregnancy. At minimum, the serum creatinine level is measured and a urine spot protein:creatinine ratio is determined. No long-term permanent consequences accompany kidney donation done before pregnancy. However, the incidence of subsequent preeclampsia is greater (Davis, 2019; Steele, 2019; Vannevel, 2018).

URINARY TRACT INFECTIONS

Asymptomatic or *covert bacteriuria* is frequent in pregnancy and is an infection precursor. True infections of the urinary tract are the most prevalent bacterial infections during pregnancy. Symptomatic infection includes *cystitis*, or it may involve the renal calyces, pelvis, and parenchyma to cause *pyelonephritis*.

Organisms from the normal perineal flora cause urinary infections. *Escherichia coli* strains most commonly cause nonobstructive pyelonephritis. In approximately 90 percent of these organisms, *adhesins* such as P- and S-fimbriae are present. These are cell-surface protein structures that enhance bacterial adherence to vaginal and uroepithelial cells and virulence (Hooton, 2012; Spurbeck, 2011). Maternal deaths have been attributed to *E coli* bearing Dr^+ and P adhesins (Sledzińska, 2011).

Urinary stasis, vesicoureteral reflux, and diabetes mellitus predispose to symptomatic upper urinary infections. Moreover, data suggest that pregnant women have more severe sequelae from urosepsis. As one influence, the T helper cell (Th1:Th2)

ratio of normal pregnancy is reversed (Chap. 4, p. 61). Additionally, various perturbations of cytokine expression have been reported (Chaemsaithong, 2013).

In the puerperium, several risk factors also predispose a woman to urinary infections. Bladder sensitivity to intravesical fluid tension is often diminished as a consequence of labor trauma or conduction analgesia (Chap. 36, p. 638). Also, the sensation of bladder distention can be masked by discomfort from an episiotomy, periurethral laceration, or vaginal wall hematoma. Normal postpartum diuresis, while usually protective, may worsen bladder overdistention, and catheterization performed to relieve retention may lead to urinary infection.

Asymptomatic Bacteriuria

This refers to persistent, actively multiplying bacteria within the urinary tract in asymptomatic women. It is defined as one or more bacterial species that has a count $\geq 10^5$ colony-forming units/mL determined by urine culture of a voided specimen (Infectious Disease Society of America, 2019). Its prevalence in sexually active nonpregnant women is 2 to 6 percent (Hooten, 2000; Nicolle, 2003). The highest incidence is in African-American multiparas with sickle-cell trait, and the lowest incidence is in affluent white women of low parity. Asymptomatic infection is also more common in women with diabetes (Schneeberger, 2014). In most women, bacteriuria is recurrent or persistent, and thus it frequently is discovered during prenatal care. The incidence during pregnancy is similar to that in nonpregnant women and varies from 2 to 7 percent (Nicolle, 2003).

Bacteriuria is typically already present at the time of the first prenatal visit. An initial positive urine culture result should prompt treatment, after which, fewer than 1 percent of women develop a symptomatic UTI (Whalley, 1967). It may be prudent to treat lower concentrations, because pyelonephritis develops in some women with colony counts of only 20,000 to 50,000 organisms/mL (Lucas, 1993).

Significance

If asymptomatic bacteriuria (ASB) is not treated, approximately 25 percent of affected women will develop symptomatic infection during pregnancy. Eradication of bacteriuria with antimicrobial agents prevents most of these. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017), as well as the U.S. Preventive Services Task Force (2019), recommend screening for bacteriuria at the first prenatal visit (Chap. 10, p. 181). Standard urine cultures may not be cost effective when the prevalence is low. Instead, less expensive screening tests such as the leukocyte esterase and nitrite dipstick are cost-effective (Chu, 2018). At Parkland Hospital, culture screening is done because of a 5- to 8-percent prevalence of bacteriuria. Susceptibility determination is not necessary because initial treatment is empirical (Hooton, 2012). Last, a special agar-coated dipstick culture technique has excellent positive and negative predictive values (Rogozińska, 2016).

Other than pyelonephritis prevention, it is unclear whether ASB treatment provides other benefits. In many studies, there was no distinction from symptomatic infection. For example, in a cohort of 25,746 mother-newborn pairs, Schieve and coworkers (1994) reported UTI to be associated with increased risks for low-birthweight neonates, preterm delivery, pregnancy-associated hypertension, and anemia. These findings vary from those of Gilstrap and colleagues (1981b) and Whalley (1967), who studied asymptomatic infection. A California database study reported 160,000 women with UTIs were treated in the emergency department or hospital (Baer, 2021). These presumed symptomatic infections were associated with a 1.4-fold higher preterm delivery rate in those <37 weeks.

Treatment

Bacteriuria responds to empirical treatment with any of several antimicrobial regimens listed in Table 56-1. *E coli* is the most common species isolated in pregnant women (Le Blanc, 1964; Nicolle, 2003). Selection can be based on in vitro susceptibilities. However, in our extensive experience, empirical oral treatment for 10 days with nitrofurantoin macrocrystals, 100 mg at bedtime, is usually effective. Lumbiganon and associates (2009) reported satisfactory results with a 7-day oral course of nitrofurantoin, 100 mg given twice daily. Single-dose antimicrobial therapy also has been used with success for bacteriuria. The important caveat is that, regardless of regimen given, the recurrence rate approximates 30 percent. This may indicate covert upper tract infection and the need for longer therapy.

TABLE 56-1. Oral Antimicrobial Agents Used for Treatment of Pregnant Women with Asymptomatic Bacteriuria

Single-dose treatment
Amoxicillin, 3 g
Ampicillin, 2 g
Cephalosporin, 2 g
Nitrofurantoin, 200 mg
Trimethoprim-sulfamethoxazole, 320/1600 mg
3-day course
Amoxicillin, 500 mg three times daily
Ampicillin, 250 mg four times daily
Cephalosporin, 250 mg four times daily
Nitrofurantoin, 50 to 100 mg four times daily or 100 mg twice daily
Trimethoprim-sulfamethoxazole, 160/800 mg two times daily
Other
Nitrofurantoin, 100 mg four times daily for 10 days
Nitrofurantoin, 100 mg twice daily for 5 to 7 days
Nitrofurantoin, 100 mg at bedtime for 10 days
For treatment failures
Nitrofurantoin, 100 mg four times daily for 21 days
Suppression for bacterial persistence or recurrence
Nitrofurantoin, 100 mg at bedtime for remainder of pregnancy

Periodic surveillance is necessary to prevent recurrent UTIs (Schneeberger, 2015). The first recurrence is considered a treatment failure and extended therapy for 21 days is considered. For women with persistent or frequent ASB, suppressive therapy for the remainder of pregnancy can be given. We routinely use nitrofurantoin, 100 mg orally at bedtime. Its rare but serious side effects are pulmonary and hepatic toxicity.

Cystitis and Urethritis

According to the Centers for Disease Control and Prevention, 7.2 percent of pregnant women were treated as an outpatient for a UTI in 2014 (Ailes, 2018). Cystitis is characterized by dysuria, urgency, and frequency but causes few associated systemic findings. Pyuria and bacteriuria are usually found. Microscopic hematuria is common, and occasionally gross hematuria stems from hemorrhagic cystitis. Although cystitis is usually uncomplicated, the upper urinary tract may become involved by ascending infection. Almost 40 percent of pregnant women with acute pyelonephritis have preceding symptoms of lower tract infection (Gilstrap, 1981a).

Women with cystitis respond readily to any of several regimens. Most of the three-day regimens listed in Table 56-1 are usually 90-percent effective. Single-dose therapy is less effective, and if it is used, concomitant pyelonephritis must be confidently excluded.

Lower urinary tract symptoms with pyuria accompanied by a sterile urine culture may be from urethritis caused by *Chlamydia trachomatis*. Mucopurulent cervicitis usually coexists, and azithromycin therapy is effective (Chap. 68, p. 1212).

Acute Pyelonephritis

Infection of the renal parenchyma is the most common serious nonobstetrical medical complication of pregnancy. One study of the Nationwide Inpatient Sample found that nearly 29,000 hospitalizations in 2006 were for acute pyelonephritis in pregnancy (Jolley, 2012). The highest rates were noted for adolescents at 17.5 per 1000 and for Hispanic women at 10.1 per 1000. In another study of more than 70,000 pregnancies in a managed care organization, 3.5 percent of antepartum admissions were for urinary infections (Gazmararian, 2002). The seriousness is underscored by the observations of Snyder and coworkers (2013) that pyelonephritis was the leading cause of septic shock during pregnancy. Moreover, in a 2-year audit of admissions to the Parkland Hospital Obstetrical Intermediate Care Unit, 12 percent of antepartum admissions were for sepsis caused by pyelonephritis (Zeeman, 2003). Of concern, maternal urosepsis may be related to an increased incidence of cerebral palsy in preterm newborns (Jacobsson, 2002). Fortunately, data do not suggest serious long-term maternal sequelae (Raz, 2003).

Clinical Findings

Renal infection develops more frequently in the second half of pregnancy, and nulliparity and young age are risk factors (Hill, 2005). Pyelonephritis is unilateral and right-sided in more than half of cases, and it is bilateral in a fourth. Its abrupt onset is marked by fever, shaking chills, and aching pain in one or both lumbar regions. Anorexia, nausea, and vomiting may worsen dehydration. Tenderness usually can be elicited by percussion in one or both costovertebral angles. The urinary sediment contains many leukocytes, frequently in clumps, and numerous bacteria. The differential diagnosis includes, among others, labor, chorioamnionitis, appendicitis, placental abruption, or infarcted leiomyoma.

Bacteremia is demonstrated in 15 to 20 percent of these women. *E coli* is isolated from urine or blood in 70 to 80 percent of infections, *Klebsiella pneumoniae* in 3 to 5 percent, *Enterobacter* or *Proteus* species in 3 to 5 percent, and gram-positive organisms, including group B *Streptococcus* and *Staphylococcus aureus*, in up to 10 percent of cases (Hill, 2005; Wing, 2000). Evidence of sepsis is common, and this is discussed in detail in Chapter 50 (p. 888).

During care, plasma creatinine is monitored, because 5 percent of pregnant women develop renal dysfunction despite aggressive fluid resuscitation (Hill, 2005). Follow-up studies have demonstrated that this endotoxin-induced damage is reversible in the long term (Whalley, 1975). In up to 10 percent of women, varying degrees of respiratory insufficiency, including frank pulmonary edema, may result from endotoxin-induced alveolar injury (Cunningham, 1987; Sheffield, 2005; Snyder, 2013). In some cases, pulmonary injury may be so severe that it causes *acute respiratory distress syndrome (ARDS)*.

Uterine activity from endotoxins is common and is related to fever severity. In a study by Millar and associates (2003), women with pyelonephritis averaged 5 contractions per hour at admission, and this declined to 2 per hour within 6 hours of intravenous fluid and antimicrobial administration. β-agonist therapy for tocolysis raises the likelihood of respiratory insufficiency from permeability edema because of the sodium- and fluid-retaining properties of those agents (Chap. 50, p. 883). In one study, the incidence of pulmonary edema in women with pyelonephritis who were given β-agonists was 8 percent—a fourfold increase compared with that expected (Towers, 1991).

Endotoxin-induced *hemolysis* is common, and approximately a third of patients with pyelonephritis develop anemia (Cox, 1991). With recovery, hemoglobin regeneration is normal because acute infection does not affect erythropoietin production (Cavenee, 1994).

Management

One scheme for management of acute pyelonephritis is shown in Table 56-2. Although we obtain blood cultures when the patient temperature exceeds 39°C, prospective trials show them to be of limited clinical utility (Wing, 2000). *Intravenous hydration to ensure adequate urinary output is the cornerstone of treatment.* Antimicrobials also are begun promptly with the caution that they may initially worsen endotoxemia from bacterial lysis. Ongoing surveillance for worsening of sepsis is monitored by serial determinations of urinary output, blood pressure, pulse, temperature, and oxygen saturation. High fever should be lowered with a cooling blanket and acetaminophen. This is especially important in early pregnancy because of possible teratogenic effects of hyperthermia.

TABLE 56-2. Management of the Pregnant Woman with Acute Pyelonephritis

Hospitalize patient
Obtain urine and blood cultures
Evaluate hemogram, serum creatinine, and electrolytes
Monitor vital signs frequently, including urinary output—consider indwelling catheter
Establish urinary output ≥50 mL/h with IV crystalloid solution
Administer IV antimicrobial therapy (see text)
Obtain chest radiograph if there is dyspnea or tachypnea
Repeat hematology and chemistry studies in 48 h
Change to oral antimicrobials when afebrile
Discharge when afebrile 24 h, consider antimicrobial therapy for 7-10 d
Repeat urine culture 1–2 wks after antimicrobial therapy completed

IV = intravenous.
From Lucas, 1994; Sheffield, 2005.

Antimicrobial therapy usually is empirical, and ampicillin plus gentamicin; cefazolin or ceftriaxone; or an extended-spectrum antibiotic were all 95-percent effective in randomized trials (Sanchez-Ramos, 1995; Wing, 1998, 2000). Fewer than half of *E coli* strains are sensitive to ampicillin in vitro, but gentamicin plus ampicillin or plus a cephalosporin generally have a synergistic effect and excellent activity (Johnson, 2018). Serum creatinine levels are monitored if nephrotoxic drugs are given. Initial treatment at Parkland Hospital is ampicillin plus gentamicin. Some recommend suitable substitutes if bacterial studies show in vitro resistance. With any of the regimens discussed, response is usually prompt, and 95 percent of women are afebrile by 72 hours (Hill, 2005; Wing, 2000). After discharge, most recommend oral therapy to complete 10 to 14 days (Hooton, 2012; Johnson, 2018).

Recurrent infection—either covert or symptomatic—is common and develops in 30 to 40 percent of women following completion of pyelonephritis treatment. Unless other measures are taken to ensure urine sterility, nitrofurantoin, 100 mg orally at bedtime given for the remainder of the pregnancy, reduces bacteriuria recurrence.

Persistent Infection

Generally, stepwise defervescence of approximately 1°F per day follows intravenous hydration and antimicrobial therapy. Upwards of 20 percent of women are febrile for more than 4 days (Valent, 2017). With persistent spiking fever or lack of clinical improvement by 48 to 72 hours, urinary tract obstruction, calculi, or abscess is considered (Johnson, 2018). In these women, renal sonography is recommended to search for these.

Obstruction manifests by abnormal ureteral or pyelocaliceal dilation. Nephrolithiasis, however, is not always seen in a renal sonogram (Butler, 2000; Maikranz, 1987). If stones are strongly suspected despite a nondiagnostic sonographic examination, a plain abdominal radiograph will identify nearly 90 percent. Another option is the modified *one-shot intravenous pyelography* (p. 995) (Butler, 2000). Last, persistent infection can be due to an intrarenal or perinephric abscess or phlegmon (Cox, 1988; Rafi, 2012). MR imaging is preferred for abscess detection if renal sonography is nonconclusive (Rubilotta, 2014).

Obstruction relief is important, and we have found that percutaneous nephrostomy is preferable because the stents are more easily replaced. Another method is cystoscopic placement of a double-J ureteral stent. These stents are usually left in place until after delivery and often become encrusted and need replacing (Lindquester, 2021). Last, in some women, surgical removal of stones may be needed (p. 1000). Renal abscesses larger than 3 cm may necessitate percutaneous drainage or surgical treatment (Coelho, 2007; Mandal, 2017; Siegel, 1996).

Outpatient Management of Pyelonephritis

This is an option for nonpregnant women with uncomplicated pyelonephritis (Fox, 2017; Johnson, 2018). Wing and colleagues (1999) described such management in 92 pregnant women who were first given in-hospital intramuscular ceftriaxone, two 1-g doses 24 hours apart. At this point, one third of the group was considered suitable for outpatient therapy, and these women were randomly assigned either to discharge and oral antimicrobials or to continued hospitalization with intravenous therapy. A third of the outpatient management group was unable to adhere to the treatment regimen and was admitted. These findings suggest that outpatient management of pyelonephritis is applicable only to very few pregnant women.

■ Reflux Nephropathy

This refers to loss of nephron mass from patchy interstitial scarring and tubular atrophy due to high-pressure reflux of sterile urine from the bladder to the kidneys. In adults, long-term complications include hypertension, which may be severe if renal damage is demonstrable (Beck, 2018). Moreover, reports describing 879 pregnancies in 432 women with reflux nephropathy indicate that impaired renal function and bilateral renal scarring were associated with higher rates of pregnancy-associated hypertensive disorders (Attini, 2018). Many also had surgical correction of reflux as children, and these women commonly have bacteriuria when pregnant (Mor, 2003). In other women with reflux nephropathy, no clear history implicates recurrent cystitis, acute pyelonephritis, or obstructive disease (Gebäck, 2016). Chronic renal disease and pregnancy outcome is discussed further later (p. 1003).

NEPHROLITHIASIS

Kidney stones develop in 9 percent of women during their lifetime with an average age of onset in the third decade (Curhan, 2018). Calcium salts make up approximately 80 percent of stones, and hyperparathyroidism should be excluded. Calcium oxalate stones are most common in young nonpregnant women, but in pregnancy most stones—65 to 75 percent—are calcium phosphate or hydroxyapatite (Tan, 2013).

Nephrolithiasis is more common in women with prior pregnancies than in nulligravidas. Normal physiological changes of the urinary system may promote stone formation, and elevation of urinary pH reduces calcium phosphate solubility (Reinstatler, 2017). More than half of patients who have a stone typically form another stone within 10 years.

Contrary to past teachings, a low-calcium diet *promotes* stone formation. Current recommendations to prevent recurrences include hydration and a diet low in sodium and protein (Curhan, 2018). Thiazide diuretics also diminish stone formation. In general, obstruction, infection, intractable pain, and heavy bleeding are indications for stone removal. Extraction by a flexible basket via cystoscopy, although used less often than in the past, is still a reasonable consideration for pregnant women. In nonpregnant patients, stone destruction by *lithotripsy* is preferred to surgical therapy in most cases. Limited information guides the use of lithotripsy during pregnancy, and it is not generally recommended.

■ Stone Disease During Pregnancy

The reported incidence of stone disease complicating pregnancy varies widely. At the low end, Butler and coworkers (2000) found an incidence of 0.3 admissions per 1000 pregnancies in more than 186,000 deliveries at Parkland Hospital. In an Israeli study, the incidence in nearly 220,000 pregnancies was 0.8 per 1000 (Rosenberg, 2011). Most stone episodes are diagnosed in the second and third trimesters of pregnancy (Dai, 2021). Bladder stones are rare, but recurrent infection and labor obstructed by stones have been reported (Ait Benkaddour, 2006; Ruan, 2011).

Data are conflicting whether women with kidney stones have an increased risk for adverse pregnancy outcomes. Swartz and colleagues (2007) reported a preterm delivery rate of 10.6 percent in women with nephrolithiasis compared with 6.4 percent in normal controls. A nationwide case-control study from Taiwan also reported 20- to 40-percent increases in low-birthweight newborns and preterm births (Chung, 2013). To the contrary, a case-control study from Hungary reported that pregnancy outcomes, including preterm delivery, were similar in women with and without stone disease (Banhidy, 2007). Comparable conclusions were drawn from the Israeli study noted earlier (Rosenberg, 2011). Women who have formed stones prior to pregnancy have a higher incidence of gestational diabetes and preeclampsia (Tangren, 2018).

Diagnosis

More than 90 percent of pregnant women with nephrolithiasis present with pain. However, some evidence suggests that pregnant women may have fewer symptoms with stone passage because of normal urinary tract dilation (Tan, 2013). Gross hematuria is less common than in nonpregnant women and has an incidence of 2 to 23 percent (Butler, 2000; Lewis, 2003).

Sonography is the first-line study to visualize stones, but as discussed above, many are undetected (McAleer, 2004). Abnormal urinary tract dilation or absent ureteral "jets" of urine into the bladder are indirect indicators of urolithiasis (Fig. 56-1). If abnormal dilation is seen but no stone is visualized, one-shot pyelography may be useful.

Helical computed tomography (CT) scanning is preferred imaging for nonpregnant individuals. In pregnancy, MR imaging is the second-line test following a nondiagnostic sonographic evaluation (Masselli, 2013). However, if CT imaging is needed, White and colleagues (2007) recommend unenhanced helical CT and cite an average fetal radiation dose to be 7 mGy.

Management

Treatment depends on symptoms and gestational age (Semins, 2013). Intravenous hydration and analgesics are given. Patients strain collected urine to identify passed stones. In half of women with symptomatic stones, infection will be identified, and this is treated vigorously. Although calculi infrequently cause symptomatic obstruction during pregnancy, persistent pyelonephritis should prompt a search for obstruction due to nephrolithiasis.

Approximately 75 percent of symptomatic women will improve with conservative therapy, and the stone usually passes spontaneously (Tan, 2013). Others require an invasive procedure such as ureteral stenting, ureteroscopy, percutaneous nephrostomy, transureteral laser lithotripsy, or basket extraction (Butler, 2000; Hosseini, 2017). Watterson and coworkers

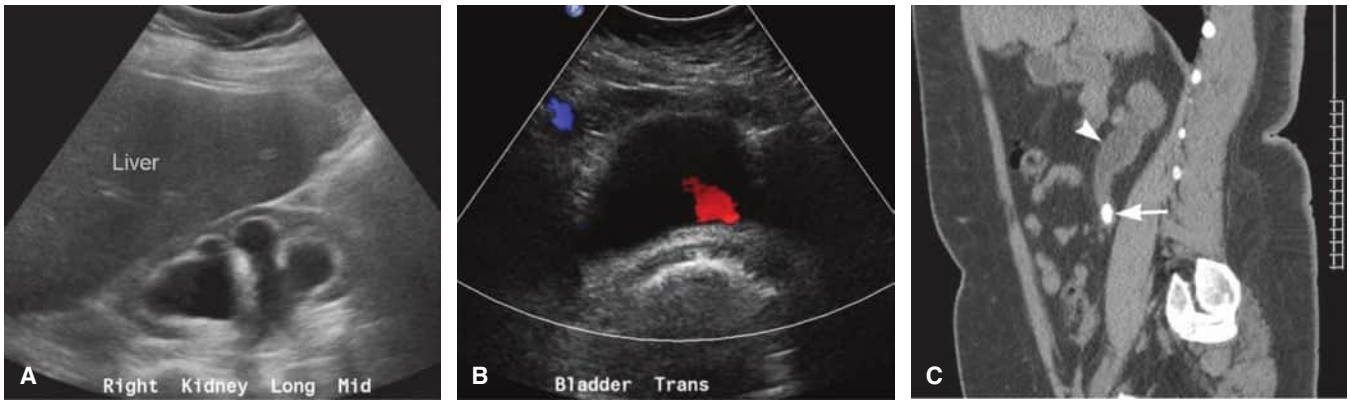

FIGURE 56-1 **A.** Sonographic image of the right upper quadrant demonstrates severe hydronephrosis and thinned echogenic renal parenchyma. **B.** Application of color Doppler during sonography of the bladder reveals a urine jet (*red streak*) from the left ureteral orifice. No flow was noted from the right orifice during observation. **C.** Sagittal CT image shows an obstructing stone in the mid right ureter (*arrow*) and hydroureteronephrosis (*arrow head*).

(2002) described successful transureteral holmium:YAG laser lithotripsy in nine of 10 women. Ultimately, less than 2 percent of symptomatic pregnant women require surgical exploration following one of the procedures listed above (Swartz, 2007). The need for fluoroscopy limits the utility of percutaneous nephrolithotomy. Extracorporeal shock-wave lithotripsy is contraindicated in pregnancy.

PREGNANCY AFTER RENAL TRANSPLANTATION

In 2020, more than 100,000 registrants were waiting for renal transplantations through the Organ Procurement and Transplantation Network—OPTN (2020). The 1-year graft survival rate is 95 percent for those from living donors and is 90 percent from deceased donors. Survival rates approximately doubled in the 1990s, due in large part to the introduction of cyclosporine and muromonab-CD3 (Orthoclone OKT3) to prevent and treat organ rejection. The latter is a monoclonal antibody against the CD3 receptor of T cells. Since then, mycophenolate mofetil and tacrolimus have further reduced acute rejection episodes. However, the former is teratogenic (Briggs, 2017). In the report from the National Transplant Pregnancy Registry, 23 percent of fetuses exposed to mycophenolate had birth defects (Coscia, 2010). Importantly, resumption of renal function after transplantation promptly restores fertility in reproductive-aged women (Yaprak, 2019). Thus, these women should be counseled to use contraception, especially those treated with mycophenolate. In one study, more than half of transplant recipients reported that they were not counseled regarding contraception (French, 2013).

Pregnancy Outcomes

Women with solid organ transplant have higher severe maternal morbidity rates (Sabr, 2019). Deshpande and associates (2011) reviewed the outcomes of more than 4700 pregnancies in renal transplant recipients. Approximately 70 percent of pregnancies resulted in a live birth. However, rates of preeclampsia, gestational diabetes, and preterm delivery were substantially greater. Similar outcomes were described for the Australian and New Zealand Transplant Registry (Wyld, 2013). In the United Kingdom, Bramham and colleagues (2013) identified a live-birth rate that exceeded 90 percent in renal transplant recipients. Half were delivered before 37 weeks' gestation, but only 9 percent before 32 weeks. Low birthweight complicated half of pregnancies, and growth restriction complicated 25 percent. Notably, the incidence of fetal malformations was not increased, except in those who took mycophenolate mofetil.

The incidence of preeclampsia is high in all transplant recipients. In the UK National Cohort Study reported by Bramham and associates (2013), the incidence of preeclampsia was 22 percent. From their review, Josephson and McKay (2011) cite an incidence of one third of pregnancies but question the validity of this frequency. Importantly, in some cases, rejection is difficult to distinguish from preeclampsia. That said, the incidence of rejection episodes approximates only 2 percent (Bramham, 2013). Viral infections—especially polyomavirus hominis 1, also called *BK virus*—are frequent. In addition, gestational diabetes is found in approximately 5 percent. Both are likely related to immunosuppression therapy. Similar outcomes have been reported by several other investigators (Al Duraihimh, 2008; Cruz Lemini, 2007; Ghafari, 2008).

The Italian Society of Nephrology recommends that women who have undergone transplantation satisfy several requisites before attempting pregnancy (Cabiddu, 2018). First, women should be in good general health for at least 1 to 2 years after transplantation. Second, renal function should be stable. Parameters include a GFR ≥60 mL/min, serum creatinine level <2 mg/dL, and proteinuria <500 mg/d. Third, there should be no recent evidence for graft rejection and no treatment with teratogenic drugs. Last, hypertension should be absent or well controlled.

Cyclosporine and tacrolimus are given routinely to renal transplantation recipients. Coincident with expected pregnancy-related intravascular volume expansion, cyclosporine blood levels decline during pregnancy. However, this was not reported to be associated with rejection episodes (Thomas, 1997). Unfortunately, these agents are nephrotoxic and may also cause renal hypertension. In fact, they likely contribute substantively to the chronic renal disease that develops in 10 to 20 percent of patients with nonrenal solid organ transplantation (Goes, 2007).

Concern persists regarding the possible late effects in offspring subjected to immunosuppressive therapy in utero. These include malignancy, germ cell dysfunction, and malformations in the children of the offspring. In addition, cyclosporine is secreted in breast milk (Moretti, 2003). In two small studies, these children had normal neurological and intellectual function (Morales-Buenrostro, 2019; Schreiber-Zamora, 2019).

Last, pregnancy-induced renal hyperfiltration theoretically may impair long-term graft survival. However, Sturgiss and Davison (1995) found no evidence for this in one study of 34 allograft recipients followed for a mean of 15 years.

Management

Close surveillance is necessary. Covert bacteriuria is treated, and if it is recurrent, suppressive treatment is given for the remainder of the pregnancy. Serial hepatic enzyme concentrations and blood counts are monitored for toxic effects of azathioprine and cyclosporine. Some recommend measurement of serum cyclosporine levels. Gestational diabetes is more common if corticosteroids are taken, and in these cases overt diabetes must be excluded with glucose tolerance testing done at the initiation of prenatal care. Surveillance for opportunistic infections from herpesvirus, cytomegalovirus, and toxoplasmosis is important because these infections are common. Some recommend surveillance for BK virus in women known to be infected, however, diagnosis and treatment are problematic.

Renal function is monitored, and the GFR usually increases 20 to 25 percent. If a significant rise in the serum creatinine level is detected, its cause must be determined. Possibilities include acute rejection, cyclosporine toxicity, preeclampsia, infection, and urinary tract obstruction. Evidence of pyelonephritis or graft rejection should prompt admission for aggressive management. Imaging studies and kidney biopsy may be indicated.

The woman is carefully monitored for development or worsening of underlying hypertension, and especially of superimposed preeclampsia. Management of hypertension during pregnancy is the same as for patients without an organ transplant (Chap. 53, p. 950).

Vigilant fetal surveillance is indicated because of the higher incidences of fetal-growth restriction and preterm delivery. Although cesarean delivery is reserved for obstetrical indications, occasionally the transplanted kidney obstructs labor, and the overall cesarean delivery rate approaches 80 percent (Bramham, 2013; Madej, 2018; Rocha, 2013).

POLYCYSTIC KIDNEY DISEASE

This usually autosomally dominant systemic disease primarily affects the kidneys. Its basic pathophysiology is a *ciliopathy* that affects renal tubules, although only approximately 5 percent develop cysts (Zhou, 2018). The incidence is about 1 in 1000 births and it causes approximately 5 to 10 percent of end-stage renal disease in the United States. Although genetically heterogeneous, almost 85 percent of cases are due to *PKD1* gene mutations on chromosome 16, and the other 15 percent to *PKD2* mutations on chromosome 4. Prenatal diagnosis is available if the mutation has been identified in a family member or if linkage has been established in the family. Preimplantation genetic screening reduces the risk of affected fetuses to 1 to 2 percent (Murphy, 2018).

Renal complications more commonly affect men than women, and symptoms usually appear in the third or fourth decade. Flank pain, hematuria, proteinuria, abdominal masses, and associated calculi and infection are frequent findings. Hypertension develops in 75 percent, and progression to renal failure is a major problem. Superimposed acute renal failure also may develop from infection or obstruction from ureteral angulation. Specifically, renal cyst may displace and create angles along the normal ureteral course.

Other organs are commonly involved. Asymptomatic *hepatic cysts* coexist in a third of patients with polycystic kidneys. Hepatic involvement is more common and more aggressive in women than in men. Approximately 10 percent of patients with polycystic kidney disease die from rupture of an associated *intracranial berry aneurysm*. Up to a fourth of patients have *cardiac valvular lesions*, which include mitral valve prolapse and mitral, aortic, and tricuspid valvular incompetence.

Pregnancy Outcomes

The prognosis for pregnancy in women with polycystic kidney disease depends on the degree of associated hypertension and renal insufficiency. Urinary infections are common. Chapman and coworkers (1994) compared pregnancy outcomes in 235 affected women who had 605 pregnancies with those of 108 unaffected family members who had 244 pregnancies. Composite perinatal complication rates were similar—33 versus 26 percent—but hypertension, including preeclampsia, was more common in women with polycystic kidneys. Pregnancy does not seem to accelerate the natural disease course (Lindheimer, 2007).

GLOMERULAR DISEASES

The glomerulus and its capillaries are subject to numerous conditions and agents that can lead to acute and chronic diseases. Glomerular damage can be caused by toxins or infections or from systemic disorders such as hypertension or diabetes. It may also be idiopathic. When there is capillary inflammation, the process is termed *glomerulonephritis*, and in many of these cases, an autoimmune process is involved. Glomerular disease or glomerulonephritis may result from a single stimulus such as that following group A streptococcal infections. It may also be a manifestation of a multisystem disease such as systemic lupus erythematosus or diabetes (Blom, 2017).

Persistent glomerulonephritis eventually leads to decline of renal function. Progression is variable and often does not become apparent until chronic renal insufficiency is diagnosed. Lewis and Neilsen (2018) group glomerular injuries into six syndromes based on clinical patterns (Table 56-3). Some underlying disorders—examples include infections, vasculitides, and diabetes—can result in one clinical pattern in different individuals. Last, disorders within each of these categories

TABLE 56-3. Patterns of Clinical Glomerulonephritis

Acute nephritic syndromes: poststreptococcal, infective endocarditis, SLE, antiglomerular basement membrane disease, IgA nephropathy, ANCA vasculitis, Henoch-Schönlein purpura, cryoglobulinemia, membranoproliferative and mesangioproliferative glomerulonephritis
Pulmonary-renal syndromes: Goodpasture, ANCA vasculitis, Henoch-Schönlein purpura, cryoglobulinemia
Nephrotic syndromes: minimal change disease, focal segmental glomerulosclerosis, membranous glomerulonephritis, diabetes, amyloidosis, others
Basement membrane syndromes: antiglomerular basement membrane disease, others
Glomerular vascular syndromes: atherosclerosis, chronic hypertension, sickle-cell disease, thrombotic microangiopathies, antiphospholipid antibody syndrome, ANCA vasculitis, others
Infectious disease–associated syndromes: poststreptococcal, infective endocarditis, HIV, HBV, HCV, syphilis, others

ANCA = antineutrophilic cytoplasmic antibodies; HBV = hepatitis B virus; HCV = hepatitis C virus; HIV = human immunodeficiency virus; IgA = immunoglobulin A; SLE = systemic lupus erythematosus.

may be seen in young women, and thus, these may already be established before pregnancy or may first manifest then.

As with any renal disorder, goals to achieve optimal pregnancy outcomes aim to stabilize rapid disease progression, minimize proteinuria with use of appropriate immunosuppressive agents, control hypertension, and delay pregnancy until these are achieved.

Acute Nephritic Syndromes

Acute glomerulonephritis may result from any of several causes (see Table 56-3). The clinical presentation usually includes hypertension, hematuria, red-cell casts, pyuria, and proteinuria. Varying degrees of renal insufficiency and salt and water retention result in edema, hypertension, and circulatory congestion (Lewis, 2018). The prognosis and treatment of nephritic syndromes depends on their etiology. Some recede spontaneously or with treatment. However, in some patients, *rapidly progressive glomerulonephritis* leads to end-stage renal failure. In others, *chronic glomerulonephritis* develops and manifests as slowly progressive renal disease.

The prototype is *acute poststreptococcal glomerulonephritis*, which is historically interesting because it was confused with eclampsia until the mid-1800s. *Immunoglobulin A (IgA) nephropathy*, also known as *Berger disease*, is the most common form of acute glomerulonephritis worldwide (Blom, 2017). The isolated form of IgA nephropathy occurs sporadically, and it may be related to *Henoch-Schönlein purpura* as the systemic form. Another isolated nephritis type may be due to anti–glomerular basement membrane antibodies, which are typically IgG. These IgG antibodies may also involve the lungs to manifest as a pulmonary-renal syndrome with alveolar hemorrhage, which is termed *Goodpasture syndrome*.

Pregnancy

Acute nephritic syndromes during pregnancy can be difficult to differentiate from severe preeclampsia. One example is systemic lupus erythematosus with a flare during the second half of pregnancy (Zhao, 2013). In some cases, renal biopsy may be necessary to determine etiology and direct management (Lindheimer, 2013; Ramin, 2006). This is discussed further in Chapter 62 (p. 1112).

Whatever the underlying etiology, glomerular diseases have profound effects on pregnancy outcome. In an older study, Packham and coworkers (1989) described 395 pregnancies in 238 women with *primary* glomerulonephritis diagnosed before pregnancy. The most common lesions identified by biopsy were membranous glomerulonephritis, IgA glomerulonephritis, and diffuse mesangial glomerulonephritis. Although most of these women had normal renal function, half developed hypertension, a fourth was delivered preterm, and the perinatal mortality rate after 28 weeks' gestation was 80 per 1000. As expected, the worst perinatal outcomes were in women with impaired renal function, early or severe hypertension, and nephrotic-range proteinuria. O'Shaughnessy and colleagues (2017) confirmed these findings. In 48 pregnancies complicated by glomerulonephritis, a third developed preeclampsia, 39 percent had a doubling of protein excretion, and 27 percent had a ≥50-percent rise in serum creatinine levels. Half of the pregnancies ended in preterm birth and 13 percent in perinatal death.

Similar outcomes have been reported for pregnancies in women with IgA nephropathy. From one review of 376 pregnancies, investigators reported a perinatal mortality rate of 12-percent; preterm delivery, 9 percent; low birthweight, 10 percent; and preeclampsia, 7 percent (Liu, 2016). Progression of renal insufficiency during pregnancy is controversial. From their reports, Su and coworkers (2017), but not Wang and colleagues (2019), found that women with IgA nephropathy had renal insufficiency progression during pregnancy.

Nephrotic Syndromes

Heavy proteinuria is the hallmark of the nephrotic syndromes. Several primary and secondary kidney disorders cause immunological- or toxic-mediated injury and glomerular capillary-wall breakdown that allows excessive filtration of plasma proteins. In addition to heavy urine protein excretion, the syndrome is characterized by hypoalbuminemia, hypercholesterolemia, and edema. Hypertension is frequently comorbid. This, coupled with albumin nephrotoxicity, contributes to eventual renal insufficiency.

Some of the more common causes of the nephrotic syndrome are listed in Table 56-4. Treatment depends on etiology, and renal biopsy will disclose microscopic abnormalities that may help direct care. Edema is problematic, especially during pregnancy. Normal amounts of dietary protein of high biological value are encouraged, and this practice contrasts with high-protein diets, which increase proteinuria. The incidence of thromboembolism is greater and varies with the severity of hypertension, proteinuria, and renal insufficiency (Spotti, 2019). Renal vein thrombosis is particularly worrisome, although both arterial and venous thromboses may develop. Explanations for this risk are platelet hyperactivity, urinary loss of antithrombotic factors, and increased production of prothrombotic factors by the liver (Mirrakhimov, 2014). Some recommend that

TABLE 56-4. Causes of the Nephrotic Syndrome in Adults

Focal segmental glomerulosclerosis (FSGS) (35%): viruses, hypertension, reflux nephropathy, sickle-cell disease
Membranous glomerulonephritis (~20%): idiopathic (most cases), malignancy, infection, connective tissue diseases
Minimal change disease (MCD) (10–15%): primary idiopathic (most cases), drug-induced (NSAIDs), allergies, viral infections
Diabetic nephropathy: most common cause of ESRD
Glomerular deposition diseases: light-chain, amyloidosis

ESRD = end-stage renal disease; NSAIDs = nonsteroidal antiinflammatory drugs.

women with a serum albumin <2 g/dL or 24-hour urinary protein excretion >3.5 g should be given thromboprophylaxis throughout pregnancy (Blom, 2017). Some cases of nephrosis from primary glomerular disease respond to glucocorticosteroids and other immunosuppressants or cytotoxic drug therapy. In most cases caused by infection or drugs, proteinuria recedes once the underlying cause is corrected.

Pregnancy

Maternal and perinatal outcomes in women with a nephrotic syndrome depend on its underlying cause and severity. Whenever possible, these should be ascertained, and renal biopsy may be indicated to determine if there is a treatable etiology. Half of women with nephrotic-range proteinuria will have higher daily protein excretion as pregnancy progresses (Packham, 1989). In women with nephrosis cared for at Parkland Hospital, we reported that two thirds had protein excretion that exceeded 3 g/d (Stettler, 1992). At the same time, however, if these women had only mild degrees of renal dysfunction, they displayed a normally augmented GFR across pregnancy (Cunningham, 1990).

Management of edema during pregnancy can be particularly challenging, as it is intensified by normally rising hydrostatic pressure in the lower extremities. In some women, massive vulvar edema may develop in those with comorbid conditions such as diabetes, syphilis, preeclampsia, and others (Fig. 56-2) (Jakobi, 1995). Another major problem is that up to half of these women with nephrosis have chronic hypertension that may require treatment (Chap. 53, p. 950). In these, as well as in previously normotensive women, preeclampsia is common and often develops early in pregnancy (Morgan, 2016).

Most women with a nephrotic syndrome who do not have severe hypertension or renal insufficiency will have successful pregnancy outcomes. Conversely, if there is renal insufficiency, moderate to severe hypertension, or both, the prognosis is much worse. Our experiences caring for such women with 65 pregnancies at Parkland Hospital showed that complications are frequent (Stettler, 1992). Protein excretion during pregnancy averaged 4 g/d, and a third of the women had classic nephrotic syndrome.

FIGURE 56-2 Massive vulvar edema in a pregnant woman with marked proteinuria due to preeclampsia.

Some degree of renal insufficiency was seen in 75 percent, chronic hypertension in 40 percent, and persistent anemia in 25 percent. Importantly, preeclampsia developed in 60 percent, and 45 percent had preterm deliveries. Even so, after excluding abortions, 53 of 57 neonates were born alive. De Castro and associates (2017) reported similar results from 26 pregnancies complicated by a mean protein excretion of 8 g/d.

Long-Term Outcomes

Women identified to have nephrotic syndromes either before or during pregnancy are at risk for serious long-term adverse outcomes. Of the women cared for at Parkland Hospital, at least 20 percent of women followed for 10 years progressed to end-stage renal failure (Stettler, 1992). Similarly, Chen and associates (2001) reported short-term outcomes in 15 women with nephrotic syndromes. By 2 years, three of these women had died, three had developed chronic renal failure, and two had progressed to end-stage renal disease. Women with serum creatinine levels >1.4 mg/dL and 24-hour protein excretion >1 g/d have the shortest renal survival times following pregnancy (Imbasciati, 2007).

CHRONIC KIDNEY DISEASE

This describes a pathophysiological process that can progress to end-stage renal disease. The National Kidney Foundation (2019) describes six stages of chronic kidney disease (CKD) defined by decreasing GFR. It progresses from stage 0, in which GFR is ≥90 mL/min/1.73 m^2, to stage 5, in which GFR is <15 mL/min/1.73 m^2.

Several diseases result in progressively declining renal function, including the glomerular diseases discussed earlier. Those that most commonly lead to end-stage disease requiring dialysis and kidney transplantation include diabetes mellitus, chronic hypertension, glomerulonephritis, and polycystic kidney disease (Bargman, 2018).

Most reproductive-aged women with these just-mentioned diseases have varying degrees of renal insufficiency, proteinuria, or both. To counsel regarding fertility and pregnancy outcome, the degree of renal functional impairment and of associated hypertension are assessed. In general, successful pregnancy outcome may be more related to these two factors than to the specific underlying renal disorder. An overall prognosis can be estimated by considering women with CKD in arbitrary categories of renal function (Davison, 2011). These include normal or *mild impairment*—defined as a serum creatinine <1.5 mg/dL; *moderate impairment*—defined as a serum creatinine 1.5 to 3.0 mg/dL; and *severe renal insufficiency*—defined as a serum creatinine >3.0 mg/dL. Some recommend using these older categories, although others suggest adopting the classification of the National Kidney Foundation described above (Davison, 2011; Piccoli, 2010, 2011). Thus, obstetricians must be familiar with both.

■ Pregnancy and Chronic Kidney Disease

The severity of renal insufficiency, along with any underlying hypertension, strongly influences pregnancy outcome. Additionally, comorbidities secondary to a systemic disorder—for

example, diabetes or systemic lupus erythematosus—portend a worse prognosis (Blom, 2017). For all women with CKD, the incidences of hypertension and preeclampsia, preterm and growth-restricted neonates, and other problems are high. Low-dose aspirin starting at 12 to 28 weeks is recommended to help lower preeclampsia rates (Chap. 41, p. 705).

Loss of renal tissue is associated with compensatory intrarenal vasodilation and hypertrophy of the surviving nephrons. The resultant hyperperfusion and hyperfiltration eventually damage surviving nephrons to cause *nephrosclerosis* and worsening renal function. With mild renal insufficiency, pregnancy causes greater augmentation of renal plasma flow and GFR (Helal, 2012). With progressively worsening renal function, renal plasma flow is augmented little, if any. In one study, only half of women with moderate renal insufficiency demonstrated pregnancy-augmented glomerular filtration, and women with severe disease had no increase (Cunningham, 1990).

Importantly, chronic renal insufficiency also curtails normal pregnancy-induced hypervolemia. Blood volume expansion during pregnancy is related to disease severity and correlates inversely with serum creatinine concentration. As shown in Figure 56-3, women with mild to moderate renal dysfunction have blood volume expansion that averages 55 percent above nonpregnant volumes. However, with severe renal insufficiency, volume expansion averages only 25 percent, which is similar to that seen with hemoconcentration from eclampsia. In addition, these women have variable degrees of chronic anemia due to intrinsic renal disease. Thus, they are at risk for hypovolemia and acute blood loss anemia with even normal blood loss at delivery.

Renal Disease with Preserved Function

In some women, although glomerular disease has not yet caused renal insufficiency, incidences of pregnancy complications are still increased. As shown in Table 56-5, these problems are less frequent than in cohorts of women with moderate and severe renal insufficiency. Two older studies illustrate this. In one, Surian and colleagues (1984) described outcomes of 123 pregnancies in women with biopsy-proven glomerular disease. Although only a few of these women had renal dysfunction, 40 percent developed obstetrical or renal complications. In another study of 395 pregnancies in women with preexisting glomerulonephritis and minimal renal insufficiency, impaired renal function developed in 15 percent of these women during pregnancy, and 60 percent had worsening proteinuria (Packham, 1989). Only 12 percent had antecedent chronic hypertension, however, more than half of the pregnancies were complicated by hypertension. The perinatal mortality rate was 140 per 1000, and even without early-onset or severe hypertension or nephrotic-range proteinuria, the rate was 50 per 1000. Importantly, in 5 percent of these women, worsening renal function was permanent.

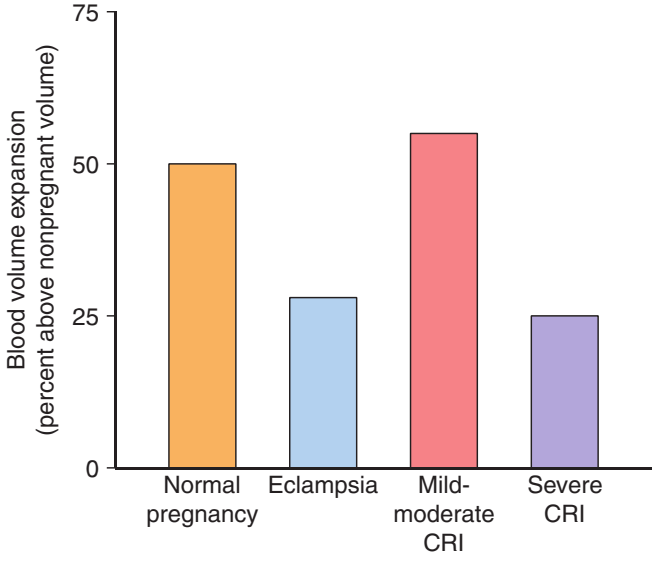

FIGURE 56-3 Blood volume expansion in 44 normally pregnant women at term compared with 29 who had eclampsia; 10 with moderate chronic renal insufficiency (CRI)—serum creatinine 1.5 to 2.9 mg/dL; and four with severe CRI—serum creatinine ≥3.0 mg/dL. (Data from Cunningham, 1990; Zeeman, 2009.)

TABLE 56-5. Complications (%) Associated with Chronic Kidney Disease During Pregnancy

Complication	Preserved Function	Renal Insufficiency: Moderate and Severe	Renal Insufficiency: Severe
Chronic hypertension	25	30–70	50
Gestational hypertension	20–50	30–50	75
Worsening renal function	8–15	20–43	35
Permanent dysfunction	4–5	10–20	35
Preterm delivery	7	30–60	73
Fetal-growth restriction	8–14	30–38	57
Perinatal mortality	5–14	4–7	0

Data from Alsuwaida, 2011; Cunningham, 1990; Farwell, 2013; He, 2018; Imbasciati, 2007; Maruotti, 2012; Nevis, 2011; Piccoli, 2010, 2011; Stettler, 1992; Trevisan, 2004; Zhang, 2015.

Chronic Renal Insufficiency

As noted, pregnancy complication rates are higher in women with CKD and renal insufficiency compared with women who have preserved renal function. Furthermore, adverse outcomes are generally directly related to the degree of renal impairment. Of the more recent reports shown in Table 56-5, outcomes of women with moderate or severe renal insufficiency are usually not separated. A systematic review of 1514 pregnancies in women with CKD described increased odds ratios of preeclampsia, 10.4; preterm delivery, 6.3; fetal-growth restriction, 4.9; and cesarean delivery, 2.7 (Zhang, 2015).

Other investigators have described pregnancies complicated by moderate or severe renal insufficiency (Cunningham, 1990;

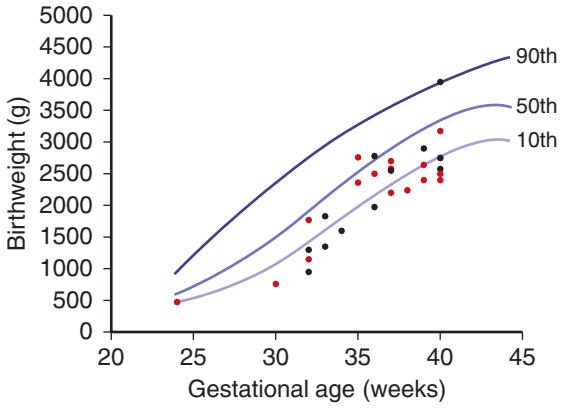

FIGURE 56-4 Birthweight percentiles of infants born to 29 women at Parkland Hospital with mild to moderate renal insufficiency—serum creatinine 1.4–2.4 mg/dL (*black points*) and severe renal insufficiency—serum creatinine ≥2.5 mg/dL (*red points*). (Data from Cunningham, 1990; Stettler, 1992. Growth curves are those reported by Alexander, 1996.)

Imbasciati, 2007; Jones, 1996). Despite a high incidence of chronic hypertension, anemia, preeclampsia, preterm delivery, and fetal-growth restriction, perinatal outcomes were generally acceptable. As shown in Figure 56-4, fetal growth is frequently impaired and related to renal dysfunction severity.

Management

Prenatal care for women with CKD incorporates several important aspects. Frequent monitoring of blood pressure is paramount, and serum creatinine levels and 24-hour protein excretion are quantified as indicated. Bacteriuria is treated to lower the risk of pyelonephritis and further nephron loss. Protein-restricted diets are not recommended. In some women with anemia from chronic renal insufficiency, a response is seen with recombinant erythropoietin. However, hypertension is a common side effect. Serial sonography is performed to follow fetal growth. The differentiation between worsening hypertension and superimposed preeclampsia is problematic. Preliminary data indicate that the angiogenic biomarkers *placental growth factor (PlGF)* and its soluble receptor, *soluble fms-like tyrosine kinase 1 (sFlt-1)*, may be useful to separate chronic from gestational hypertension (Fishel Bartal, 2020). This is described in Chapter 40 (p. 694).

Long-Term Effects

Pregnancy may accelerate CKD progression by augmenting hyperfiltration and glomerular pressure to worsen nephrosclerosis (Bargman, 2018). Women with severe renal insufficiency have greater susceptibility. Jungers and associates (1995) reported few long-term pregnancy-related adverse effects in 360 women with chronic glomerulonephritis and antecedent normal renal function. In a study from Parkland Hospital, 20 percent of pregnant women with moderate to severe renal insufficiency developed end-stage renal failure by a mean of 4 years (Cunningham, 1990). He and coworkers (2018) confirmed these findings in women who had stage 3 or 4 CKD.

As noted, progression is common for many women with chronic renal disorders. At 1 year after pregnancy, Jones and Hayslett (1996) reported that 10 percent of the women had developed end-stage renal failure—stage 5 CKD. Similar findings in women with a median follow-up of 3 years were described by Imbasciati and colleagues (2007). By this time, end-stage disease was apparent in 30 percent of women whose prepregnancy serum creatinine was ≥1.4 mg/dL and who had proteinuria >1 g/d.

Chronic proteinuria is also a marker for subsequent development of renal failure. In one study, 20 percent of women with chronic proteinuria discovered during pregnancy progressed to end-stage renal failure within several years (Stettler, 1992). Another study reported that an equal number of nonpregnant women had identical loss of function when similar durations were compared (Zhang, 2015). It may be that pregnancy does not hasten an already predetermined declining renal function.

Dialysis During Pregnancy

Significantly impaired renal function is accompanied by subfertility that may be corrected with chronic renal replacement therapy—either hemodialysis or peritoneal dialysis (Wiles, 2019b). Not unexpectedly, maternal complications are common and include severe hypertension, placental abruption, heart failure, and sepsis. To illustrate this, the outcomes of 233 pregnancies in women undergoing dialysis are shown in Table 56-6. The high incidences of hypertension, low birthweight, and preterm delivery result in a perinatal mortality rate of 250 per 1000. Piccoli and associates (2016) performed a systematic review and described 681 pregnancies in 647 women undergoing dialysis. Of these, 616 had hemodialysis and 65 had peritoneal dialysis. They chronicled a high incidence of hypertension, preterm delivery, and fetal-growth restriction, and the perinatal mortality was 180 per 1000. They found an inverse relationship between hours of dialysis per week and adverse outcomes. Last, they reported that hemodialysis was superior to peritoneal dialysis.

For the woman already undergoing either method of dialysis, it seems reasonable to continue that method with consideration for its increasing frequency. In the woman who has never been dialyzed, the threshold for initiation during pregnancy is unclear. Hladunewich and colleagues (2016) recommend consideration for dialysis when the creatinine clearance is 20 mL/min or less. Extension of dialysis frequency to five to six times weekly may be necessary to avoid abrupt volume changes that cause hypotension.

Hladunewich and coworkers (2011) recommend attention to certain protocols that include replacement of substances lost through dialysis. Multivitamin doses are doubled, and oral calcium and iron salts are provided along with sufficient dietary protein and calories. Chronic anemia is treated with erythropoietin. To meet pregnancy changes, extra calcium is added to the dialysate along with less bicarbonate.

ACUTE KIDNEY INJURY

Previously termed *acute renal failure*, acute kidney injury (AKI) is now used to describe impairment of kidney function over days

TABLE 56-6. Pregnancy Outcomes in Women Undergoing Dialysis During Pregnancy

	Pregnancies			Pregnancy Outcomes (%)			
Study (Year)	N	Delivery (weeks)	Birthweight (g)	Hypertension	Hydramnios	Perinatal Mortality	Surviving Infants
Toma (1999)	54	31.9	1545	35	44	33	67
Chao (2002)	13	32	1540	72	46	31	69
Tan (2006)	11	31	1390	36	18	18	82
Chou (2008)	13	30.8	1510	57	71	50	50
Luders (2010)	52	32.7	1555	67	40	13	87
Shahir (2013)	13	NS	2130	19[a]	14	22	78
Jesudason (2014)	77	33.8	1750	NS	NS	20	80
Approximate averages	233	~32	~1600	~50	~44	~25	~75

[a]Preeclampsia only.
NS = not stated.

to weeks that leads to retention of nitrogenous and other waste products normally excreted by the kidneys. Current definitions include a rise in a serum creatinine level of at least 0.3 mg/dL within 48 hours, or ≥50 percent increase from baseline within a week, or urine output reduced to <0.5 mL/kg per hour for >6 hours (Waikar, 2018).

Criteria for diagnosis in pregnancy have not been standardized (Gonzalez Suarez, 2019). Most studies use a definition in which serum creatinine levels rise ≥0.3 mg/dL from baseline. Animal studies have shown that pregnancy protects the kidney from acute ischemic injury (Popkov, 2018). Although the incidence of AKI in pregnancy has dropped substantially, it still occasionally causes significant obstetrical morbidity and mortality. In a Canadian study, the incidence was reported to be 2.68 per 10,000 births between 2009 and 2010 (Mehrabadi, 2014). Outcomes are available from four older studies comprising a total of 266 women with AKI (Drakeley, 2002; Nzerue, 1998; Sibai, 1990; Turney, 1989). Approximately 70 percent had preeclampsia, 50 percent had obstetrical hemorrhage, and 30 percent had a placental abruption. Almost 20 percent required dialysis, and the maternal mortality rate approximated 15 percent.

Although obstetrical cases of AKI requiring dialysis are less frequent today, acute renal ischemia is still commonly associated with severe preeclampsia and hemorrhage (Conti-Ramsden, 2019; Jim, 2017; Prakash, 2018). Notable contributors are placental abruption and hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome. Sepsis is another, especially in resource-poor countries (Acharya, 2013). AKI also often complicates acute fatty liver of pregnancy. Nelson and colleagues (2013) reported some degree of renal insufficiency in virtually all of 52 such women cared for at Parkland Hospital (Chap. 58, p. 1034). Dehydration caused by severe hyperemesis gravidarum also can lead to AKI (Hill, 2002). Other causes include thrombotic microangiopathies (Chap. 59, p. 1060).

Diagnosis and Management

In most women, renal failure develops postpartum, thus management is usually not complicated by fetal considerations. Diagnostically, an acute rise in serum creatinine levels is most often due to renal ischemia. But oliguria also is an important sign of acutely impaired renal function. In obstetrical cases, both prerenal and intrarenal factors commonly coincide. For example, with total placental abruption, severe hypovolemia results from massive hemorrhage, and frequently associated preeclampsia causes preexistent renal ischemia (Chap. 40, p. 689).

When azotemia is severe and oliguria persists, some form of renal replacement treatment may be indicated. Hemofiltration or dialysis is initiated before patients markedly deteriorate, and hemodynamic measurements are normalized. Medication dose adjustments are imperative, and magnesium sulfate is a prominent example (Waikar, 2018). Early dialysis appears to reduce the mortality rate appreciably and may enhance the extent of renal function recovery. With time, renal function usually returns to normal or near normal. Even so, women in subsequent pregnancies have higher incidences of hypertension and adverse fetal outcomes (Tangren, 2017).

Prevention

AKI in obstetrics is most often due to acute blood loss and especially that associated with preeclampsia. Thus, it may often be prevented by the following means:

1. Prompt and vigorous volume replacement with crystalloid solutions and blood in instances of massive hemorrhage, such as in placental abruption, placenta previa, uterine rupture, and postpartum uterine atony (Chap. 44, p. 771).
2. Delivery or termination of pregnancies complicated by severe preeclampsia or eclampsia, and careful blood transfusion if blood loss is more than average (Chap. 41, p. 712).
3. Close observation for early signs of sepsis and shock in women with pyelonephritis, septic abortion, chorioamnionitis, or other pelvic infections (Chap. 50, p. 887).
4. Avoidance of loop diuretics to treat oliguria before ensuring that blood volume and cardiac output are adequate for renal perfusion.
5. Judicious use of vasoconstrictor drugs to treat hypotension, and only after it has been determined that pathological vasodilation is the cause.

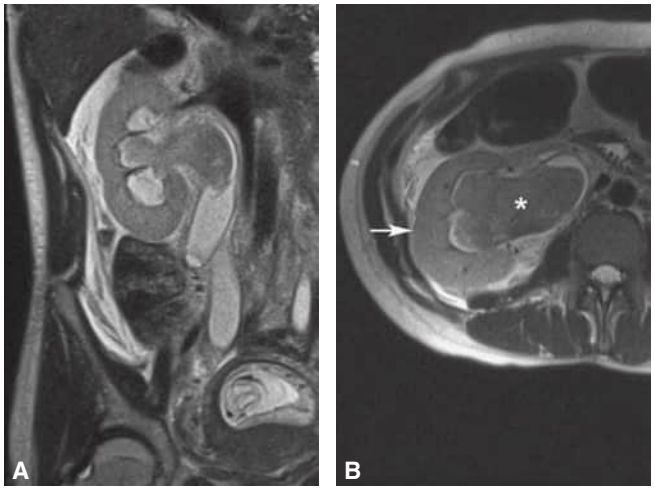

FIGURE 56-5 A. Magnetic resonance image in a coronal plane of a pregnant woman with unilateral hydronephrosis caused by ureteral obstruction. The serum creatinine was 8 mg/dL and decreased to 0.8 mg/dL after a percutaneous nephrostomy tube was placed. **B.** Left kidney (*arrow*) and associated hydronephrosis (*asterisk*) are again noted in this axial plane image.

Irreversible ischemic renal failure caused by *acute cortical necrosis* has become exceedingly uncommon in obstetrics. Before widespread availability of dialysis, it complicated a fourth of obstetrical renal failure cases (Grünfeld, 1987; Turney, 1989). Most cases followed placental abruption, preeclampsia-eclampsia, and endotoxin-induced shock. Once common with septic abortion, this is a rare cause in the United States today (Jim, 2017). Histologically, the lesion appears to result from thrombosis of segments of the renal vascular system. The lesions may be focal, patchy, confluent, or gross. Clinically, renal cortical necrosis follows the course of acute renal failure, and its differentiation from acute tubular necrosis is not possible during the early phase. The prognosis depends on the extent of the necrosis. Recovery of function is variable, and stable renal insufficiency may result.

■ Obstructive Renal Failure

Rarely, bilateral ureteral compression by a very large pregnant uterus obstructs ureters to cause severe oliguria and azotemia. An example is shown in Figure 56-5. Brandes and Fritsche (1991) reviewed 13 cases that were the consequence of a markedly overdistended uterus. They described a woman with twins who developed anuria and a serum creatinine level of 12.2 mg/dL at 34 weeks' gestation. After amniotomy, urine flow resumed at 500 mL/h, and a rapid decline in serum creatinine levels to normal range followed. Eckford and Gingell (1991) described 10 women in whom ureteral obstruction was relieved by stenting. The stents were left in place for a mean of 15.5 weeks and removed 4 to 6 weeks postpartum.

We have observed this phenomenon on several occasions. In our experience, women with previous urinary tract surgery for reflux are more likely to have such obstructions (Satin, 1993). Partial ureteral obstruction may be accompanied by fluid retention and significant hypertension. When the obstructive uropathy is relieved, diuresis ensues and hypertension dissipates. In one woman with massive hydramnios (9.4 L) and an anencephalic fetus, amniocentesis and removal of some of the amnionic fluid was followed promptly by diuresis, a decline in the plasma creatinine concentration, and an improvement of hypertension.

LOWER URINARY TRACT LESIONS

■ Urethral Diverticulum

Infrequently complicating pregnancy, this type of diverticulum is thought to originate from an enlarging paraurethral gland abscess that ruptures into the urethral lumen (Fig. 56-6). As infection clears, the remaining dilated diverticular sac and its ostium into the urethra persist. Associated findings may be urine collecting within and then dribbling from the sac, pain, palpable mass, and recurrent urinary infections. In general, a diverticulum is managed expectantly during pregnancy. Rarely, drainage may be necessary, or surgery required (Iyer, 2013). If additional antepartum evaluation is needed, MR imaging is preferred for its superior soft-tissue resolution and ability to define complex diverticula (Dwarkasing, 2011; Pathi, 2013).

■ Urinary Tract Fistulas

Fistulas found during pregnancy likely existed previously, but in rare cases, they form during pregnancy. In developed countries, *vesicovaginal fistula* following a McDonald cerclage has been reported (Massengill, 2012). These fistulas may also form with the prolonged obstructed labor that is more commonly seen in resource-poor countries. In these cases, the genital tract is compressed between the fetal head and bony pelvis. Brief pressure is not significant, but prolonged pressure leads to tissue necrosis and subsequent fistula formation (Wall, 2012). *Vesicouterine fistulas* that developed after prior cesarean delivery have been described (DiMarco, 2006; Manjunatha, 2012). Rarely, *vesicocervical fistula* may follow cesarean delivery or may form if the anterior cervical lip is compressed against the symphysis pubis (Dudderidge, 2005).

FIGURE 56-6 Asymptomatic urethral diverticulum, seen as a midline bulge beneath the urethral meatus (*arrow*), identified during initial prenatal care examination.

CHAPTER 57

Gastrointestinal Disorders

During normal pregnancy, the gastrointestinal (GI) tract and its appendages undergo remarkable anatomical, physiological, and functional alterations. These changes, which are discussed in detail in Chapter 4 (p. 70), can appreciably alter clinical findings normally relied on for diagnosis and treatment. Moreover, as pregnancy progresses, GI findings become more difficult to assess. The clinical examination is often obscured by a large uterus that displaces abdominal organs and can alter the location and intensity of pain and tenderness.

GENERAL CONSIDERATIONS

Diagnostic Techniques

Endoscopy

Several endoscopic methods can be used to evaluate the gastrointestinal (GI) tract during pregnancy without reliance on radiographic techniques. With fiberoptic endoscopic instruments, the esophagus, stomach, duodenum, and colon can be inspected (Savas, 2014; Song, 2018). The proximal jejunum also can be studied, and the ampulla of Vater cannulated to perform *endoscopic retrograde cholangiopancreatography—ERCP* (Fogel, 2014; Hedström, 2017). Experience in pregnancy with *video capsule endoscopy* for small-bowel evaluation remains limited (Bandorski, 2016). Normal pregnancy-related slowing of GI motility and thus increased transit time as well as the recorder capsule's electromagnetic field are theoretical concerns.

Upper gastrointestinal endoscopy is used for diagnosis and management of several problems. Common bile duct exploration and drainage are used for choledocholithiasis (Chap. 58, p. 1043). Sclerotherapy and placement of *percutaneous endoscopic gastrostomy (PEG)* tubes also are performed endoscopically.

Colonoscopy is indispensible for viewing the entire colon and distal ileum. Except for the midtrimester, reports of colonoscopy during pregnancy are limited, but most results suggest that it should be performed if necessary (De Lima, 2015; Ludvigsson, 2017). Pregnancy indications include chronic abdominal pain, hematochezia, and diarrhea (Cappell, 2011). Bowel preparation is completed using polyethylene glycol electrolyte (GoLYTELY) or sodium sulfate (Suprep) solutions (American Society for Gastrointestinal Endoscopy, 2015). With these, most women avoid serious dehydration that may cause diminished uteroplacental perfusion. In select cases, tap water enemas

TABLE 57-1. Preprocedural Considerations for Gastrointestinal Endoscopy During Pregnancy

Plan consultation with an obstetrician, gastroenterologist, and anesthesiologist
Place patient in left lateral decubitus position
Use lowest effective dose of sedation necessary
Give prophylactic antibiotics as indicated. Penicillin, cephalosporin, erythromycin, and clindamycin are safe options
Minimize procedure time
Obtain fetal heart tones at the discretion of the obstetrician. In general, pre- and post-procedure heart tones are adequate
For colonoscopy, favor preparation with PEG-ES or with tap water enemas depending on GI level to be evaluated

GI = gastrointestinal; PEG-ES = polyethylene glycol electrolyte solution.
From American Society for Gastrointestinal Endoscopy, 2012, 2015.

may be an alternative for rectosigmoidoscopy to avoid some of these risks.

Endoscopic procedures should be performed when indicated and ideally in the second trimester (American Society for Gastrointestinal Endoscopy, 2012; Ludvigsson, 2017). A multidisciplinary approach with obstetricians, gastroenterologists, and anesthesiologists is prudent. Table 57-1 outlines preprocedural considerations in pregnancy.

Noninvasive Imaging Techniques

The ideal technique for GI tract imaging during pregnancy is abdominal sonography. However, the gravid uterus may obscure abdominal organs making evaluation difficult. Magnetic resonance (MR) imaging allows inspection of the abdomen and retroperitoneal space yet avoids radiation exposure from computed tomography (CT) (Khandelwal, 2013). Examples are MR cholangiopancreatography (MRCP) and MR enterography (MRE) (Oto, 2009; Stern, 2014). These and other imaging modalities, and their safe use in pregnancy, are discussed in Chapter 49.

Laparotomy and Laparoscopy

Surgery is lifesaving for certain GI conditions—perforative appendicitis being the most common example. Intraabdominal surgery is the most frequently performed nonobstetrical procedure during pregnancy (Devroe, 2019). Laparoscopic procedures have replaced traditional surgical techniques for many abdominal disorders during pregnancy (Ye, 2019). These are discussed in detail with descriptions of surgical technique in Chapter 49 (p. 867) and in *Cunningham and Gilstrap's Operative Obstetrics*, 3rd edition (Kho, 2017). Guidelines for laparoscopy during pregnancy have been provided by the American College of Obstetricians and Gynecologists (2019) and the Society of American Gastrointestinal and Endoscopic Surgeons (Pearl, 2017).

■ Nutritional Support

Specialized nutritional support can be delivered *enterally*, usually via nasogastric tube feedings, or *parenterally* by venous catheter access, either peripherally or centrally.

When possible, enteral alimentation is preferable because it has fewer serious complications (Hoffer, 2018; Stokke, 2015). In obstetrical patients, very few conditions prohibit enteral nutrition as a first effort to prevent catabolism. For extreme cases, such as recalcitrant hyperemesis gravidarum, percutaneous endoscopic gastrostomy with a jejunal port (PEG-J tube) has been described.

Parenteral nutrition provides nutrients when the intestinal tract must be quiescent. *Peripheral parenteral nutrition (PPN)* administers dilute nutrient admixtures and is appropriate for short-term use. Central venous access is necessary for *central parenteral nutrition (CPN)* because its hyperosmolarity requires rapid dilution in a high-flow vascular system (Robinson, 2018; Worthington, 2017). These solutions provide 24 to 40 kcal/kg/d, principally as a hypertonic glucose solution. Various conditions may prompt CPN during pregnancy (Table 57-2). The most common indications are short bowel syndrome and dysmotility disorders, and feeding duration averages 33 days (Billiauws, 2017).

TABLE 57-2. Some Conditions Treated with Enteral or Parenteral Nutrition During Pregnancy[a]

Achalasia
Anorexia nervosa
Appendiceal rupture
Bowel obstruction
Burns
Cholecystitis
Crohn disease
Diabetic gastropathy
Esophageal injury
Hyperemesis gravidarum
Jejunoileal bypass
Malignancies
Ostomy obstruction
Pancreatitis
Preeclampsia syndrome
Short bowel syndrome
Stroke
Ulcerative colitis

[a]Complications arranged alphabetically.
From Billiauws, 2017; Folk, 2004; Guglielmi, 2006; Mahadevan, 2019; Porter, 2014; Russo-Stieglitz, 1999; Saha, 2009; Spiliopoulos, 2013.

Parenteral nutrition complications are frequent and may be severe (Hoffer, 2018). The most common is catheter sepsis, and Folk (2004) reported a 25-percent incidence in 27 women with hyperemesis gravidarum. The Centers for Disease Control and Prevention provides detailed guidelines to prevent catheter-related sepsis (O'Grady, 2011). Other maternal complications include upper-extremity venous thrombosis, volume overload, and reversible liver dysfunction. Perinatal complications are rare, however, fetal subdural hematoma caused by maternal vitamin K deficiency has been described (Sakai, 2003).

Appreciable morbidity is also associated with long-term use of a *peripherally inserted central catheter (PICC)*. Again, infection is the most common serious long-term complication (Hoffer, 2018; Holmgren, 2008). In a series of 84 such catheters inserted in 66 pregnant women, Cape and coworkers (2014) reported a 56-percent complication rate, and bacteremia was the most frequent. For short-term nutrition lasting a few weeks, PICC placement and its greater benefit-versus-risk ratio seems reasonable (Worthington, 2017).

UPPER GASTROINTESTINAL TRACT DISORDERS

Hyperemesis Gravidarum

Mild to moderate nausea and vomiting are especially common in pregnant women until approximately 16 weeks' gestation (Chap. 10, p. 191). In a small but significant proportion of these, however, it is severe and unresponsive to simple dietary modification and antiemetics. *Hyperemesis gravidarum* is defined variably as severe unrelenting nausea and vomiting that produces weight loss, dehydration, ketosis, alkalosis from loss of hydrochloric acid, and hypokalemia. Acidosis develops from partial starvation. In some women, transient hepatic dysfunction develops, and biliary sludge accumulates (Table 58-1, p. 1031). Other causes should first be considered because hyperemesis gravidarum is a diagnosis of exclusion.

Study criteria are not standardized, and thus population incidences vary (Koot, 2018). However, an ethnic or familial predilection has been described (London, 2017). In several population-based studies, the hospitalization rate for hyperemesis gravidarum was 0.5 to 2.1 percent (Fiaschi, 2019; Vikanes, 2013). Up to 25 percent of those hospitalized in a previous pregnancy for hyperemesis will again require admission (Nurmi, 2018).

The etiopathogenesis of hyperemesis gravidarum is unknown and is likely multifactorial. High or rapidly rising serum levels of pregnancy-related hormones such as human chorionic gonadotropin (hCG), estrogen, progesterone, placental growth hormone, prolactin, thyroxine, and adrenocortical hormones are implicated (London, 2017; Verberg, 2005). Other associated hormones include ghrelins, leptin, nesfatin-1, and peptide YY 3–36 (Albayrak, 2013; Gungor, 2013).

Superimposed on this hormonal cornucopia are many biological and environmental factors. Moreover, in some but not all severe cases, interrelated psychological components play a major role (Mitchell-Jones, 2017; Senturk, 2017). Factors that increase the risk for admission include hyperthyroidism, previous pregnancy complicated by hyperemesis, diabetes, GI illnesses, some restrictive diets, and asthma (Fell, 2006; Fiaschi, 2016; Mullin, 2012). An association of *Helicobacter pylori* infection has been proposed, but evidence is inconclusive (Goldberg, 2007; London, 2017). Chronic marijuana use may cause the similar *cannabinoid hyperemesis syndrome* (Alaniz, 2015; Andrews, 2015). And for unknown reasons—perhaps estrogen-related—a female fetus raises the risk but smoking and obesity decrease it by 1.5-fold (Cedergren, 2008; Fiaschi, 2016). Some have reported a relationship between severe hyperemesis gravidarum and anemia, venous thromboembolism (VTE), gestational hypertension, and preeclampsia (Fiaschi, 2018). An association between hyperemesis and preterm birth is unclear (Kleine, 2017). Koren and colleagues (2018) suggested that prolonged vomiting may cause metabolic abnormalities that interfere with fetal brain development. No long-term maternal consequences follow hyperemesis. Specifically, two population-based studies found no unfavorable cardiovascular risks in Norwegian women (Fossum, 2017, 2018).

Complications

Vomiting may be prolonged, frequent, and severe, and a list of potentially fatal complications is given in Table 57-3. Various degrees of acute kidney injury from dehydration are encountered, and rhabdomyolysis may be contributory (Lassey, 2016). Rarely, we and others have encountered women with renal failure requiring dialysis (Dayangan Sayan, 2018; Hill, 2002). *Mallory-Weiss* tears result from continuous retching. Other complications include pneumothorax, pneumomediastinum, diaphragmatic rupture, and gastroesophageal rupture—*Boerhaave syndrome* (American College of Obstetricians and Gynecologists, 2018; Chen, 2012).

At least two serious vitamin deficiencies have been reported with hyperemesis in pregnancy. One is *Wernicke encephalopathy* from thiamine deficiency (Di Gangi, 2012; Palacios-Marqués, 2012). A systematic review reported that ocular signs, confusion, and ataxia were common, and approximately 60 percent had this triad (Oudman, 2019). In some women, an abnormal electroencephalogram (EEG) may be seen, and usually MR imaging shows findings (Oudman, 2019; Vaknin, 2006; Zara,

TABLE 57-3. Some Serious and Life-Threatening Complications Reported with Hyperemesis Gravidarum[a]

Acute kidney injury—may require dialysis
Depression—cause versus effect?
Diaphragmatic rupture
Esophageal rupture—Boerhaave syndrome
Hyperalimentation complications
Hypokalemia—arrhythmias, cardiac arrest
Hypoprothrombinemia—vitamin K deficiency
Mallory–Weiss tears—bleeding, pneumothorax, pneumomediastinum, pneumopericardium
Rhabdomyolysis
Wernicke encephalopathy—thiamine deficiency

[a]Complications arranged alphabetically.

2012). One woman had recurrent encephalopathy in a subsequent pregnancy (Stephens, 2019). Maternal deaths have been described, and long-term sequelae include blindness, convulsions, and coma (Oudman, 2019; Selitsky, 2006). *Vitamin K* is a second potential deficiency. Maternal coagulopathy, fetal intracranial hemorrhage, and vitamin K embryopathy have been reported (Kawamura, 2008; Lane, 2015; Nijsten, 2021).

Management

One management algorithm for nausea and vomiting of pregnancy is shown in Figure 57-1. Most women with mild to moderate symptoms respond to outpatient therapy with any of several first-line antiemetic agents (Boelig, 2018, McParlin, 2016). One mainstay is *Diclegis*—a combination of doxylamine (10 mg) plus pyridoxine (10 mg). The usual dose is two tablets orally at bedtime, and it appears safe and effective (Briggs, 2017; Koren, 2014). If relief is insufficient, one additional first-morning tablet is added to the bedtime dose. This can be further escalated to include one first-morning, one midafternoon, and two bedtime tablets (Duchesnay Inc., 2018). At our institution, for cost savings, we prescribe these two agents individually. The formula is one half of a 25-mg Unisom (doxylamine) tablet plus a 25-mg vitamin B_6 (pyridoxine) tablet. The same graduated dosing is used but does not exceed three total daily doses.

Ondansetron (Zofran) is slightly more effective than the combination of doxylamine and pyridoxine (Oliveira, 2014; Pasternak, 2013). In some studies, the former has been associated with birth defects (Briggs, 2017). However, after a recent systematic review of Cochrane and Reprotox databases, authors concluded that ondansetron is not teratogenic (Kaplan, 2019). Other drawbacks include potential maternal effects from prolonged QT-interval and serotonin syndrome. For these reasons it is preferably reserved for severe cases after 8 weeks' gestation (Lavecchia, 2018).

When simple measures fail, intravenous (IV) crystalloid solutions are given to correct dehydration, ketonemia, electrolyte deficits, and acid-base imbalances. Hypokalemia is common, and cardiac arrest has been reported (Walch, 2018). No benefits are gained by infusing 5-percent dextrose along with crystalloids (Tan, 2013). Thiamine, 100 mg, is usually diluted in 1 L of the selected crystalloid to prevent Wernicke encephalopathy for women who require IV hydration and have vomited for more than 3 weeks (Giugale, 2015). It is infused at the maintenance rate desired for patient hydration. This thiamine dose is provided daily for the next 2 to 3 days and is followed by IV multivitamins if IV hydration continues (Levichek, 2002).

If vomiting persists after rehydration and failed outpatient management, hospitalization is recommended (American College of Obstetricians and Gynecologists, 2018). IV hydration is continued and antiemetics such as promethazine, prochlorperazine, chlorpromazine, or metoclopramide are given parenterally (Table 57-4). Several antiemetics are associated with the long-QT syndrome, discussed in Chapter 52 (p. 936). Outpatient treatment regimens at the hospital also are effective (McCarthy, 2014).

Some, but not all, studies indicate that treatment with *glucocorticosteroids* is not effective (Sridharan, 2020; Yost, 2003). They are recommended only for refractory cases because of their putative teratogenicity (American College of Obstetricians and Gynecologists, 2018).

With persistent vomiting after hospitalization, appropriate steps should be taken to exclude possible underlying diseases as a cause of hyperemesis.

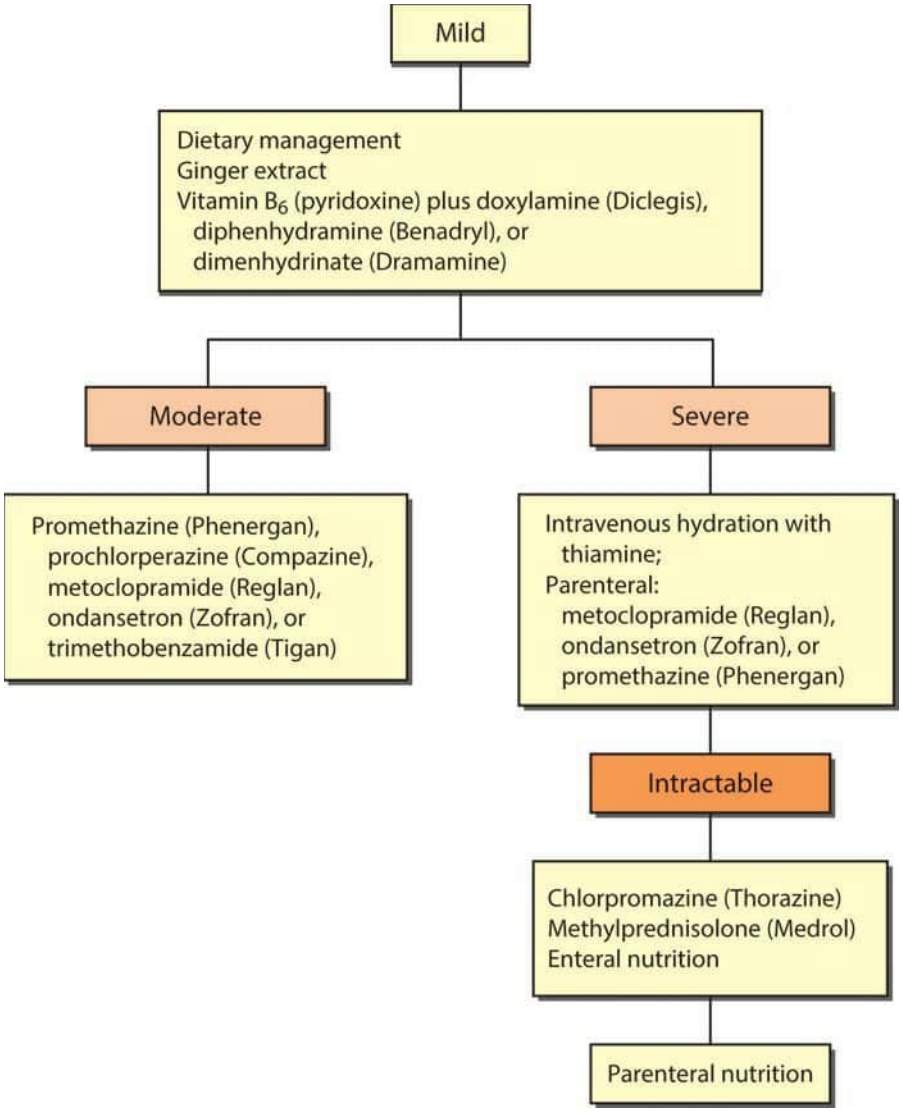

FIGURE 57-1 Algorithm for outpatient and inpatient management of pregnancy nausea and vomiting, and hyperemesis gravidarum.

TABLE 57-4. Medications for Gastrointestinal Disorders in Pregnancy

Medication (Brand Name)	Usual Dosing	Route(s)
Options for nausea and vomiting		
Antihistamine		
Doxylamine + pyridoxine (Diclegis)[a]	At bedtime; up to 4 times daily	PO
Phenothiazines	**Every 6 hr**	
Promethazine (Phenergan)[c]	12.5–25 mg	IM, IV, PO, PR
Prochlorperazine (Compazine)[c]	5–10 (25 PR) mg	IM, IV, PO, PR
Chlorpromazine (Thorazine)[c]	25–50 mg	IM, PO
Serotonin antagonist	**Every 8 hr**	
Ondansetron (Zofran)[b]	8 mg	IV, PO
Benzamides	**Every 6 hr**	
Metoclopramide (Reglan)[b]	5–15 mg	IM, IV, PO
Trimethobenzamide (Tigan)	300 mg	PO
Oral options for gastroesophageal reflux disease (GERD)		
Proton-pump inhibitors		
Pantoprazole (Protonix)[b]	40 mg daily for up to 8 wks	
Lansoprazole (Prevacid)[b]	15 mg daily for up to 8 wks	
Omeprazole (Prilosec, Zegerid)[c]	20 mg daily for 4–8 wks	
Dexlansoprazole (Dexilant)[c]	30 mg daily for up to 4 wks	
H2-receptor antagonists		
Cimetidine (Tagamet)[b]	400 mg 4 times daily for up to 12 wks 800 mg twice daily for up to 12 wks	
Nizatidine (Axid)[b]	150 mg twice daily	
Famotidine (Pepcid)[b]	20 mg twice daily up to 6 wks	

[a]Food and Drug Administration category A.
[b]Food and Drug Administration category B.
[c]Food and Drug Administration category C.
IM = intramuscularly; IV = intravenously; PO = orally; PR = rectally.

That said, in one study, endoscopy did not change management in 49 women (Debby, 2008). Other potential sources include gastroenteritis, cholecystitis, pancreatitis, hepatitis, peptic ulcer, and pyelonephritis. In addition, severe preeclampsia and fatty liver are more likely after midpregnancy. Although clinical thyrotoxicosis has been implicated as a cause of hyperemesis, it is more likely that abnormally elevated serum thyroxine levels are a surrogate for higher-than-average serum hCG levels (Sun, 2014). This is discussed further in Chapter 5 (p. 97). In our experiences, serum free thyroxine levels normalize quickly with hydration and emesis treatment.

With treatment, most women will have a positive response and may be sent home with oral antiemetic therapy. The readmission rate is 25 to 35 percent in most prospective studies. Risks for anxiety and depression are increased in these women (Mitchell-Jones, 2017; Senturk, 2017). At Parkland Hospital, more than one third of women with hyperemesis required readmission. Patient characteristics had limited utility in predicting the risk of readmission. For example, maternal demographics, substance use, psychiatric illness, and initial hospitalization length were not associated with readmission (White, 2018). If psychiatric and social factors contribute to the illness, the woman usually improves remarkably while hospitalized (Swallow, 2004). However, symptoms relapse in a fourth of these women, and some go on to develop *posttraumatic stress syndrome* (Chap. 64, p. 1150) (Christodoulou-Smith, 2011; McCarthy, 2011; Nurmi, 2018). For some women, hyperemesis may be an indication for elective termination (Poursharif, 2007).

Grooten and colleagues (2017) showed that early enteral tube feeding has no advantages. However, in the small percentage of women who have recalcitrant vomiting after intensive therapy, consideration is given for enteral nutrition (p. 1013). Stokke and associates (2015) described successful use of nasojejunal feeding for up to 41 days in 107 such women. Use of sonography to confirm correct tube placement has been described and avoids radiation exposure (Swartzlander, 2013). PEG-J tubes also have been reported (Saha, 2009; Schrag, 2007).

Only a very few women will require parenteral nutrition (American College of Obstetricians and Gynecologists, 2018; Yost, 2003). In a study of 599 women, however, Peled and coworkers (2014) reported that 20 percent required central parenteral nutrition.

Gastroesophageal Reflux Disease

Symptomatic reflux is seen in up to 15 percent of nonpregnant individuals (Kahrilas, 2018). The spectrum of sequelae includes esophagitis, stricture, Barrett esophagus, and adenocarcinoma.

The main symptom of reflux is *pyrosis* (heartburn), which is especially common in pregnancy. In one study, its prevalence rose from 26 percent in the first trimester to 36 percent in the second and 51 percent in the third trimester (Fill Malfertheiner, 2017). The retrosternal burning sensation stems from esophagitis caused by gastroesophageal reflux of stomach acid, which follows relaxation of the lower esophageal sphincter. The diagnosis is typically made from symptoms alone.

Symptoms usually respond to abstaining from tobacco and alcohol, eating small meals, elevating the head of the bed, limiting postprandial recumbency, and avoiding "trigger" foods. These may include fatty foods, tomato-based foods, and coffee. Oral antacids are first-line therapy. If severe symptoms persist, a proton-pump inhibitor is given and an H_2-receptor antagonist and sucralfate can be added (see Table 57-4). Both classes are generally safe for use in pregnancy (Briggs, 2017). From preliminary data, proton-pump inhibitors taken early in pregnancy may increase the risk for preeclampsia (Hastie, 2019). Sucralfate is the aluminum salt of sulfated sucrose and inhibits pepsin. Approximately 10 percent of the aluminum salt is absorbed, and this agent is considered safe for pregnant women (Briggs, 2017). A 1-g sucralfate tablet is taken orally 1 hour before each of the three meals and at bedtime for up to 8 weeks. Antacids are not used within a half hour before or after sucralfate doses. Despite attempts with these options, if relief is not attained, endoscopy should be considered. *Misoprostol* is contraindicated because it stimulates labor (Chap. 26, p. 490).

In nonpregnant patients, surgical fundoplication can be performed (Kahrilas, 2018). Although the procedure is not done during pregnancy, Biertho and colleagues (2006) described 25 women who had undergone laparoscopic Nissen fundoplication before pregnancy. Only 20 percent had reflux symptoms during pregnancy.

Hiatal Hernia

The older literature is informative regarding hiatal hernias in pregnancy. Upper gastrointestinal radiographs performed in 195 women in late pregnancy showed that 20 percent of 116 multiparas and 5 percent of 79 nulliparas had a hiatal hernia (Rigler, 1935). Of 10 women studied postpartum, hernia persisted in three at 1 to 18 months.

The relationship of hiatal hernia with reflux esophagitis is not clear. One study demonstrated no association and showed that the lower esophageal sphincter functioned effectively even when displaced intrathoracically (Cohen, 1971). Nevertheless, during pregnancy, hiatal hernias may cause vomiting, epigastric pain, and bleeding from ulceration. Schwentner (2011) reported severe herniation requiring surgical repair in a woman with a 12-week gestation. Curran and coworkers (1999) described a 30-week pregnancy complicated by gastric outlet obstruction from a paraesophageal hernia.

Diaphragmatic Hernia

These are caused by herniations of abdominal contents through either the foramen of Bochdalek or Morgagni. Fortunately, they rarely complicate pregnancy. In one review of 18 pregnant women who developed acute obstruction within a diaphragmatic hernia, the maternal mortality rate was 45 percent (Kurzel, 1988). Herniation has been reported in one woman who had antireflux surgery in early pregnancy (Brygger, 2013). Several case reports also describe spontaneous diaphragmatic rupture from elevated intraabdominal pressure during delivery (Chen, 2012; Sharifah, 2003). Surgical treatment is considered in symptomatic gravidas and is individualized according to gestational age and clinical setting (Ménassa, 2019; Whang, 2018).

Achalasia

In this rare motility disorder, the lower esophageal sphincter fails to relax properly with swallowing. The esophageal muscularis also displays nonperistaltic contraction activity (Kahrilas, 2018). The defect is caused by inflammatory destruction of the myenteric (Auerbach) plexus within smooth muscle of the lower esophagus and its sphincter. Postganglionic cholinergic neurons are unaffected, and thus sphincter stimulation is unopposed.

Symptoms are dysphagia, chest pain, and regurgitation. Barium swallow radiography demonstrates *bird beak* or *ace of spades* narrowing at the distal esophagus. Endoscopy is performed to exclude gastric carcinoma, and manometry is confirmatory.

During pregnancy, normal physiological relaxation of the lower esophageal sphincter in women with achalasia theoretically should not occur. In one series, half of these women had worsened symptoms, but reflux is uncommon (Vogel, 2018). In other pregnancy studies, most women did not have worsening symptoms (Khudyak, 2006). At least one maternal death was reported at 24 weeks' gestation and perforation of a 14-cm-diameter megaesophagus was implicated (Fassina, 1995).

Management of achalasia includes a soft diet and anticholinergic drugs. With persistent symptoms, other options include nitrates, calcium-channel antagonists, and botulinum toxin A injected locally (Hooft, 2015; Kahrilas, 2018). Balloon dilation of the sphincter may be necessary, and 85 percent of nonpregnant patients respond (Vogel, 2018). *One caveat is that esophageal perforation is a serious complication of dilation.* If dilation or medical therapy fail to provide relief, myotomy is considered. In one report, a 29-week pregnant woman with achalasia was treated for 10 weeks with peripheral parenteral nutrition, and surgical myotomy was done postpartum (Spiliopoulos, 2013).

Peptic Ulcer Disease

The lifetime prevalence of acid peptic disorders in women is 10 percent (Del Valle, 2018). Erosive ulcer disease involves the stomach and duodenum. Gastroduodenal ulcers commonly are caused by chronic gastritis from *Helicobacter pylori*, or they develop from nonsteroidal antiinflammatory drug (NSAID) use. Neither is common in pregnancy (McKenna, 2003; Weyermann, 2003). Rosen and coworkers (2021) reported 2535 pregnant women with peptic ulcer disease and found that complications were less frequent than in nonpregnant controls.

Acid secretion also is important, and this underlies the efficacy of antisecretory agents. Natural gastroprotection during

pregnancy probably originates from physiological changes that include reduced gastric acid secretion, decreased motility, and considerably increased mucus secretion (Hytten, 1991). Despite this, ulcer disease may be underdiagnosed because of frequent treatment for reflux esophagitis (Mehta, 2010). In the past 55 years at Parkland Hospital, during which time we have cared for more than 600,000 pregnant women, we have encountered very few who had proven ulcer disease. Perforation is rare (Goel, 2014). Before appropriate therapy was commonplace, Clark (1953) studied 313 pregnancies in 118 women with ulcer disease and noted a clear remission during pregnancy in almost 90 percent. However, benefits were short lived. Symptoms recurred in more than half by 3 months postpartum and in almost all by 2 years.

The mainstay of management is eradication of *H pylori* and prevention of NSAID-induced disease. Antacids are usually self-prescribed, but other first-line therapy is a proton-pump inhibitor or H_2-receptor blocker (see Table 57-4) (Del Valle, 2018; Laine, 2012). Sucralfate can be added and provides a protective coating at the ulcer base.

With active ulcers, a search for *H pylori* is undertaken. Diagnostic aids include the urea breath test, serological testing, fecal testing, or endoscopic biopsy. If any of these yield positive results, combination antimicrobial plus proton-pump inhibitor therapy is indicated (Chey, 2017). Several effective oral treatment regimens do not include tetracycline and can be used during pregnancy. One 14-day regimen includes clarithromycin, 500 mg twice daily, which is paired either with amoxicillin, 1000 mg twice daily or with metronidazole, 500 mg three times daily. These antibiotics are given with a proton-pump inhibitor (Del Valle, 2018).

Upper Gastrointestinal Bleeding

In some women, persistent vomiting is accompanied by worrisome upper gastrointestinal bleeding. Occasionally, a peptic ulcer is the source. However, most of these women have small linear mucosal tears near the gastroesophageal junction—*Mallory-Weiss tears* (p. 1014). Bleeding usually responds promptly to conservative measures that include IV proton-pump inhibitors and topical antacids (Laine, 2012). Transfusions may be needed, and if bleeding persists, endoscopy is usually indicated (O'Mahony, 2007). With sustained retching, the less common, but more serious, esophageal rupture—*Boerhaave syndrome*—may develop from high esophageal pressure.

SMALL BOWEL AND COLON DISORDERS

The small bowel has diminished motility during pregnancy. Lawson and colleagues (1985) showed that the small bowel mean transit times of 99, 125, and 137 minutes in each successive trimester, respectively, were slower than 75 minutes when nonpregnant. Muscular relaxation of the colon is accompanied by increased absorption of water and sodium that predisposes to constipation. This complaint is reported by almost 25 percent of women at some time during pregnancy and the puerperium (Everson, 1992). Symptoms are usually only mildly bothersome, and initial treatment includes increasing fluid intake (>8 glasses/d) and fiber consumption (20 to 35 g/d) (Body, 2016). If these lifestyle modifications fail, bulk-forming agents such as methylcellulose may be added, and in severe cases the stimulant laxative bisacodyl. We have encountered several pregnant women who developed megacolon from impacted stool. These women almost invariably had chronically abused stimulatory laxatives.

Acute Diarrhea

The estimated monthly prevalence of diarrhea among adults is 3 to 7 percent (DuPont, 2014). Diarrhea can be classified as acute (<2 weeks), persistent (2 to 4 weeks), and chronic (>4 weeks). Most cases of acute diarrhea are caused by infectious agents, and a third result from foodborne pathogens. The large variety of viruses, bacteria, helminths, and protozoa that cause diarrhea in adults also afflict pregnant women. These are usually accompanied by vomiting, fever, and abdominal pain. Some of these are discussed in Chapter 64 (p. 1197).

Evaluation of acute diarrhea depends on its severity and duration. Some indications for evaluation include profuse watery diarrhea with dehydration, grossly bloody stools, fever >38°C, duration >48 hr without improvement, recent antimicrobial use, and diarrhea in the immunocompromised patient (Camilleri, 2018; DuPont, 2014). Cases of moderately severe diarrhea with fecal leukocytes or gross blood may be treated with empirical antibiotics rather than evaluation. However, risks and benefits should be considered, and it is reasonable to withhold treatment until stool testing is completed to exclude infection. Some features of the more common acute diarrheal syndromes and their treatment are shown in Table 57-5.

The mainstay of treatment is IV hydration using normal saline or Ringer lactate and potassium supplementation in amounts to restore maternal blood volume and to ensure uteroplacental perfusion. Vital signs and urine output are monitored for signs of sepsis. For moderately severe nonfebrile illness without bloody diarrhea or recent travel, antimotility agents such as loperamide (Imodium) may be useful. An initial 4-mg (two capsules) dose can be followed with another 2-mg capsule after subsequently passed watery stools. Dosages should not exceed 8 mg/d, and loperamide is not used for more than 48 h. Bismuth subsalicylate (Pepto-Bismol) also may alleviate symptoms. The recommended dosage is 30 mL (525 mg) of its liquid form or two tablets (263 mg/tablet) chewed well each 30 to 60 min and not to exceed eight doses in 24 h. The drug will produce harmless black stools (Riddle, 2016).

Judicious use of antimicrobial agents is warranted. For moderately to severely ill women, some recommend empirical treatment with ciprofloxacin, 500 mg twice daily for 3 days. Specific pathogens are treated as needed when identified (see Table 57-5). Syndromes for which treatment is usually unnecessary include those caused by *Escherichia coli*, staphylococcal species, *Bacillus cereus*, and norovirus. Severe illness caused by *Salmonella* species is treated with ciprofloxacin or trimethoprim-sulfamethoxazole; by *Campylobacter* species with azithromycin; by *Clostridioides difficile* with oral vancomycin or fidaxomicin; and by *Giardia* species and *Entamoeba histolytica* with metronidazole (DuPont, 2014; McDonald, 2018; Rocha-Castro, 2016).

TABLE 57-5. Etiology, Clinical Features, and Treatment of Common Acute Diarrheal Syndromes

Agents	Incubation	Emesis	Pain	Fever	Diarrhea	Treatment
Toxin producers	1–72 hr	3–4+	1–2+	0–1+	3–4+, watery	
1. *Staphylococcus* spp.						1. None
2. *C perfringens*						2. None
3. *E coli* (enterotoxin)						3. Ciprofloxacin
4. *B cereus*						4. None
Enteroadherent	1–8 days	0–1+	1–3+	0–2+	1–2+, watery, mushy	
1. *E coli*						1. Ciprofloxacin
2. *Giardia* spp.						2. Tinidazole
3. Helminths						3. As detected
Cytotoxin producers	1–3 days	0–1+	3–4+	1–2+	1–3+, watery, then bloody	
1. *C difficile*						1. Vancomycin
2. *E coli* (hemorrhagic)						2. None
Inflammatory						
Minimal	1–3 days	1–3+	2–3+	3–4+	1–3+, watery	
1. *Rotavirus*						1. None
2. *Norovirus*						2. None
Variable	12 hr–11 days	0–3+	2–4+	3–4+	1–4+ watery or bloody	
3. *Salmonella* spp.						3. Ciprofloxacin

Clostridioides difficile Infection

Formally known as *Clostridium difficile*, this anaerobic gram-positive bacillus is transmitted by the fecal-oral route. In a study from China, 3.7 percent of normal gravidas were colonized (Ye, 2016). It is the most frequent nosocomial infection in the United States. In 2011, 453,000 cases of *C difficile* and 29,000 associated deaths were reported by the Centers for Disease Control and Prevention (Lessa, 2015). Its incidence in pregnant women has doubled during the past decade (Ruiter-Ligeti, 2018). The most important risk factor is antibiotic use, and the highest risk is with aminopenicillins, clindamycin, cephalosporins, and fluoroquinolones. Other risk factors include inflammatory bowel disease, immunosuppression, advanced age, and gastrointestinal surgery. Most cases are hospital-acquired, however, 10 percent are community-acquired cases (Gerding, 2018). With severe colitis, the infection-related mortality rate is 5 percent.

Laboratory diagnosis from a stool sample uses nucleic-acid amplification testing (NAAT) for *C difficile* itself or uses an enzyme-immunoassay-based algorithm for a unique *C difficile* enzyme or its toxins A and B (McDonald, 2018). Less often, infection may be diagnosed endoscopically (Fig. 57-2). Only patients with new-onset diarrhea and ≥3 unformed stool of unexplained etiology should be tested, and posttreatment testing is not recommended. Prevention is by soap-and-water hand

TABLE 57-6. Some Shared and Differentiating Characteristics of Inflammatory Bowel Disease

	Ulcerative Colitis	Crohn Disease
Shared Characteristics		
Hereditary	More than 100 disease-associated genetic loci–a third shared; Jewish predominance; familial in 5–10% of cases; Turner syndrome; immune dysregulation	
Other	Chronic and intermittent with exacerbations and remissions; extraintestinal manifestations: arthritis, erythema nodosum, uveitis	
Differentiating Characteristics		
Major symptoms	Diarrhea, tenesmus, rectal bleeding, cramping pain; chronic, intermittent; anemia	Fibrostenotic–recurrent RLQ colicky pain; fever Fistulizing–cutaneous, bladder, interenteric
Bowel involvement	Mucosa and submucosa of large bowel; usually begins at rectum (40% proctitis only); continuous disease	Deep layers small and large bowel; commonly transmural; discontinuous involvement; strictures and fistulas
Endoscopy	Granular and friable erythematous mucosa; bleeding; rectal involvement	Patchy; segmental colitis; rectum spared; perianal involvement
Serum antibodies	Antineutrophil cytoplasmic (pANCA) ~70%	Anti–*S cerevisiae* ~50%
Complications	Toxic megacolon; strictures; arthritis; cancer (3–5%)	Fistulas; arthritis; toxic megacolon; small bowel obstruction
Management	Medical; proctocolectomy curative	Medical; segmental and fistula resection

RLQ = right lower quadrant; *S cerevisiae* = *Saccharomyces cerevisiae*.

washing, and infected individuals are isolated. Treatment consists of stopping the offending antibiotics and giving 10 days of oral vancomycin, 125 mg four times daily, or fidaxomicin (Dificid), 200 mg twice daily (McDonald, 2018). The risk of recurrence after an initial episode is 20 percent. Fecal microbial transplantation may become standard for recurrent clostridial colitis (Saeedi, 2017).

Inflammatory Bowel Disease

Two presumably noninfectious forms of intestinal inflammation are ulcerative colitis and Crohn disease. Differentiation between these is important because treatment differs. That said, they both share common features, and sometimes are indistinguishable if Crohn disease involves the colon. The features shown in Table 57-6 permit a reasonably confident diagnostic differentiation in most cases. The etiopathogenesis is enigmatic in both, but a genetic predisposition is suspected, especially for Crohn disease. Inflammation is thought to result from dysregulated mucosal immune function in response to commensal microbiota, with or without an autoimmune component (Friedman, 2018).

Ulcerative Colitis

This is a mucosal disorder with inflammation confined to the superficial luminal layers of the colon. It typically begins at the rectum and extends proximally for a variable distance. In approximately 40 percent of cases, disease is confined to the rectum or the rectosigmoid, but 20 percent have pancolitis. For unknown reasons, prior appendectomy protects against ulcerative colitis (Friedman, 2018). Endoscopic findings include mucosal granularity and friability that is interspersed with mucosal ulcerations and a mucopurulent exudate (see Fig. 57-2).

Major symptoms of ulcerative colitis include diarrhea, rectal bleeding, tenesmus, and abdominal cramps. The disease is characterized by exacerbations and remissions. *Toxic megacolon* and catastrophic hemorrhage are particularly dangerous complications that may necessitate colectomy. *Extraintestinal manifestations* include arthritis, uveitis, and erythema nodosum. The risk of associated colon cancer approaches 1 percent per year. With either ulcerative colitis or Crohn disease, risks for VTE are higher in even asymptomatic women (Friedman, 2018; Mahadevan, 2019).

Crohn Disease

Also known as regional enteritis, Crohn ileitis, or granulomatous colitis, Crohn disease has more protean manifestations than ulcerative colitis. It involves not only the mucosa but also the deeper bowel layers (see Fig. 57-2). Lesions can be seen throughout the entire GI tract, from the mouth to the anus, but it typically is segmental (Friedman, 2018). Approximately 30 percent of patients have only small-bowel involvement, 25 percent have isolated colonic involvement, and 40 percent have both, usually with the terminal ileum and colon involved. Perianal fistulas and abscesses develop in a third of those with colonic involvement.

Symptoms depend on which bowel segment(s) is involved. Thus, complaints may include lower-right-sided cramping abdominal pain, diarrhea, weight loss, low-grade fever, and obstructive symptoms. The disease is chronic with exacerbations and remissions, and importantly, it cannot be cured medically or surgically. Approximately a third of patients require surgery within the first year after diagnosis, and thereafter, the rate is 5 percent per year. Reactive arthritis is common, and the GI cancer risk, although not as great as with ulcerative colitis, is increased substantially.

Inflammatory Bowel Disease and Fertility

Subfertility in women is linked to active disease, but normal fertility is likely with quiescent colitis (Mahadevan, 2019). Subfertility may also be partially attributed to sulfasalazine, which causes reversible sperm abnormalities (Feagins, 2009).

For women requiring surgical resection, a laparoscopic approach has a higher subsequent fertility rate (Beyer-Berjot, 2013). With colectomy, however, although fertility is improved, up to half of women will be persistently infertile (Bartels, 2012; Lee, 2019a). Sexual function and fertility are only modestly affected by ileal pouch–anal anastomosis (Hor, 2016).

Inflammatory Bowel Disease and Pregnancy

Because ulcerative colitis and Crohn disease are relatively common in young women, these disorders are encountered with some frequency in pregnancy. In many studies, the outcomes are grouped together for both entities. For example, in a study from Australia, Shand and colleagues (2016) reported a prevalence of 1 inflammatory bowel disease (IBD) case in 320 births. In this regard, some generalizations can be made. First, consensus supports that pregnancy does not increase the likelihood of an IBD flare (Mahadevan, 2019). Indeed, in a 10-year surveillance of women in the European Collaborative on Inflammatory Bowel Disease, the likelihood of a flare during pregnancy was lower than the preconceptional rate (Riis, 2006). Although most women with quiescent disease in early pregnancy do not have relapses, when a flare develops, it may be severe. Also, and as discussed subsequently, active disease in early pregnancy increases the likelihood of disease relapse during pregnancy (de Lima-Karagiannis, 2016).

In general, most usual treatment regimens may be continued during pregnancy. Diagnostic evaluations should be undertaken if needed to direct management, and surgery should be performed if indicated (Mahadevan, 2019). Fecal calprotectin, an inflammatory biomarker in stool samples, is a valid tool in pregnancy to identify IBD flares (Julsgaard, 2017; Lichtenstein, 2018; Rubin, 2019).

At first glance, it appears that adverse pregnancy outcomes are increased with IBD (Boyd, 2015; Getahun, 2014). Initially, this was attributed to the fact that most studies included women with either form of disease. Specifically, Crohn disease was noted to be linked to excessive morbidity. But, according to Reddy (2008) and others, these adverse outcomes were in women with severe disease and multiple recurrences. Indeed, in the prospective European case-control ECCO-EpiCom study of 332 pregnant women with IBD, outcomes were similar in women with ulcerative colitis or Crohn disease compared with unaffected pregnant women (Bortoli, 2011). Still, women with active disease during pregnancy have an increased frequency of preterm births (Kammerlander, 2017; Shand, 2016). Importantly, perinatal mortality rates are not appreciably increased.

Ulcerative Colitis and Pregnancy. In one review of 755 pregnancies, colitis that was quiescent at conception worsened in approximately a third of pregnancies (Fonager, 1998). In women with active disease at the time of conception, approximately 45 percent worsened, 25 percent remained unchanged, and only 25 percent improved. These observations are similar to those described in a review by Miller (1986) as well as in later reports (de Lima-Karagiannis, 2016; Oron, 2012).

Osteoporosis is a significant complication in up to a third of affected women. Thus, vitamin D—800 IU daily—and calcium—1200 mg daily—are given. Folic acid, 2 to 4 mg orally daily, is recommended preconceptionally and during the first trimester for neural-tube defect prevention (Mahadevan, 2019). This high dose counteracts the antifolate actions of sulfasalazine. Flares may be caused by psychogenic stress, and reassurance is important. Last, the venous thromboembolism risk is doubled, but thromboprophylaxis is not routinely provided (Hansen, 2017).

Management for colitis for the most part mirrors that outside of pregnancy. Treatment of active colitis and maintenance therapy incorporate drugs that deliver 5-aminosalicyclic acid (5-ASA), also known as mesalamine. *Sulfasalazine (Azulfidine)* is the prototype, and its 5-ASA moiety inhibits prostaglandin synthase in colonic mucosa. Others include *olsalazine (Dipentum), balsalazide (Colazal),* and delayed-release 5-ASA derivatives *(Apriso, Asacol, Pentasa, Lialda)*. Glucocorticoids are beneficial and are given orally, parenterally, or by enema for moderate or severe disease that does not respond to 5-ASA. Corticosteroids provide a high remission rate for active disease, but they are not given for maintenance therapy (Friedman, 2018). Recalcitrant disease is managed with immunomodulating drugs, including *azathioprine*, *6-mercaptopurine*, *cyclosporine*, or *tacrolimus*, which all appear relatively safe in pregnancy (Briggs, 2017; Mozaffari, 2015). Importantly, *methotrexate* is teratogenic and contraindicated in pregnancy (Chap. 8, p. 152).

In the past, biologics were reserved for recalcitrant, moderate to severe disease. Because of their considerable efficacy, however, these medications are now frequently given *initially* for this severity of disease to prevent future complications. These agents are antibodies against tumor necrosis factor alpha (TNF-α). Those recommended for IBD treatment are shown in Table 57-7 (Mahadevan, 2019). Women who begin pregnancy while taking biologics should continue these through pregnancy until several weeks before delivery to help avoid maternal infections from immunosuppression. These agents are administered

TABLE 57-7. Biologics Used to Treat Inflammatory Bowel Disease in Pregnancy

Drug (Brand Name)	Recommendations
Adalimumab (Humira)	Last dose 2–3 wks before EDC
Certolizumab pegol (Cimzia)	Continue throughout pregnancy
Infliximab (Remicade)	Last dose 6–10 wks before EDC
Natalizumab (Tysabri)	Last dose 4–6 wks before EDC
Ustekinumab (Stelara)	Last dose 6–10 wks before EDC
Vedolizumab (Entyvio)	Last dose 6–10 wks before EDC

EDC = estimated date of confinement.

IV or subcutaneously. Several studies support their safety in pregnancy, although there are concerns that their discontinuance may prompt a relapse (Chaparro, 2018; Friedman, 2018; Luu, 2018). Another worry is that they may cause immunosuppression in the newborn, and early neonatal vaccination with live-attenuated agents are delayed for at least 6 months (Esteve-Solé, 2017; Julsgaard, 2016).

Colorectal endoscopy is performed as indicated. Surgical management is tailored to disease severity (Killeen, 2017). During pregnancy, colectomy and ostomy creation for fulminant colitis may be needed as a lifesaving measure, and it has been described during each trimester. Dozois (2006) reviewed 42 such cases and found that, in general, outcomes have been good with partial or complete colectomy. Parenteral nutrition is occasionally needed for women with prolonged exacerbations.

For women with an ileal pouch and an anal anastomosis, frequency of bowel movements, fecal incontinence, and pouchitis may temporarily worsen with pregnancy. The last is an inflammatory condition of the ileoanal pouch probably due to bacterial proliferation and stasis. Pouchitis usually responds to ciprofloxacin or metronidazole. In one rare case, adhesions to the growing uterus led to ileal pouch perforation (Aouthmany, 2004).

In general, women with uncomplicated colitis can be delivered vaginally (Foulon, 2017). That said, the cesarean delivery rate in these women is increased (Burke, 2017). It is controversial whether women who have had a prior proctocolectomy and ileal pouch–anal anastomosis can be safely delivered vaginally. Hahnloser (2004) reviewed delivery routes in women with 235 pregnancies before and 232 pregnancies after ileoanal pouch surgery. Functional outcomes were similar, and it was concluded that cesarean delivery should be reserved for obstetrical indications. To the contrary, following their systematic review, Foulon and coworkers (2017) recommended cesarean delivery with the caveat that *uncomplicated* vaginal delivery was safe.

As discussed, quiescent ulcerative colitis likely has minimal adverse effects on pregnancy outcome. Modigliani (2000) reviewed perinatal outcomes in 2398 pregnancies and reported them to be not substantively different from those in the general obstetrical population. Specifically, the incidences of spontaneous abortion, preterm delivery, and stillbirth were remarkably low. These authors and others also describe a cesarean delivery rate that was substantially higher than that for normal controls (Burke, 2017; Mahadevan, 2015). The previously described ECCO-EpiCom study reported similar outcomes in 187 gravidas with ulcerative colitis compared with normal control women (Bortoli, 2011).

Crohn Disease and Pregnancy. In general, Crohn disease activity during pregnancy is related to its status around the time of conception. In a cohort study of 279 pregnancies conceived by 186 women whose disease was inactive at conception, a fourth relapsed during pregnancy (Fonager, 1998). In 93 with active disease at conception, however, two thirds either remained active or worsened. Other reviews describe similar findings (Miller, 1986; Oron, 2012).

Calcium, vitamin D, and folic acid supplementation mirror that for ulcerative colitis. For maintenance during asymptomatic periods, no regimen is universally effective. *Sulfasalazine* is effective for some, but the newer 5-ASA formulations are better tolerated. Glucocorticoids induce a 60- to 70-percent remission rate (Friedman, 2018). *Prednisone* therapy may control moderate to severe flares but is less effective for small-bowel involvement. Immunomodulators such as *azathioprine*, *6-mercaptopurine*, *cyclosporine,* and *tacrolimus* are used for active disease and for maintenance. These appear relatively safe during pregnancy (Chaparro, 2018; Luu, 2018). As discussed in Chapter 8 (p. 152), methotrexate is contraindicated in pregnancy. As with ulcerative colitis, treatment with TNF-α inhibitors is often used initially for active Crohn disease and maintenance (see Table 57-7) (Friedman, 2018; Mahadevan, 2019).

Endoscopy or conservative surgery is indicated for complications (Killeen, 2017). Patients with small-bowel involvement are more likely to require surgery for complications that include fistulas, strictures, obstruction, abscesses, and intractable disease. In an earlier study, an abdominal surgical procedure was required during 5 percent of pregnancies (Woolfson, 1990). Parenteral nutrition has been used successfully during severe recurrences. Those with an ileal loop colostomy may have significant problems. Unless there is a perianal fistula or active perianal disease, women with Crohn disease usually can undergo vaginal delivery without complications (Foulon, 2017; Mahadevan, 2019).

As discussed, Crohn disease compared with ulcerative colitis is associated with higher adverse pregnancy outcome rates. Outcomes are probably related to disease activities. In a case-control Danish study, Norgård (2007) reported a twofold risk of preterm births. Dominitz (2002) reported a two- to threefold increased risk for preterm delivery, low birthweight, fetal-growth restriction, and cesarean delivery in 149 women with Crohn disease. Recall, however, that the ECCO-EpiCom study found pregnancy outcomes to be similar to those in unaffected women.

■ Ostomy and Pregnancy

A colostomy or an ileostomy can be problematic during pregnancy because of its location (Hux, 2010). In a report of 82 pregnancies in 66 women with an ostomy, *stomal dysfunction* was common, but it responded to conservative management in most cases (Gopal, 1985). Surgical intervention was necessary, however, in three of six women who developed *bowel obstruction* and in another four with *ileostomy prolapse*—almost 10 percent overall. In this older study, only a third of 82 women underwent cesarean delivery, but Takahashi (2007) described six of seven cesarean deliveries in women with Crohn disease and a stoma. Although adhesions usually are involved with an obstructed ileostomy, the enlarging uterus may act to cause obstruction (Porter, 2014). Last, Farouk and coworkers (2000) reported that pregnancy did not worsen long-term ostomy function.

■ Intestinal Obstruction

The incidence of bowel obstruction is not increased during pregnancy, although it generally is more difficult to diagnose. Meyerson (1995) reported a 20-year incidence of 1 case in

17,000 deliveries at two Detroit hospitals. Of acute abdomen cases in pregnancy, adhesive disease leading to small-bowel obstruction was second only to appendicitis—15 versus 30 percent, respectively (Unal, 2011). Approximately half of cases are due to adhesions from previous pelvic surgery that includes cesarean delivery (Andolf, 2010; Lyell, 2011). Another 25 percent of bowel obstruction is caused by volvulus, which may involve sigmoid colon, cecum, or small bowel. These have been reported in late pregnancy or early puerperium (Al Maksoud, 2015; Bade, 2014). Bokslag (2014) and Wax (2013) and their colleagues described small-bowel obstruction in pregnancy following the currently popular Roux-en-Y gastric bypass, which is performed for weight loss. Intussusception is occasionally encountered (Bosman, 2014; Moliere, 2019). Bowel obstruction subsequent to colorectal surgery for cancer was increased threefold in women who had open versus laparoscopic surgery (Haggar, 2013). Last, Serra and coworkers (2014) described a massive ventral hernia with intestinal obstruction.

Most cases of intestinal obstruction during pregnancy result from pressure of the growing uterus on intestinal adhesions. This is more likely around midpregnancy when the uterus becomes an abdominal organ; in the third trimester when the fetal head descends; or immediately postpartum when uterine size acutely shrinks (Davis, 1983). Perdue (1992) reported that 98 percent of affected pregnant women had either continuous or colicky abdominal pain, and 80 percent had nausea and vomiting. Abdominal tenderness was found in 70 percent, and abnormal bowel sounds noted in only 55 percent. Plain abdominal radiographs following soluble contrast showed evidence of obstruction in 90 percent of affected women. Plain radiographs, however, are less accurate for diagnosing small-bowel obstruction, and we and others have found that CT and MR imaging can be diagnostic (Essilfie, 2007; Moliere, 2019). Colonoscopy can be both diagnostic and therapeutic for colonic volvulus (Dray, 2012; Khan, 2012).

During pregnancy, mortality rates with obstruction can be excessive because of difficult and thus delayed diagnosis, reluctance to operate during pregnancy, and the need for emergency surgery (Firstenberg, 1998; Shui, 2011). In an older report of 66 pregnancies, Perdue and associates (1992) described 6-percent maternal and 26-percent fetal mortality rates. Two of the four women who died were in late pregnancy, and they had bowel perforation from sigmoid or cecal volvulus caused by adhesions.

Colonic Pseudo-Obstruction

Also known as *Ogilvie syndrome*, pseudo-obstruction is caused by adynamic colonic ileus. It is characterized by massive abdominal distention with cecal and right-hemicolonic dilation (Fig. 57-3). Approximately 10 percent of all cases are associated with pregnancy, and its reported frequency is 1 case in 1500 births (Reeves, 2015). The syndrome usually develops postpartum—90 percent after cesarean delivery—but it has been reported antepartum. In a review, perforation was common, especially if the cecal diameter exceeded 12 cm (Jayaram, 2017). More recently, treatment with an IV infusion of neostigmine, 2 mg, given during cardiac monitoring usually results in prompt decompression (Song, 2018). In some cases, colonoscopic decompression is performed, and in others, laparotomy is needed for perforation (Rawlings, 2010).

Appendicitis

The lifetime incidence for appendicitis ranges from 7 to 10 percent (Flum, 2015). Thus, evaluation for possible appendicitis is relatively common during pregnancy. Theilen and colleagues (2017) studied 171 such women during a 5-year period, but only 14 women ultimately were found to have pathologically confirmed appendicitis. After clinical and imaging evaluation, the frequency of suspected appendicitis drops and that of confirmed appendicitis in more than 8 million women ranged from 1 case in 1000 to 5500 births (Abbasi, 2014; Hée, 1999; Mazze, 1991).

It is repeatedly—and appropriately—emphasized that pregnancy makes the diagnosis of appendicitis more difficult. Nausea

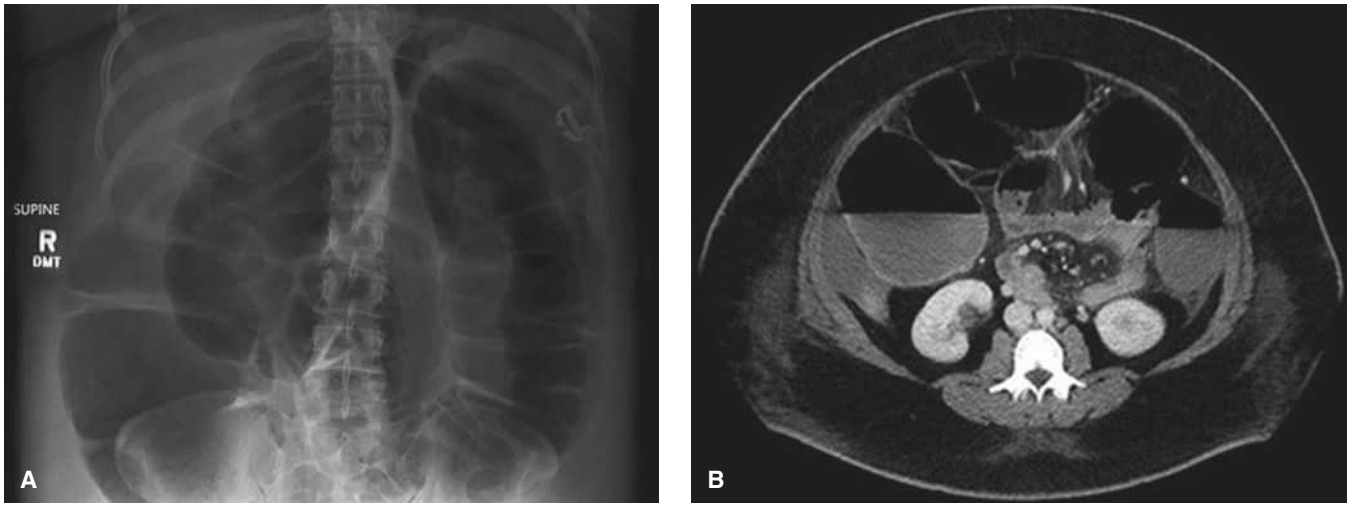

FIGURE 57-3 Ogilvie syndrome. Massive dilation of colon due to pseudo-obstruction in a woman following cesarean delivery. **A.** Abdominal radiograph. **B.** Axial image from computed tomography.

and vomiting accompany normal pregnancy, but also, as the uterus enlarges, the appendix commonly moves upward and outward from the right lower quadrant (Baer, 1932; Erkek, 2015; Pates, 2009). Another often-stated reason for late diagnosis is that some degree of leukocytosis accompanies normal pregnancy. That said, Theilen and coworkers (2017) observed that a white cell count >18,000/μL made the diagnosis tenfold more likely. Neutrophilic shift is another (Gentles, 2020). Pregnant women—especially in late gestation—frequently do not have clinical findings "typical" for appendicitis. Thus, it commonly is confused with cholecystitis, labor, pyelonephritis, renal colic, placental abruption, or uterine leiomyoma degeneration.

Most reports indicate increasing morbidity and mortality rates with advancing gestational age. And, as the appendix is progressively deflected upward by the growing uterus, omental containment of infection becomes increasingly unlikely. It is indisputable that appendiceal perforation is more common during later pregnancy (Abbasi, 2014). In the studies by Andersson (2001) and Ueberrueck (2004), the incidence of perforation was approximately 8, 12, and 20 percent in successive trimesters.

Diagnosis

Persistent abdominal pain and tenderness are the most reproducible findings. Right lower quadrant pain is the most frequent, although pain migrates upward with appendiceal displacement (Mourad, 2000). For initial evaluation, sonographic abdominal imaging is reasonable in suspected appendicitis, even if to exclude an obstetrical cause of pain (Butala, 2010). That said, *graded compression sonography* is difficult because of cecal displacement and uterine imposition (Pedrosa, 2009). *Appendiceal computed tomography* is more sensitive and accurate than sonography to confirm suspected appendicitis (Katz, 2012; Raman, 2008). Specific views can be designed to diminish fetal radiation exposure (Chap. 49, p. 873).

When available, MR imaging is the preferred modality for evaluation of suspected appendicitis in pregnancy (Fig. 57-4).

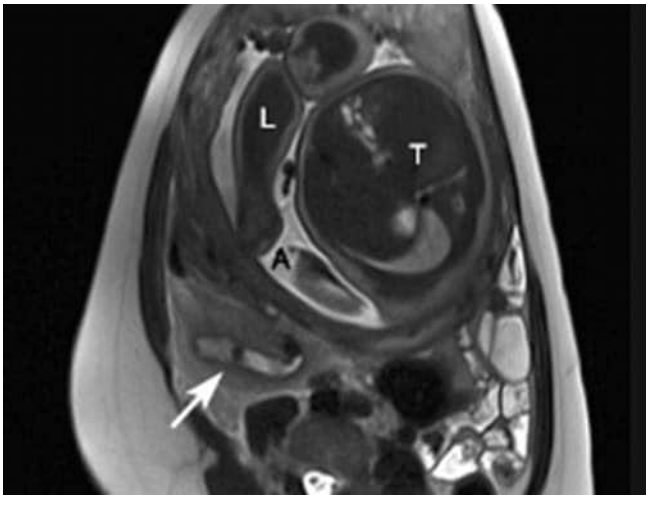

FIGURE 57-4 Magnetic resonance T2 flair image of acute appendicitis in a midtrimester pregnancy. The bright signal is inflammation and the block dot is a fecalith that can be seen in the midappendix (*arrow*). The fetal trunk (*T*) and leg (*L*) and amnionic fluid (*A*) are seen within the gravid uterus superior to the appendix. (Reproduced with permission by Dr. Christina Herrera.)

MR imaging has high diagnostic yield and accuracy, and it also provides alternative diagnoses (Fonseca, 2014; Theilen, 2015). One metaanalysis of 30 studies cited positive- and negative-predictive values of 96 and 99.5 percent, respectively, for MR imaging (Duke, 2016). Others report similar findings (Burke, 2015; Kave, 2019). However, Aguilera and colleagues (2018) found a sensitivity of only 18 percent in pregnant women.

Management

When appendicitis is suspected, most recommend prompt surgical exploration. Although diagnostic errors may lead to removal of a normal appendix, surgical evaluation is preferable to postponed intervention and generalized peritonitis (Abbasi, 2014). In earlier reports, the diagnosis was verified in only 60 to 70 percent of pregnant women. As indicated above, however, with CT and MR imaging, these figures have improved (Duke, 2016; Theilen, 2015). Still and importantly, the accuracy of diagnosis is inversely proportional to gestational age.

Currently, laparoscopic resection is almost always used to treat suspected appendicitis during the first two trimesters. In a report from a Swedish database of nearly 2000 laparoscopic appendectomies, perinatal outcomes were similar to those of more than 1500 open laparotomies done before 20 weeks' gestation (Reedy, 1997). Conversely, in their review, Wilasrusmee and coworkers (2012) reported a higher rate of fetal loss with laparoscopy. Authors of three more recent systematic reviews indicate that the level of evidence is not strong enough to demonstrate a preferred approach to appendectomy (Frountzas, 2019; Lee, 2019b; Walker, 2014). It has evolved that in many centers, laparoscopic appendectomy is also performed in most cases during the third trimester (Donkervoort, 2011). This is encouraged by others, including the Society of American Gastrointestinal and Endoscopic Surgeons (Pearl, 2017; Sekar, 2019; Soper, 2011).

Before exploration, IV antimicrobial therapy is begun, usually with a second-generation cephalosporin or third-generation penicillin. Unless there is gangrene, perforation, or a periappendiceal phlegmon, antimicrobial therapy can usually be discontinued after surgery. Without generalized peritonitis, the prognosis is excellent. Seldom is cesarean delivery indicated at the time of appendectomy. Uterine contractions are common, and although some clinicians recommend tocolytic agents, we do not. de Veciana (1994) reported that tocolytic use substantially increased the risk for pulmonary-permeability edema caused by sepsis (Chap. 50, p. 883).

Antimicrobial versus Surgical Treatment

Because of European studies, some advocate that many cases of appendicitis can be treated successfully with IV antimicrobials alone (Flum, 2015; Talan, 2019). In one study, 6 percent of pregnant women with appendicitis were treated medically, and these gravidas had "considerably" elevated risks for septic shock, peritonitis, and VTE compared with surgically managed cases (Abbasi, 2014). In another study of 20 women, failure rate was 25 percent (Joo, 2017). At this time, we discourage this practice until appropriate studies have been done with pregnant women. Certainly, if elected, such treatment should exclude women with obstructive appendicitis, and the threshold to convert to surgical treatment must be low.

Pregnancy Outcomes

Appendicitis increases the likelihood of preterm labor, especially if peritonitis has developed. Spontaneous labor after 23 weeks ensues with greater frequency following surgery for appendicitis compared with surgery for other indications (Ibiebele, 2019; Won, 2017). In one study, the fetal loss rate was 22 percent if surgery was performed after 23 weeks' gestation. Three large population-based studies attest to the adverse outcomes from appendicitis in pregnancy. From the California State Inpatient Database, the fetal loss rate was 20 percent (Won, 2017). A nationwide study from Taiwan found that risks for low birthweight and preterm delivery rose 1.5- to 2-fold when outcomes in 908 women with acute appendicitis were compared with those of controls (Wei, 2012). Last, an Australian population-based study reported an almost twofold increased incidence of preterm birth following appendectomy (Ibiebele, 2019).

CHAPTER 58

Hepatic, Biliary, and Pancreatic Disorders

Disorders of the liver, gallbladder, and pancreas together constitute a formidable list of complications that may arise in pregnancy. Some stem from preexisting conditions, and some are unique to gestation. The relationships of several of these with pregnancy can be intriguing and challenging.

HEPATIC DISORDERS

Liver diseases complicating pregnancy are placed into three general categories. The first includes those specific to pregnancy and resolve either spontaneously or following delivery. Hyperemesis gravidarum, intrahepatic cholestasis, acute fatty liver, and *HELLP syndrome*—which is characterized by hemolysis, elevated liver enzyme levels, and low platelet counts, are examples. The second category involves acute hepatic disorders that are coincidental to pregnancy, such as acute viral hepatitis. Last are chronic liver diseases that predate pregnancy, such as chronic viral or autoimmune hepatitis, cirrhosis, or esophageal varices.

Laboratory testing can aid differentiation of these disorders. Hepatic dysfunction from hyperemesis gravidarum may manifest as mildly elevated serum bilirubin and transaminase levels (Chap. 57, p. 1014). Others listed in Table 58-1 can show more marked findings. One example, severe preeclampsia syndrome, discussed in Chapter 40 (p. 689), can be further complicated by the HELLP syndrome, which can rarely cause liver failure (Casey, 2020).

Importantly, several normal pregnancy-induced physiological changes induce appreciable liver-related clinical and laboratory manifestations (Chap. 4, p. 70 and Appendix, p. 1229). Abnormalities such as increased serum alkaline phosphatase levels, palmar erythema, and spider angiomas are common during normal pregnancy. In addition, higher levels of estrogen, progesterone, and other pregnancy hormones alter expression of the cytochrome P450 system. For example, hepatic CYP1A2 expression declines, but that of CYP2D6 and CYP3A4 rises. The latter pair possibly affects metabolism of commonly used therapeutic agents in pregnancy (Dallmann, 2018; Ornoy, 2019). Cytochrome enzymes are also expressed in the placenta. The net effect is complex and likely influenced by gestational age and organ of expression (Isoherranen, 2013). Despite these functional changes, no major hepatic histological changes are induced by normal pregnancy.

Acute Liver Failure in Pregnancy

Fortunately, liver failure is uncommon during pregnancy. Of the various causes, drug-induced liver injury (DILI) is probably the most frequent non-pregnancy-related etiology (Hoofnagle, 2019). Acetaminophen toxicity is the most prevalent cause in the United States (Lee, 2018). Other sources of liver failure include acute fatty liver of pregnancy (AFLP), fulminant viral hepatitis, environmental toxins, autoimmune hepatitis, shock liver, and alternative medicines. In a highly selective study of 70 referred women with a hepatic encephalopathy, half were caused by AFLP and half were associated with HELLP syndrome (Casey, 2020).

The treatment of acute liver failure in pregnancy mirrors that for nonpregnant individuals. Therapy targets the underlying etiology, and a team of obstetricians, maternal-fetal medicine and critical care specialists, hepatologists, and transplant surgeons is

TABLE 58-1. Clinical Findings with Liver Diseases in Pregnancy

Diagnosis	Onset	Symptoms	AST (U/L)	Bili (mg%)	Cr (mg%)	Hematological	Comments
Hyperemesis gravidarum	Early	N&V	<300	1–4	NL or elevated (prerenal)	NL	Common, infant vitamin K deficiency, Wernicke encephalopathy, Boerhaave syndrome
ICP	Late	Pruritus ± jaundice	<200	1–5	NL	NL	Common (0.5–2%), bile acids (>10 μmol/L), normal hepatic function
AFLP	Late	N&V (70%), HTN/ preeclampsia, RUQ pain	145–565	2–8	>0.9	Thrombocytopenia, coagulopathy ± DIC, nucleated red cells, hemolysis, echinocytosis	Low glucose, cholesterol <220 mg/dL, fibrinogen <300 mg/dL
HELLP	Late	Preeclampsia, RUQ pain	75–250 (initial)	1–2	<1.0	Thrombocytopenia, mild hemolysis	Common (7–10% of preeclampsia), normal hepatic function
Hepatitis							
Viral	Variable, chronic, episodic	Jaundice, RUQ pain, fatigue	400–5000	20	NL	Coagulopathy if cirrhotic, thrombocytopenia	Common (1–3%), serological tests for hepatitis A, B, C, E
Autoimmune	Variable, chronic, episodic	Jaundice, RUQ pain, fatigue	100–1000	3–10	NL	Coagulopathy if cirrhotic, thrombocytopenia	Uncommon, ANA+, anti-LKM1, anti–smooth muscle
NAFLD	Variable, chronic, episodic	Obese, diabetes, ± RUQ pain	NL to slightly elevated	NL	NL	NL	Common (6–8%), sonographic findings, MR imaging/ CT findings, ± metabolic syndrome, NASH, cirrhosis

AFLP = acute fatty liver of pregnancy; ANA = antinuclear antibodies; AST = aspartate transaminase; Bili = bilirubin; BP = blood pressure; Cr = creatinine; CT = computed tomography; DIC = disseminated intravascular coagulation; HELLP = hemolysis, elevated liver enzymes, low platelets; HTN = hypertension; ICP = intrahepatic cholestasis of pregnancy; LKM1 = liver, kidney microsome 1; MR = magnetic resonance; NAFLD = nonalcoholic fatty liver disease; NASH = nonalcoholic steatohepatitis; NL = normal; N&V = nausea and vomiting; RUQ = right upper quadrant.

assembled. Laboratory studies initially include serum levels of transaminases, bilirubin, amylase, lipase, electrolytes, creatinine, albumin, fibrinogen, lactate, and total cholesterol; complete blood count; and coagulation studies (Bacak, 2016). Etiology-targeted testing is described fully in later sections but broadly includes viral and autoimmune serological assays and testing for acetaminophen, iron, and copper toxicity. Computed tomography (CT) and magnetic resonance (MR) imaging may be needed to investigate hepatic structure. For a pregnancy-related etiology, delivery is undertaken. Because of comorbid coagulopathy, vaginal delivery is preferable if it can be achieved expeditiously and fetal condition allows. Hepatotoxic agents are avoided, coagulopathy is corrected, and monitoring for cerebral edema and increased intracranial pressure is necessary (Brown, 2018). Liver transplantation is problematic during pregnancy, but delivery before transplantation is considered if necessary (Bacak, 2016).

Intrahepatic Cholestasis of Pregnancy

Characterized by pruritus, jaundice, or both, this condition has been called recurrent jaundice of pregnancy, cholestatic hepatosis, and icterus gravidarum. Intrahepatic cholestasis of pregnancy (ICP) is more common in multifetal pregnancy, and genetic influences are significant (Sticova, 2018). Because of this, its incidence varies by population. In North America, the overall incidence approximates 1 case in 500 to 1000 pregnancies, but its rate nears 5.6 percent among pregnant Latina women in Los Angeles (Lee, 2006). Historically, indigenous women from Chile and Bolivia also have a relatively high incidence of ICP. For unknown reasons, this incidence has decreased since the 1970s and is now less than 2 percent (Reyes, 2016). In Sweden, China, and Israel, the incidence varies from 0.25 to 1.5 percent (Luo, 2015).

Pathogenesis

The cause of ICP is unclear, but changes in various sex steroid hormone levels are implicated. In one study, women treated with vaginal progesterone for preterm labor prophylaxis showed a fourfold increase in the ICP rate (Zipori, 2020). Current research focuses on the numerous mutations in the many genes that control hepatocellular transport systems. One example is mutations of the *ABCB4* gene, which encodes multidrug resistance protein 3 (MDR3) associated with *progressive familial intrahepatic cholestasis.* Another is error in the *ABCB11* gene, which encodes a bile-salt export pump (Reichert, 2018). Other potential gene products are the farnesoid X receptor and transporting ATPase encoded by *ATP8B1* (Abu-Hayyeh, 2016; Sticova, 2018). The latter predisposes to drug-induced cholestasis. In this regard, we have encountered impressive cholestatic jaundice in gravidas taking azathioprine following renal transplantation.

Following the inciting cause(s), bile acids are incompletely cleared and accumulate in plasma. Hyperbilirubinemia results from retention of conjugated pigment, but total plasma concentrations rarely exceed 4 to 5 mg/dL. Alkaline phosphatase levels are usually elevated even more than for normal pregnancy. Serum transaminase levels are normal to moderately elevated but seldom exceed 200 U/L (see Table 58-1). Liver biopsy shows mild cholestasis with bile plugs in the hepatocytes and canaliculi of the centrilobular regions. Inflammation or necrosis is absent. These changes disappear after delivery but often recur in subsequent pregnancies or with estrogen-containing contraceptives.

Clinical Presentation

Generalized pruritus that shows predilection for the palms and soles usually develops in late pregnancy or occasionally earlier. Constitutional symptoms are absent, and skin changes are limited to excoriations from scratching.

Serum transaminase and bile acid levels are measured in women with suspected ICP. As a threshold for comparison, total serum bile acid levels typically remain <10 μmol/L throughout normal pregnancy (Egan, 2012). Elevated total serum bile acid or transaminase levels plus pruritus supports an ICP diagnosis. Biochemical tests may be abnormal at presentation or may follow initial pruritus after several weeks. Moreover, a rise in transaminase levels may precede an increase in serum bile acid levels (Wood, 2018b). Approximately 10 percent of women have concurrent jaundice.

With normal liver enzyme levels or with specific skin findings, pruritus may instead reflect other dermatological disorders (Chap. 65, p. 1155). Sonography may be warranted to exclude cholelithiasis and biliary obstruction (p. 1042). Moreover, *acute viral hepatitis* is an unlikely diagnosis because of the usually low serum transaminase levels seen with ICP. Conversely, underlying *chronic hepatitis C* is associated with a significantly greater risk of developing ICP, which may be as much as 20-fold higher (Marschall, 2013).

Management

Pruritus may be troublesome and is thought to result from elevated serum bile salt concentrations. Antihistamines and topical emollients usually provide some relief. Cholestyramine is reported to be effective, but this compound also lowers absorption of fat-soluble vitamins. This may lead to vitamin K deficiency and fetal coagulopathy. Subsequent fetal intracranial hemorrhage and stillbirth have been reported (Matos, 1997).

Currently, the most popular treatment is with ursodeoxycholic acid (Actigall), which relieves pruritus and reduces serum levels of bile salts and liver enzymes (Bacq, 2012; Parízek, 2016). It is available as 300-mg capsules. Oral dosing is 10 to 15 mg/kg maternal body weight daily, which is divided into two or three doses (Tran, 2016). In a large randomized trial, the maternal "itch score" was not significantly lower with ursodeoxycholic acid compared with placebo (Chappell, 2019). From our experiences at Parkland Hospital, however, pruritus typically improves after 2 to 3 weeks of ursodeoxycholic acid therapy (Yule, 2021). Such treatment has also been reported to lower risks for stillbirth and fetal distress and is discussed subsequently.

Other described treatments include therapeutic plasma exchange and rifampin (Liu, 2018; Ovadia, 2018). A randomized trial comparing ursodeoxycholic acid and rifampicin is underway (Australian New Zealand Clinical Trials Registry, 2019).

Perinatal Outcomes

Early reports describe excessive adverse fetal outcomes in women with ICP. However, data from the past two decades are ambiguous concerning increased perinatal mortality rates and whether close fetal surveillance is preventive. Sheiner and coworkers (2006) described no differences in perinatal outcomes in 376 affected pregnancies compared with their overall obstetrical population. However, rates of labor induction and cesarean delivery in affected women were significantly higher. In a study of 5477 women with ICP from a database of 1.2 million births, neonates had a lower 5-minute Apgar score, but the stillbirth rate was not greater (Wikström Shemer, 2013). The latter rate was thought to reflect a higher labor induction rate, which at the time of the study was recommended to avoid stillbirth.

In some studies, complications developed more frequently in women with higher total bile acid levels (Di Mascio, 2019; Herrera, 2018; Ovadia, 2019). These studies described stillbirths

despite normal findings during antenatal testing. One study of 693 Swedish women found a greater perinatal mortality rate in women with bile acids levels >40 μmol/L (Glantz, 2004). In others, an increased stillbirth risk was noted in women whose serum bile acid levels were >100 μmol/L (Brouwers, 2015; Chappell, 2019, Kawakita, 2015). Chappell and associates (2019) also found that ursodeoxycholic acid treatment did not lower perinatal death rates. The use of antenatal fetal testing was not described. In a metaanalysis of 5557 women with ICP, Ovadia and colleagues (2019) concluded that serum bile acid levels >100 μmol/L were associated with stillbirth.

Other adverse perinatal outcomes also have been described. Brouwers and colleagues (2015) found higher rates of spontaneous preterm birth (19 percent) and meconium-stained amniotic fluid (48 percent), despite active management leading to earlier delivery. Novel associations of ICP with preeclampsia, gestational diabetes, and large for gestational age also are reported (Wikström Shemer, 2013).

In summary, management is directed at early delivery to mitigate the relatively uncommon incidence of fetal death. Treatment with ursodeoxycholic acid does not always improve maternal symptoms or protect against stillbirth. It is problematic that antenatal testing does not reliably forecast impending fetal death. We do not routinely employ these for uncomplicated ICP. The precise gestational age for labor induction is uncertain, but many authors recommend 37 weeks' gestation (Wood, 2018b). At Parkland Hospital, we routinely induce labor at 38 weeks if symptoms worsen or if serum bile acid levels exceed 40 μmol/L.

Fetal Effects of Bile Acids

As noted, evidence supports that maternal serum bile acid levels >100 μmol/L contribute to fetal death and meconium passage. Fetal death may be related to the cardiotoxicity of bile acids, which causes cardiac dysfunction and presumably cardiac arrest. In an ex-vivo preparation of cardiac myocytes, cholic acid lowered beating rates in a dose-dependent fashion, while elevating intracellular calcium concentration (Gao, 2014). Prolongation of the fetal cardiac PR interval and successful reversal with ursodeoxycholic acid has been described (Rodríguez, 2018; Strehlow, 2010). Last, Ozel and coworkers (2018) demonstrated impaired global ventricular function in fetuses of pregnancies complicated by ICP.

■ Acute Fatty Liver of Pregnancy

The most frequent cause of acute liver failure during pregnancy is acute fatty liver—also called *acute fatty metamorphosis* or *acute yellow atrophy.* It is characterized by accumulation of microvesicular fat that literally "crowds out" normal hepatocytic function (Fig. 58-1). Grossly, the liver is small, soft, yellow, and greasy. In its worst form, the incidence approximates 1 case per 10,000 births (Nelson, 2013). AFLP recurring in subsequent pregnancy is rare (Usta, 1994).

Etiopathogenesis

Although the underlying cause remains unclear, many cases of AFLP are associated with recessively inherited mitochondrial

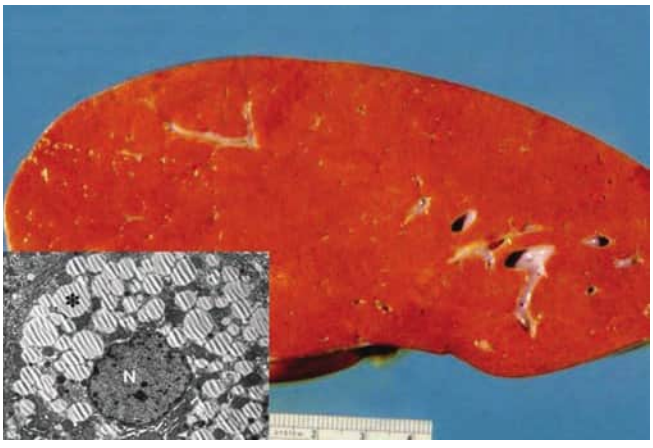

FIGURE 58-1 Acute fatty liver of pregnancy. Cross section of the liver from a woman who died as the result of pulmonary aspiration and respiratory failure. The liver has a greasy yellow appearance. Inset: Electron photomicrograph of a swollen hepatocyte containing numerous microvesicular fat droplets (*). The nucleus (*N*) remains centered within the cell in contrast to the case with macrovesicular fat deposition. (Reproduced with permission from Dr. Don Wheeler.)

abnormalities of fatty acid oxidation. Several mutations for the mitochondrial trifunctional protein enzyme complex that catalyzes the last oxidative steps in the pathway are implicated. The most common are the *G1528C* and *E474Q* missense mutations of the gene on chromosome 2 that codes for long-chain-3-hydroxyacyl-CoA dehydrogenase (LCHAD) (Liu, 2017a). Mutations for medium-chain acyl-CoA dehydrogenase (MCAD) and for carnitine palmitoyltransferase 1 (CPT1) deficiency are others. These are similar to mutations in children with Reye-like syndromes.

Sims and colleagues (1995) observed that some *homozygous* LCHAD-deficient children with Reye-like syndromes had *heterozygous* mothers with AFLP. This was also seen in women with a compound heterozygous fetus. Although some conclude that *only* heterozygous LCHAD-deficient mothers are at risk for ALFP when their fetus is homozygous, this is not always true (Liu, 2017a). An association between fatty acid β-oxidation enzyme defects and severe preeclampsia, especially in women with HELLP syndrome, is also controversial (Chap. 40, p. 693). Most observations derive from retrospective study of mothers with a child who later developed Reye-like syndrome. One case-control study compared 50 mothers of children with a fatty acid oxidation defect and 1250 mothers of matched control infants (Browning, 2006). During their pregnancy, 12 percent of mothers with an affected child developed HELLP syndrome and 4 percent developed AFLP. Comparatively, only 0.9 percent of control women developed liver problems. Despite these findings, the clinical, biochemical, and histopathological findings are sufficiently disparate and support that severe preeclampsia, with or without HELLP syndrome, and AFLP are distinct syndromes (American College of Obstetricians and Gynecologists, 2012; Byrne, 2020).

Clinical Findings

AFLP almost always manifests in the last trimester and rarely midpregnancy (Wong, 2020). From Parkland Hospital,

TABLE 58-2. Comparison of Clinical Findings at the Time of Admission in 67 Women with Acute Fatty Liver of Pregnancy and 67 with HELLP Syndrome

Factor	AFLP	HELLP	*p* Value
Clinical findings (%)			
Hypertension	62	94	<0.001
Abdominal pain	34	46	0.18
Nausea/vomiting	63	19	<0.001
Laboratory values			
AST (u/L)	278 [146, 564]	135 [77, 250]	<0.001
Creatinine (mg/dL)	1.6 [1, 2]	0.6 [1, 1]	<0.001
Fibrinogen (mg/dL)	200 [95, 298]	455 [367, 519]	<0.001
Bilirubin (mg/dL)	2.9 [1, 6]	0.6 [0, 1]	<0.001
Platelets (per μL)	163,000 [121, 205]	115,000 [78, 150]	<0.001
LDH (u/L)	464 [361, 749]	552 [439, 759]	0.19
Glucose (mg/dL)	88 [68, 102]	98 [83, 114]	0.011

AFLP = acute fatty liver of pregnancy; AST = aspartate transaminase; HELLP = hemolysis, elevated liver enzymes, and low platelets; LDH = lactic acid dehydrogenase.
Data from Byrne, 2020; Nelson, 2020.

Nelson and colleagues (2013) described 51 women with AFLP at a mean gestational age of 37 weeks (range 31.7 to 40.9 weeks). Approximately 41 percent were nulliparous and 20 percent were delivered at 34 weeks' gestation or earlier. Women with a multifetal gestation account for 20 percent of cases (Vigil-De Gracia, 2011).

AFLP has a broad spectrum of clinical features and severity, and symptoms usually advance over several days. Persistent nausea and vomiting are major complaints. Degrees of malaise, anorexia, epigastric pain, and progressive jaundice vary. In almost all severe cases, acute liver injury causes profound endothelial cell activation, capillary leakage, and hemoconcentration; acute kidney injury; ascites; and sometimes pulmonary permeability edema (Bernal, 2013). Half of affected women have hypertension, proteinuria, and edema, alone or in combination. Notably, these signs also suggest preeclampsia.

As shown in Tables 58-1 and 58-2, degrees of moderate to severe liver dysfunction are manifest by hypofibrinogenemia, hypocholesterolemia, and prolonged clotting times. Serum bilirubin levels usually are <10 mg/dL, and serum transaminase levels are modestly elevated and usually <1000 U/L. An AFLP diagnosis is arrived at by clinical and laboratory findings. Biopsy is unnecessary. The Swansea criteria proposed by Ch'ng and associates (2002) as a screening tool and predictor of severity shows suitable sensitivity (Table 58-3) (Morton, 2018; Wang, 2017).

Hemolysis can be severe and is thought to stem from effects of hypocholesterolemia on erythrocyte membranes (Cunningham, 1985). Laboratory evidence includes leukocytosis, nucleated red cells, mild to moderate thrombocytopenia, and increased serum levels of lactic acid dehydrogenase (LDH) or decreased haptoglobin levels. The peripheral blood smear demonstrates echinocytosis. However, the hematocrit is often high or within the normal range because of hemoconcentration. With severe hemoconcentration, uteroplacental perfusion is reduced and this, along with maternal acidosis, can cause fetal death. Likewise, maternal and fetal acidemia are associated with a high incidence of fetal jeopardy and a concordantly high cesarean delivery rate.

The degree of clotting dysfunction varies and can be potentially life threatening, especially if cesarean delivery is undertaken. Coagulopathy is caused by diminished hepatic procoagulant synthesis, although some evidence supports

TABLE 58-3. Swansea Criteria for AFLP Diagnosis[a]

Clinical features
Vomiting
Abdominal pain
Encephalopathy
Polydipsia/polyuria

Laboratory features

Bilirubin >0.8 mg/dL	AKI or Cr >1.7 mg/dL
Glucose <72 mg/dL	Ammonia >47 μmol/L
WBC >11,000/μL	Coagulopathy or PT >14 s
AST or ALT >42U/L	Urea >340 μmol/L

Ultrasound features
Ascites or echogenic liver

Histologic features
Microvesicular steatosis

[a]The presence of six or more features without another explanation for them supports a diagnosis of AFLP.
AFLP = acute fatty liver of pregnancy; AKI = acute kidney injury; ALT = alanine transaminase; AST = aspartate transaminase; PT = protime; WBC = white blood cell count.

increased consumption from disseminated intravascular coagulopathy. As shown in Table 58-2, hypofibrinogenemia can be profound. Of 51 women cared for at Parkland Hospital, almost one third had a plasma fibrinogen level nadir below 100 mg/dL (Nelson, 2014). Elevated levels of serum D-dimers or fibrin-split products also indicate an element of consumptive coagulopathy (Lisman, 2017). Although usually modest, occasionally thrombocytopenia is marked. Among the women from Parkland Hospital, 20 percent had platelet counts <100,000/μL, and 10 percent had platelet counts <50,000/μL (Byrne, 2020).

Because liver dysfunction and kidney injury are central to AFLP, Byrne and colleagues (2020) have proposed the acronym FaCCT to differentiate AFLP from HELLP syndrome using levels of commonly available laboratory analytes: fibrinogen (<300 mg/dL) and cholesterol (<220 mg/dL), creatinine (>0.9 mg/dL), and total bilirubin (>1 mg/dL). To emphasize, the clinical features and sequelae of AFLP are attributed to liver dysfunction, whereas in HELLP syndrome the procoagulant production and function of the liver appears relatively preserved.

AFLP typically continues to worsen after diagnosis. Hypoglycemia is common, and hepatic encephalopathy, severe coagulopathy, and some degree of renal failure each develop in approximately half of women. Delivery fortunately arrests liver function deterioration, but recovery may require substantial supportive care.

Various liver imaging techniques can help confirm the diagnosis, but none is particularly reliable (Liu, 2017a). In a prospective evaluation of the Swansea criteria, only a quarter of women with AFLP had classic sonographic findings that included maternal ascites or an echogenic hepatic appearance (Knight, 2008). Although Châtel and coworkers (2016) described greater liver fat detected by MR imaging, this has not been our experience.

We have encountered several women with an underdeveloped form of AFLP. Clinical involvement is relatively minor and laboratory aberrations—usually only hemolysis and a decreased plasma fibrinogen level—herald the syndrome. Thus, the spectrum of liver involvement can include unnoticed milder cases, findings that are instead attributed to preeclampsia, or a severe form displaying overt hepatic failure and associated encephalopathy.

Management

Intensive supportive measures and sound obstetrical care are essential. Delivery of the fetus is necessary in the treatment of AFLP, and significant procrastination increases maternal and fetal risks. We prefer a trial of labor induction with close fetal surveillance. Although some recommend cesarean delivery to hasten hepatic healing, this raises maternal bleeding complication risks when coagulopathy is severe. Nonetheless, cesarean delivery is common due to fetal intolerance of labor, and rates approach 90 percent. In some cases, the fetus has already died when AFLP is diagnosed, and the delivery route is less problematic. To correct coagulopathy, transfusions with whole blood or packed red cells, along with fresh-frozen plasma, cryoprecipitate, and platelets, are usually necessary for surgery or vaginal laceration repair (Chap. 44, p. 772).

Hepatic function usually returns to normal within a week postpartum, but in the interim, intensive medical support may be required. Two associated conditions can be seen during this time. Perhaps a fourth of women have evidence for *transient diabetes insipidus.* This presumably stems from elevated vasopressinase concentrations caused by diminished hepatic production of its inactivating enzyme. Second, *acute pancreatitis* develops in approximately 20 percent.

With supportive care, recovery usually is complete. Maternal deaths are caused by liver failure, sepsis, hemorrhage, aspiration, renal failure, pancreatitis, and gastrointestinal bleeding. Two women died in the series from Parkland Hospital. One had associated encephalopathy and aspirated before intubation during transfer to our care. The other was a woman with profound liver failure and nonresponsive hypotension (Nelson, 2013). Other treatment measures have included plasma exchange and liver transplantation (Ringers, 2016; Wu, 2018).

Maternal and Perinatal Outcomes

Maternal mortality rates with AFLP approached 75 percent in the past, but the contemporaneous outlook is much better. From his review, Sibai (2007) cites an average mortality rate of 7 percent. He also cited a 70-percent preterm delivery rate and a 15-percent perinatal mortality rate, which in the past was nearly 90 percent. During the past four decades at Parkland Hospital, the maternal and perinatal mortality rates have been 4 percent and 12 percent, respectively (Byrne, 2020).

■ Viral Hepatitis

Most viral hepatitis syndromes are asymptomatic, and acute symptomatic infections are becoming less common in the United States. There are at least five distinct types of viruses causing hepatitis: A (HAV), B (HBV), D (HDV) caused by the hepatitis B–associated delta agent, C (HCV), and E (HEV). The clinical presentation of acute infection is similar in all, and although the viruses themselves probably are not hepatotoxic, the immunological response to them causes hepatocellular necrosis (Dienstag, 2018a,b). Several other viral agents can infect the liver, and two examples are cytomegalovirus and herpes simplex virus (Calix, 2020; McCormack, 2019).

Acute infections are most often subclinical and anicteric. When they are clinically apparent, nausea and vomiting, headache, and malaise may precede jaundice by 1 to 2 weeks. By the time jaundice develops, symptoms usually are improving. Low-grade fever is more common with hepatitis A. Serum transaminase levels vary, and their peaks do not correspond with disease severity. Peak levels that range from 400 to 4000 U/L are usually reached by the time jaundice develops (see Table 58-1). Serum bilirubin values typically continue to rise, and peak at 5 to 20 mg/dL, despite falling serum transaminase levels.

Severe features should prompt hospitalization. These include persistent nausea and vomiting, prolonged prothrombin time, low serum albumin level, hypoglycemia, high serum bilirubin level, or central nervous system symptoms. In most cases, clinical and biochemical recovery is complete within 1 to 2 months in all cases of hepatitis A, in most cases of hepatitis B, but in only a small proportion of those caused by hepatitis C.

Patient's feces, secretions, bedpans, and other articles in contact with the intestinal tract should be handled with glove-protected hands. In hospitals, extra precautions, such as double gloving during delivery and surgical procedures, are recommended. Due to significant exposure of health-care personnel to hepatitis B, the Centers for Disease Control and Prevention (CDC) recommend active and passive vaccination, as described later (p. 1037) (Schillie, 2018). For hepatitis C, although direct antiviral regimens have been developed, there is no vaccine. Guidelines instead recommend postexposure serosurveillance only.

Acute hepatitis has a case-fatality rate of 0.1 percent. For those requiring hospitalization, it may reach 1 percent. Most fatalities are due to *fulminant hepatic necrosis*, which in later pregnancy may resemble AFLP. In these cases, hepatic encephalopathy is the usual presentation, and the mortality rate is 80 percent. Approximately half of patients with fulminant disease have hepatitis B infection, and co-infection with the delta agent is common.

Chronic hepatitis is more prevalent than acute infection. The CDC (2019) estimates that almost 3.5 million persons in the United States are living with chronic viral hepatitis. Although most are asymptomatic, approximately 20 percent develop cirrhosis within 10 to 20 years (Dienstag, 2018a). When present, symptoms are nonspecific and usually include fatigue. In some patients, cirrhosis with liver failure or bleeding varices may be the initial finding. Also, asymptomatic chronic viral hepatitis remains the leading cause of liver cancer and the most frequent reason for liver transplantation.

Chronic viral hepatitis is usually diagnosed serologically (Table 58-4). With persistently abnormal biochemical tests, liver biopsy usually discloses active inflammation, continuing necrosis, and fibrosis that may lead to cirrhosis. Chronic hepatitis is classified by cause; grade, defined by histological activity; and stage, which is the degree of progression (Dienstag, 2018a).

Most young women with chronic viral hepatitis either are asymptomatic or have only mild liver disease. For asymptomatic women, pregnancies are usually uncomplicated. With *symptomatic* chronic active hepatitis, pregnancy outcome depends primarily on disease severity, and especially on the presence of portal hypertension (p. 1040). The few women whom we have managed have done well, but their long-term prognosis is poor. Accordingly, they should be counseled regarding possible liver transplantation as well as contraceptive and sterilization options.

TABLE 58-4. Laboratory Features of Chronic Hepatitis

Disorders	Tests	Autoantibodies
Hepatitis B	HBsAg, IgG anti-HBc, HBeAg, HBV DNA	Uncommon
Hepatitis C	Anti-HCV, HCV RNA	Anti-LKM1
Hepatitis D	Anti-HDV, HDV RNA, HBsAg, IgG anti-HBc	Anti-LKM3
Autoimmune	ANA, anti-LKM1, anti-SLA, hyperglobulinemia	ANA, anti-LKM1, anti-SLA
Cryptogenic	All negative	None

HBc = hepatitis core; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; LKM = liver, kidney microsome; SLA = soluble liver antigen.

Hepatitis A

Vaccination has reduced the incidence of hepatitis A by 95 percent. In 2019, the rate was 6 cases per 100,000 individuals in the United States (Centers for Disease Control and Prevention, 2021). HAV is an RNA picornavirus and is transmitted by the fecal–oral route and usually by contaminated food or water ingestion. The incubation period approximates 4 weeks. Individuals shed virus in their feces, and during the relatively brief period of viremia, their blood also is infectious. Signs and symptoms are often nonspecific and usually mild, although jaundice develops in most patients. Symptoms usually last less than 2 months, but 10 to 15 percent of patients may remain symptomatic or relapse for up to 6 months (Dienstag, 2018b). Early serological testing identifies immunoglobulin M (IgM) anti-HAV antibody, which may persist for several months. During convalescence, IgG antibody predominates, and it provides subsequent immunity. Hepatitis A lacks a chronic stage.

Vaccination during childhood with inactivated hepatitis viral vaccine is more than 90-percent effective. The American College of Obstetricians and Gynecologists (2018) and the Advisory Committee on Immunization Practices recommends HAV vaccination for high-risk adults (Freedman, 2020). This includes pregnant women at risk (Nelson, 2020). Candidates are persons with chronic liver disease, human immunodeficiency virus (HIV) infection, homelessness, or illegal drug use. Those working in group facilities with at-risk persons, conducting research with HAV, or traveling to or adopting from endemic areas also are included. High-risk countries are listed in the CDC (2020b) "Yellow Book"—Health Information for International Travel.

For an unvaccinated gravida who is recently exposed by close personal or sexual contact with a person with hepatitis A, passive immunization is provided by a 0.1-mL/kg dose of immune globulin. Concurrently, the first dose of the hepatitis A vaccine series is given in a separate arm (Nelson, 2020).

Pregnancy and Hepatitis A. Management of hepatitis A in pregnancy includes a balanced diet and diminished physical activity. Women with mild illness may be managed as outpatients. In developed countries, the effects of hepatitis A on pregnancy outcomes are not dramatic (American College of Obstetricians and Gynecologists, 2012, 2018). However, in resource-poor countries, both perinatal and maternal mortality rates are substantively higher. HAV is not teratogenic, and transmission to the fetus is negligible. The risk of preterm birth may be higher, and neonatal cholestasis has been reported (Urganci, 2003). Although HAV RNA has been isolated in breast milk, no cases of neonatal hepatitis A have been reported secondary to breastfeeding (Daudi, 2012).

Hepatitis B

This infection stems from a double-stranded DNA virus that is found worldwide. HBV is endemic in Africa, Central and

Southeast Asia, China, Eastern Europe, the Middle East, and certain areas of South America. In all these, infection prevalence reaches 5 to 20 percent. An estimated 1.6 million people in the United States have chronic hepatitis B (Lim, 2020). HBV is carcinogenic, and chronic infection is a known risk for hepatocellular carcinoma. For others, cirrhosis can be a long-term sequela.

HBV is transmitted by exposure to blood or other body fluids from infected individuals. In endemic countries, vertical transmission, that is from mother to fetus or newborn, accounts for at least 35 to 50 percent of chronic HBV infections. In low-prevalence countries such as the United States, which has a prevalence below 2 percent, the more frequent transmission mode is sexual contact or shared contaminated needles.

Acute hepatitis B develops after an incubation period that ranges from 40 to 150 days (Schillie, 2018). At least half of acute infections are asymptomatic. Symptoms completely resolve within 3 to 4 months in most. However, acute hepatitis B accounts for half of fulminant hepatitis cases.

Figure 58-2 details the sequence of the various HBV antigens and antibodies in acute infection. The first serological marker is hepatitis B surface antigen (HBsAg), which often precedes the rise in transaminase levels. As HBsAg disappears, antibodies to the surface antigen develop (anti-HBs), and this marks complete disease resolution. Hepatitis B core antigen (HBcAg) is an intracellular antigen and not detectable in serum. However, antibodies against this core antigen (anti-HBc) are detectable and found within weeks of HBsAg appearance. The hepatitis B e antigen (HBeAg) is present during times of high viral replication and often correlates with detectable HBV DNA. After acute hepatitis, at least 90 percent of adults recover completely, and the remainder are considered to have chronic hepatitis B.

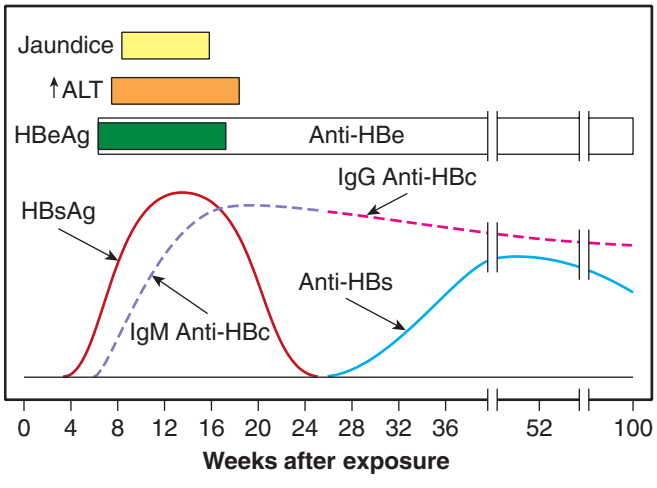

FIGURE 58-2 Sequence of various antigens and antibodies in acute hepatitis B. ALT = alanine transaminase; anti-HBc = antibody to hepatitis B core antigen; anti-HBe = antibody to hepatitis B e antigen; anti-HBs = antibody to hepatitis B surface antigen; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen. (Redrawn from Dienstag JL: Acute viral hepatitis. In Jameson JL, Fauci AS, Kasper DL, et al (eds): Harrison's Principles of Internal Medicine, 20th ed. New York, NY: McGraw Hill; 2018b, p 2347.)

Chronic HBV infection is often asymptomatic but may cause persistent anorexia, weight loss, fatigue, and hepatosplenomegaly. Extrahepatic manifestations include arthritis, generalized vasculitis, glomerulonephritis, pericarditis, myocarditis, transverse myelitis, and peripheral neuropathy. One risk factor for chronic disease is age at acquisition. Pertinent to the obstetrician, this risk exceeds 90 percent in newborns. The risk is 50 percent in young children and is less than 10 percent in immunocompetent adults (Schillie, 2018). An immunocompromised state such as with HIV infection, organ transplantation, or chemotherapy creates vulnerability.

Those with chronic HBV infection have serum test results that show HBsAg persistence. These infected persons may be asymptomatic carriers or may have chronic liver disease with or without cirrhosis or hepatocellular cancer. The presence of HPV DNA in serum tests is a marker of HBV replication. Those with high HBV replication, which is reflected in high HBV DNA levels with or without HBeAg, have the greatest likelihood of developing cirrhosis and hepatocellular carcinoma.

Pregnancy and Hepatitis B. The US Preventive Services Task Force (2019) recommends that all pregnant women be screened for HBV. This practice identifies asymptomatic cases and later allows neonatal intervention. At the first prenatal care visit, a serologic HBsAg level is obtained, and this is repeated in high-risk women again at the time of delivery. All states require cases of HBV infection to be reported, and 26 mandate that pregnant women be screened (Culp, 2016). HBV infection does not cause excessive rates of maternal morbidity or mortality (Stewart, 2013). In one regional study in the United States, 14 percent of women with HBV infection had a worsening of disease, sometimes termed a *flare*, either antepartum or in the 6 months postpartum (Kushner, 2018). A review of data from the National Inpatient Sample reported a modest rise in preterm birth rates in HBV-positive mothers but no effect on fetal-growth restriction or preeclampsia rates (Reddick, 2011). Others have shown similar results (Cui, 2017; Liu, 2017b).

Transplacental HBV infection is uncommon, and Towers and associates (2001) reported that viral DNA is rarely found in amnionic fluid or cord blood. The highest HBV DNA levels are found in women who transmitted the virus to their fetuses (Dunkelberg, 2014; Society for Maternal-Fetal Medicine, 2016).

To curb vertical transmission, newborns of seropositive mothers are given hepatitis B immune globulin (HBIG) plus the first of a three-dose hepatitis B recombinant vaccine series very soon after birth. In the absence of HBV immunoprophylaxis, 10 to 20 percent of women positive for HBsAg transmit viral infection to their infant. This rate rises to almost 90 percent if the mother is HBsAg and HBeAg positive. Administration of immunoprophylaxis and hepatitis B vaccine shortly after birth has lowered transmission dramatically and prevented approximately 90 percent of infections (Smith, 2012). But, women with high HBV viral loads—10^6 to 10^8 copies/mL—or those who are HBeAg positive still have at least a 10-percent vertical transmission rate, regardless of immunoprophylaxis (Rogan, 2019; Yi, 2016). Hill and colleagues (2002) reported

that the 2.4-percent transmission rate was not increased with breastfeeding if neonatal vaccination was completed. Although virus is present in breast milk, the incidence of transmission is not diminished by formula feeding (Shi, 2011). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2018) do not consider maternal HBV infection a contraindication to breastfeeding.

As a second transmission-prevention practice, the CDC and numerous societies now recommend antiviral therapy to decrease viral levels in gravidas whose viral load exceeds 10^6 to 10^8 copies/mL (Schillie, 2018). Newer drugs include tenofovir, an adenosine nucleoside analogue, and telbivudine, a thymidine analogue. Tenofovir is the first-line agent during pregnancy, and no dose adjustments are necessary (Cressey, 2018). These antiviral medications appear safe in pregnancy and are not associated with greater rates of congenital malformations or adverse obstetrical outcomes (Sylvester-Armstrong, 2019). Follow-up of children at age 6 to 7 years found no related problems (Wen, 2020).

Regarding efficacy, one randomized trial in Thailand showed that tenofovir compared with placebo beginning at 28 weeks' gestation did not reduce the low rate of vertical transmission if both active and passive immunoprophylaxis were given at birth to the neonate (Jourdain, 2018). In another similar randomized trial, vertical transmission rates were significantly lowered (Pan, 2016).

For high-risk mothers who are seronegative, HBV vaccine can be given during pregnancy. Candidates are persons with chronic liver disease, diabetes, HIV or HCV infection, injection drug use, occupational exposure risk, household contacts, or long-term travel to endemic areas. Those requiring dialysis, living in a long-term-care or correctional facility, or engaging in sex with multiple or HBV-infected partners also are included (Schillie, 2018).

Vaccine efficacy is similar to that for nonpregnant adults, and overall seroconversion rates approach 95 percent after three doses (Stewart, 2013). The traditional vaccination schedule of 0, 1, and 6 months may be difficult to complete during pregnancy, and compliance rates decline postpartum. Sheffield and coworkers (2006) reported that an accelerated three-dose regimen—given initially and at 1 and 4 months—resulted in seroconversion rates of 56, 77, and 90 percent, respectively. This regimen was usually easily completed during prenatal care.

Hepatitis D

Also called *delta hepatitis*, this is a defective RNA virus that is a hybrid particle with an HBsAg coat and a delta core. The HDV must co-infect with HBV either simultaneously or secondarily, and transmission is similar to HBV.

Hepatitis C

This infection stems from a single-stranded RNA virus. Transmission is via blood and other body fluids, although sexual transmission is inefficient. In the United States, adult prevalence of HCV was reported to be 2 to 5 cases per 1000 births (Prasad, 2020; Rossi, 2020). Up to a third of anti-HCV positive persons have no identifiable risk factors (Dienstag, 2018b).

Until recently, screening for HCV was encouraged only for high-risk individuals. But in 2020, the CDC recommended HCV screening for all adults at least once in a lifetime, and more regularly for those with risk factors (Schillie 2020). These are injection drug use, hemodialysis, or exposure to blood-contaminated items. The CDC also recommended prenatal HCV screening for all women regardless of risk factors. The US Preventive Services Task Force (2020) has published similar recommendations.

Chronic hepatitis C is diagnosed by identification of anti-HCV antibodies detected with a serum immunoassay. Acute HCV infection is usually asymptomatic or yields mild symptoms. Only 10 to 15 percent of patients develop jaundice. The incubation period ranges from 15 to 160 days, with a mean of 7 weeks. Transaminase levels are elevated episodically during the acute infection. HCV RNA testing confirms clinical suspicion of active or acute HCV infection. RNA levels may be found even before rises in transaminase and anti-HCV levels. Anti-HCV antibody is not detected for an average of 15 weeks and in some cases up to 1 year (Dienstag, 2018b).

Nearly 80 to 90 percent of patients with acute HCV will be chronically infected. Although most remain asymptomatic, approximately 20 to 30 percent progress to cirrhosis within 20 to 30 years. Transaminase and HCV RNA values fluctuate over time. Liver biopsy reveals chronic disease and fibrosis in up to 50 percent, however, these findings are often mild. Overall, the long-term prognosis for most patients is good.

Pregnancy and Hepatitis C. As expected, most pregnant women diagnosed with HCV have chronic disease. Aggregate reports have chronicled modestly greater fetal risks of low birthweight, neonatal intensive-care admission, preterm delivery, and mechanical ventilation (Rossi, 2020; Society for Maternal-Fetal Medicine, 2017). In some women, these adverse outcomes may have been influenced by concurrent high-risk behaviors associated with HCV infection.

The primary adverse perinatal outcome is vertical transmission of HCV infection to the fetus-neonate. This is higher in mothers with viremia (Indolfi, 2014). Airoldi and Berghella (2006) cited a rate of 1 to 3 percent in HCV-positive, RNA-negative women compared with 4 to 6 percent in those who were RNA-positive. In a report from Dublin, the vertical transmission rate in 545 women with HCV infection was 7 percent in RNA-positive women compared with none in those who were RNA-negative (McMenamin, 2008). Some have found an even higher risk when the mother is co-infected with HIV (Snidjewind, 2015; Tovo, 2016). Approximately two thirds of prenatal transmission cases occur peripartum. HCV genotype, invasive prenatal procedures, breastfeeding, and delivery mode are not associated with vertical transmission. That said, invasive procedures such as scalp-electrode fetal heart rate monitoring are avoided. HCV infection is not a contraindication to breastfeeding (Post, 2017).

No licensed vaccine is available for HCV prevention. In 2011, the first direct-acting antiviral drugs against HCV became available. Since then, second-generation prototypes with fewer adverse effects have been developed and are given as combinations to nonpregnant individuals. They are currently

not recommended for use in pregnancy except in clinical trials (Society for Maternal-Fetal Medicine, 2017). The combination of ledipasvir plus sofosbuvir shows efficacy and reassuring safety data in early clinical trials.

Hepatitis E

This infection stems from a water-borne RNA virus, which usually is enterically transmitted by contaminated water supplies. Hepatitis E is found worldwide, but the Centers for Disease Control (2020a) lists Mexico, Asia, and Africa as endemic areas. In these regions, seroprevalence rates vary by age and geography, but overall rates of 10 percent have been reported. In Mexico, Durango State has the highest rate—37 percent (Fierro, 2016).

Hepatitis E is the most common cause of acute hepatitis worldwide but rarely causes liver failure in the United States (Fontana, 2016). Epidemic outbreaks in third-world countries result in substantial morbidity and mortality rates. Pregnant women have a greater case-fatality rate than nonpregnant individuals (Li, 2020). In a metaanalysis of nearly 4000 women from Asia and Africa, maternal and fetal case-fatality rates were 21 and 34 percent, respectively (Jin, 2016a). Fulminant hepatitis, although rare, is more common in gravidas and contributes to the increased mortality rates.

A recombinant HEV vaccine has been developed and licensed in China (Zaman, 2020). It is >95 percent effective for 12 months after vaccination. Long-term efficacy is 87 percent, and protective titers are maintained for up to 4.5 years (Zhang, 2015). Preliminary data from inadvertently vaccinated pregnant women show no adverse maternal or fetal events (Wu, 2012).

Autoimmune Hepatitis

This generally progressive chronic hepatitis is more common in women and western countries. Autoimmune hepatitis frequently coexists with other types of autoimmune disease, particularly autoimmune thyroid disease and Sjögren syndrome. It is characterized by multiple autoimmune antibodies such as antinuclear (ANA), anti-smooth muscle, and anti-liver, kidney microsome 1 (LKM1) antibodies (see Table 58-1). Rates of subsequent cirrhosis vary worldwide. The less common type 2 autoimmune hepatitis has an even higher prevalence in females and typically a more aggressive presentation. The incidence peaks in childhood and adolescence.

Symptoms are typical of acute and chronic hepatitis, but a fourth of patients may be asymptomatic. Treatment employs corticosteroids, alone or combined with azathioprine (Dienstag, 2018a). Failure to respond to these two agents is more frequent in those with type 2 disease. Nearly all women with type 2 disease require long-term intensive therapy. In some patients with progressive disease and cirrhosis, hepatocellular carcinoma develops.

In general, autoimmune hepatitis—especially when severe—increases the risk of adverse pregnancy outcomes. Westbrook and coworkers (2012) reported the outcomes of 81 pregnancies in 53 women. A third had a flare, and these were more common in those not taking medication and those with active disease in the year before conception. Women with cirrhosis had more maternal and fetal complications. From a Swedish national database of 171 births, the frequencies of preterm birth, low birthweight, and diabetes were elevated, but not those of preeclampsia or cesarean delivery (Stokkeland, 2016). Another study reported delivery before 38 weeks' gestation in 25 percent of cases and development of a postpartum flare in a third (Danielsson Borssén, 2016). However, adverse outcomes were not greater in women with cirrhosis. Given the important role of procoagulant production, surveillance of coagulation indices is advised to minimize obstetrical hemorrhage complications. Also, the usual vaccines, along with pneumococcal vaccine, should be given (Furer, 2020).

Iron and Copper Overload

Chronic hepatitis and cirrhosis can result from iron and copper overload. Iron overload may stem from a primary cause, such as hereditary hemochromatosis, or from secondary complications of erythrocyte disorders (Chap. 56 p. 1052). Many gene mutations underlying hereditary hemochromatosis involve hepcidin and result in dysregulated iron transport. Some of these mutations are more common in certain populations from northern Europe (Pietrangelo, 2016; Salgia, 2015). Cardiomyopathy, diabetes, joint disease, and skin changes can coexist with liver disease. Diagnosis is made by identifying an *HFE* gene mutation and elevated serum ferritin and transferrin saturation levels. An abnormal *HFE* gene alone is not diagnostic because the mutation has low penetrance. Pregnancy outcomes are driven by the degree of liver dysfunction, although higher iron levels may affect birthweight (Dorak, 2009).

A form of neonatal hemochromatosis that does not affect the mother is now thought to be alloimmune and is called *gestational alloimmune liver disease* (Anastasio, 2016; Ibrahim, 2020). With this, maternal autoantibodies cross to the fetus and mediate dysfunction of iron homeostasis, although the antigenic target of these alloantibodies remains unclear. It is associated with significant neonatal morbidity and mortality and frequently recurs in subsequent pregnancies. In these cases, antepartum treatment with intravenous immunoglobulin (IVIG) may improve outcomes (Feldman, 2013; Roumiantsev, 2015).

Wilson disease is caused by copper overload leading to chronic hepatitis and cirrhosis. Autosomal recessive mutations of the *ATP7B* gene underlie this disorder. This gene codes for the P-type ATPase involved in copper transport to ceruloplasmin and bile (Bandman, 2015). This systemic condition can also manifest with cardiomyopathy, renal disease, neuropsychiatric symptoms, and certain endocrine abnormalities. Serum ceruloplasmin, slit-lamp examination, and 24-hour urinary copper excretion are used to identify this disease. A Kayser-Fleischer ring surrounding the iris is highly specific, but a suspected diagnosis generally requires subsequent genetic analysis confirmation.

With Wilson disease, infertility may be present, but pregnancy outcomes among affected women are influenced by disease severity (Malik, 2013). In one multicenter study of 282 pregnancies, the miscarriage rate was 26 percent, and 6 percent of the women had worsening liver disease (Pfeiffenberger, 2018).

Birth defects were not increased with chelation treatment. Maternal and neonatal outcomes were good. The American College of Gastroenterology states that few data guide which of the various chelating agents is best (Tran, 2016). These include penicillamine, zinc, and trientine, and any theoretical risks are outweighed by the risks of discontinuing therapy. The latter include not only hepatic decompensation, but also injury to the placenta and fetal liver. Accordingly, the American College of Gastroenterology recommends that pregnant women should continue their chelation therapy, although a dose reduction of 25 to 50 percent should be considered to promote wound healing in the event of a surgical delivery.

■ Nonalcoholic Fatty Liver Disease

This is the most common chronic liver disease in the United States. Unsurprisingly, because it is frequently comorbid with obesity, it is demonstrable in 25 percent of American adults (Abdelmalek, 2018). Nonalcoholic fatty liver disease (NAFLD) is a macrovesicular fatty liver condition that resembles alcohol-induced liver injury but is seen without ethanol abuse. Its most severe form—*nonalcoholic steatohepatitis (NASH)*—is an increasingly recognized condition that may occasionally progress to hepatic cirrhosis. Currently, this is the third most common indication for liver transplantation in the United States (Diehl, 2017).

Obesity, type 2 diabetes, and hyperlipidemia—*syndrome X*—frequently coexist with NAFLD (Chap. 51, p. 904). The current hypothesis suggests that these conditions may interact with other unknown etiological agents to cause multiple insults that lead to hepatic injury (Buzzetti, 2016). In one study of individuals with type 2 diabetes and normal liver enzyme levels, half had NAFLD, and those with NAFLD showed greater insulin resistance (Portillo-Sanchex, 2015). In a study of obese adolescents undergoing bariatric surgery and intraoperative core liver biopsy, more than a third had fatty liver without hepatitis. An additional 20 percent had borderline or definite NASH (Xanthakos, 2015).

Liver damage follows a progressive continuum from NAFLD to NASH and then to hepatic fibrosis that may progress to cirrhosis (Goh, 2016). The disease is usually asymptomatic, and it is a frequent explanation for elevated serum transaminase levels found during routine screening. When other liver disease is excluded, NAFLD is the cause of elevated asymptomatic transaminase levels in up to 90 percent of cases. Currently, weight loss along with control of diabetes and dyslipidemia is the only recommended treatment.

Pregnancy

During the past decade, we have encountered an increasing number of obese and diabetic gravidas with fatty liver infiltration. These women appear to have no greater rates of adverse outcomes relative to liver involvement compared with pregnant women of similar weight. However, some emerging data indicate potential concerns. In one patient registry, risks of gestational diabetes, preeclampsia, preterm birth, and low-birthweight newborns were two- to threefold higher than in unaffected women (Hagström, 2016). Yarrington and colleagues (2016) reported a high rate of gestational diabetes among nonobese women who had elevated alanine transaminase levels in the first trimester. Somewhat related, in another study, almost a fourth of women with prior gestational diabetes had NAFLD (Foghsgaard, 2017). Last, some evidence suggests that the fetus of an affected mother is at increased risk for NAFLD in adulthood (Baker, 2018).

■ Cirrhosis

Irreversible chronic liver injury with extensive fibrosis and regenerative nodules is the final common pathway for several disorders. *Laënnec cirrhosis* from chronic alcohol exposure is the most frequent cause in the general population. However, in young women, most cases are caused by *postnecrotic cirrhosis* from chronic hepatitis B or C. As discussed, many cases of *cryptogenic cirrhosis* are now known to be caused by NAFLD (Ge, 2016; Goh, 2016). Clinical manifestations of cirrhosis include jaundice, edema, coagulopathy, and metabolic abnormalities. Of associated conditions, portal hypertension can lead to gastroesophageal varices, and splenomegaly may cause thrombocytopenia. Also, the incidence of venous thromboembolism is increased. The prognosis is poor, and 75 percent have progressive disease that leads to death in 1 to 5 years.

The incidence in pregnancy was reported to be 1 case in 3300 births (Palatnik, 2017). Common complications include transient hepatic failure, variceal hemorrhage, preterm delivery, fetal-growth restriction, spontaneous bacterial peritonitis, and maternal death (Tan, 2008). Outcomes generally are poor, especially if esophageal varices coexist. Another potentially fatal cirrhosis complication arises from associated splenic artery aneurysms. Up to 20 percent of aneurysm ruptures occur during pregnancy, and 70 percent of these rupture in the third trimester (Tan, 2008). The 20-percent maternal mortality rate is likely related to the emergent diagnosis of these aneurysms (Ha, 2009).

■ Portal Hypertension and Esophageal Varices

In pregnant women, the causes of esophageal varices are equally divided between cirrhosis and extrahepatic portal vein obstruction (Andrade, 2018). Of the extrahepatic cases, some develop following portal vein thrombosis associated with one of the *thrombophilia syndromes* (Chap. 55, p. 976). Others follow thrombosis related to umbilical vein catheterization when the woman was a neonate, especially if she was born preterm. Last, the rare *Budd-Chiari syndrome* results from hepatic vein thrombosis that causes extrahepatic portal hypertension. Of 16 pregnancies complicated by this syndrome, one observational study reported favorable outcomes (Khan, 2017).

With either intrahepatic or extrahepatic resistance to flow, portal vein pressure rises from its normal range of 5 to 10 mm Hg, and values may exceed 30 mm Hg. Collateral circulation develops that carries portal blood to the systemic circulation. Blood drains into the gastric, intercostal, and other veins to reach the esophageal system, where varices develop. In rare cases, abdominal wall varices develop (Wood, 2018a). Bleeding is usually from varices near the gastroesophageal junction, and

hemorrhage can be severe. Bleeding during pregnancy from varices occurs in a third to half of affected women and is the major cause of maternal mortality in this group (Tan, 2008).

Maternal prognosis with esophageal varices largely depends on whether these rupture. The mortality rate is 18 percent if varices are associated with cirrhosis compared with 2 percent for varices without cirrhosis. Similarly, perinatal mortality rates are high in women with varices and are worse if cirrhosis caused the varices. Increased rates of neonatal demise, preterm birth, low birthweight, preeclampsia, and postpartum hemorrhage have been reported (Puljic, 2016).

Treatment is the same as for nonpregnant patients. Preventively, all patients with cirrhosis, including pregnant women, should undergo endoscopic screening for variceal dilation (Bacon, 2015). Beta-blocking drugs such as propranolol are given to decrease portal pressure and bleeding risk (Ge, 2016; Tran, 2016).

For acute bleeding and for prophylaxis, endoscopic band ligation is preferred to sclerotherapy because it avoids any potential risk of injecting sclerotherapeutic chemicals. Acute medical management for bleeding varices verified endoscopically includes the intravenous vasoconstrictors octreotide or somatostatin along with endoscopic banding. Vasopressin is less often used. If endoscopy is not available, *balloon tamponade* using a triple-lumen Sengstaken-Blakemore tube, which is placed into the esophagus and stomach to compress bleeding varices, can be lifesaving. An interventional radiology procedure—*transjugular intrahepatic portosystemic stent shunting (TIPSS)*—also can control bleeding from gastric varices that is unresponsive to other measures (Ge, 2016; Tan, 2008). We have had good outcomes with this procedure done electively during pregnancy in women with prior variceal hemorrhage (Chandramouli, 2020).

Acetaminophen Hepatotoxicity

As discussed earlier (p. 1030), acetaminophen is the most frequent cause of acute liver failure in the United States (Lee, 2018). This commonly used medication can be associated with hepatotoxicity at doses above 4 g/d, and even less in certain populations (Clark, 2012). The drug is often used during pregnancy, and overdose–either accidentally or by attempted suicide–may lead to hepatocellular necrosis and acute liver failure (Taney, 2017). Massive necrosis causes a cytokine storm and multiorgan dysfunction. Early overdose symptoms are nausea, vomiting, diaphoresis, malaise, and pallor. After a latent period of 24 to 48 hours, liver failure ensues, and it usually begins to resolve in 5 days. In a prospective Danish study, only 35 percent of patients who were treated for fulminant hepatic failure spontaneously recovered before being listed for liver transplantation (Schmidt, 2007).

The antidote is *N-acetylcysteine (NAC)*, which must be given promptly. The drug is thought to raise glutathione levels, which aid metabolism of the toxic metabolite, *N*-acetyl-*p*-benzoquinoneimine. The *Rumack-Matthew nomogram* uses serum acetaminophen levels to predict subsequent plasma hepatotoxic levels as a function of the time from acute ingestion (Rumack, 1975). The need for treatment is based on these projections, and online nomograms and calculators are available. If the plasma level exceeds 150 μg/mL 4 hours after ingestion, treatment is given. When plasma determinations are not available, empirical treatment is initiated if the ingested amount is >7.5 g. An oral loading dose of 140 mg/kg is given followed by 70 mg/kg every 4 hours for a total treatment duration of 72 hours (Heard, 2008). Both the oral and an equally efficacious intravenous dosing regimen have been reviewed by Hodgman and Garrard (2012). Although the drug reaches therapeutic concentrations in the fetus, any protective effects of NAC during acetaminophen overdose are unknown (Wiest, 2014).

After 14 weeks' gestation, the fetus has some cytochrome P450 activity necessary for metabolism of acetaminophen to the toxic metabolite. Riggs and associates (1989) reported follow-up data from the Rocky Mountain Poison and Drug Center in 60 women suffering overdose. The likelihood of maternal and fetal survival was better if the antidote was given soon after overdose. At least one 33-week fetus appears to have died as a direct result of hepatotoxicity 2 days after maternal ingestion. In another case, Wang and coworkers (1997) confirmed acetaminophen placental transfer and found maternal and cord blood levels measuring 41 μg/mL. Both the mother and the emergently delivered neonate died from hepatorenal failure.

Focal Nodular Hyperplasia

This benign lesion of the liver is characterized in most cases by a well-delineated accumulation of normal but disordered hepatocytes surrounding a central stellate scar. These usually can be differentiated from hepatic adenomas by MR and CT imaging. Except in rare situations of unremitting pain, surgery is rarely indicated, and most women remain asymptomatic during pregnancy. In one review of 20 cases, no woman had related complications during pregnancy (Rifai, 2013). Three women showed 20-percent tumor growth; in half, the tumor diminished in size; and the remaining seven tumors were unchanged across pregnancy. In another surveillance of 44 lesions with MR imaging in 30 gravidas, tumor size was unchanged in 80 percent and decreased in most of the remainder (Ramírez-Fuentes, 2013). Investigators concluded that size changes were unrelated to pregnancy, combination oral contraceptive use, or menopause. This lesion is not a contraindication to estrogen-containing contraceptives (Chap. 38, p. 673).

Hepatocellular Adenoma

This rare benign neoplasm develops most often in young women. Lesions are more common in individuals taking combination oral contraceptives or other steroid medications (Renzulli, 2019). Hepatic adenomas have a 5-percent risk of malignant transformation and a significant risk of rupture-associated hemorrhage, particularly in pregnancy. The rupture risk progresses with lesion size, and surgery is generally recommended for tumors measuring >5 cm (Agrawal, 2015). Thus, differentiation from focal nodular hyperplasia is important and can be achieved by MR or CT imaging.

Tran and associates (2016) recommend sonographic surveillance of hepatic adenomas during pregnancy. In a study of

51 pregnancies in women with an adenoma <5 cm, 25 percent of the lesions expanded approximately 14 mm (Gaspersz, 2020). In one review of 27 cases in pregnancy, 23 became apparent in the third trimester and puerperium (Cobey, 2004). No bleeding complications followed tumors measuring <6.5 cm. However, 60 percent presented with tumor rupture that resulted in seven maternal deaths and six fetal deaths. Of note, 13 of 27 women presented within 2 months postpartum, and in half, hemorrhage heralded rupture. Bleeding adenomas can be managed by angiographic embolization followed by resection (Tsilimigras, 2019).

Liver Transplantation

According to the Organ Procurement and Transplantation Network (2020) more than 177,000 liver transplantations have been performed in the United States. Analysis of the National Inpatient Sample database found 2 liver transplantations per 100,000 deliveries (Ghazali, 2017). In most studies, the 80-percent live-birth rate compares favorably with that of the general population. However, risks of preeclampsia, cesarean delivery, fetal-growth restriction, and preterm birth are significantly elevated (Coscia, 2010; Deshpande, 2012; Kanzaki, 2016). Although cesarean delivery is common, vaginal delivery is not contraindicated (Madej, 2018). Mattila and colleagues (2017) found that half of the women they cared for had maternal complications, including acute graft rejection. Importantly, 4 percent of mothers had died within a year after delivery, but this rate is comparable to that in nonpregnant liver transplantation patients.

GALLBLADDER DISORDERS

Cholelithiasis and Cholecystitis

In the United States, 17 percent of women have gallstones. Most stones contain cholesterol, and its oversecretion into bile is thought to be a major factor in stone formation. The cumulative risk of all patients with gallstones to become symptomatic is 20 percent (Lammert, 2016). For this reason, prophylactic cholecystectomy is not warranted for *asymptomatic* stones.

Symptomatic cholelithiasis typically presents with right upper or epigastric abdominal pain, bloating, belching, nausea, and fatty food intolerance. Pain stems from gallbladder contraction, which forces a stone up into the sac's neck. With subsequent gallbladder relaxation, the stone falls back to relieve the obstruction. Laboratory values are normal, and leukocytosis or elevated liver and pancreatic enzymes should warn for acute cholecystitis or pancreatitis. Standard care for symptomatic cholelithiasis is laparoscopic cholecystectomy (Cafasso, 2014). Less often, oral ursodeoxycholic acid therapy or extracorporeal shock wave lithotripsy are used, but experience with these during pregnancy is lacking.

Acute cholecystitis usually develops when a stone obstructs the cystic duct, which connects the gallbladder to the common bile duct. Bacterial infection plays a role in 50 to 85 percent of cases. In more than half of patients with acute cholecystitis, a history of prior right upper quadrant pain from biliary colic is elicited. With acute disease, pain is accompanied by anorexia, nausea and vomiting, low-grade fever, and mild leukocytosis. As shown in Figure 58-3, sonography will display stones, and both false-positive and false-negative rates range from 2 to 4 percent (Greenberger, 2018). In acute cases, medical therapy consists of intravenous fluids, antibiotics, analgesics, and in some instances, nasogastric suction. Surgical therapy follows, and laparoscopic cholecystectomy is the preferred route for most.

FIGURE 58-3 Sonogram shows multiple, hyperechoic gallstones collecting along the inferior wall of an anechoic gallbladder.

Gallbladder Disease During Pregnancy

After the first trimester, the gallbladder fasting volume and the residual volume after postprandial emptying are doubled. Incomplete emptying may result in retention of cholesterol crystals, a prerequisite for cholesterol gallstones. From studies, the combined incidence of biliary sludge and gallstones is 5 to 8 percent (Ko, 2005, 2014).

Postpartum, sludge frequently regresses, and occasionally gallstones will resorb. Still, gallbladder diseases are the most common cause of nonobstetrical admissions in the first year following delivery (Lydon-Rochelle, 2011). This is particularly true for women managed conservatively during pregnancy. Jorge and coworkers (2015) reported that half of 53 women with symptomatic cholelithiasis in pregnancy underwent later postpartum cholecystectomy. In 80 percent of these women, recurrent symptoms had developed prior to surgery.

Medical versus Surgical Management

Symptomatic cholelithiasis is common in pregnancy. Othman and colleagues (2012) showed that gravidas managed conservatively had greater pain, more recurrent emergency department visits, more hospitalizations, and higher cesarean delivery rate. Dhupar and associates (2010) reported more complications with conservative management of gallbladder disease compared with laparoscopic cholecystectomy in pregnancy. These included multiple admissions, prolonged total parenteral nutrition (TPN), and unplanned labor induction for worsening gallbladder symptoms. Therefore, operative and

endoscopic interventions are increasingly favored over conservative measures.

Acute cholecystitis during pregnancy or the puerperium is also common. Acute disease in pregnancy may be complicated by sepsis, pancreatitis, venous thromboembolism, and bowel obstruction (El-Messidi, 2018). Cholecystitis is initially managed similarly to that for nonpregnant women. In the distant past, most favored medical therapy. However, the recurrence rate during the same pregnancy is high, and 25 to 50 percent of women ultimately require cholecystectomy for persistent symptoms (Dhupar, 2010). Moreover, if cholecystitis recurs later in gestation, preterm labor is more likely and cholecystectomy is technically more difficult.

Cholecystectomy can be performed safely in all trimesters (Kwon, 2018). A metaanalysis found that cholecystectomy does not raise the risk of preterm labor or of maternal or fetal mortality (Athwal, 2016). Of surgical routes, laparoscopic cholecystectomy has evolved as the favored approach (Pearl, 2017; Shigemi, 2019). This is discussed further in Chapter 49 (p. 867). Management at Parkland Hospital favors a surgical approach, especially if biliary pancreatitis, as subsequently discussed, is comorbid (Juo, 2018).

Endoscopic Retrograde Cholangiopancreatography

Approximately 10 percent of patients with symptomatic stone disease have common duct stones (Stinton, 2012). Symptomatic biliary duct gallstones during pregnancy can be retrieved by endoscopic retrograde cholangiopancreatography (ERCP) (Fogel, 2014; Greenberger, 2018). The procedure is performed if common duct obstruction is suspected or proven. ERCP can be modified in many cases so that radiation exposure from fluoroscopy is avoided (Sethi, 2015). If standard fluoroscopy is used, a lead apron shield is placed between the radiation source and the fetus.

In 68 ERCP procedures performed in pregnant women at Parkland Hospital, all but two women had gallstones, and common duct stones were identified in half of 65 women (Tang, 2009). Stones were successfully removed in all but one woman. A biliary stent was placed in 22 percent of cases and removed after delivery. Complications were minimal, but post-ERCP pancreatitis developed in 16 percent. Pregnancy outcomes were not different from those in the general obstetrical population. As a less invasive approach, MR cholangiopancreatography (MRCP) in pregnancy has been reported (Oto, 2009).

Ascending cholangitis can complicate acute biliary obstruction. Nearly 70 percent of affected patients develop *Charcot triad*—jaundice, abdominal pain, and fever. The diagnosis is aided by sonography, and treatment is broad-spectrum antibiotics and biliary drainage by ERCP (Greenberger, 2018).

PANCREATIC DISORDERS

Pancreatitis

Acute pancreatic inflammation is triggered by factors that cause activation of pancreatic trypsinogen followed by autodigestion. It is characterized by cell-membrane disruption and proteolysis, edema, hemorrhage, and necrosis (Conwell, 2018). Up to 10 percent of patients develop necrotizing pancreatitis, which carries a mortality risk of 15 percent. This rate rises if infection develops (Cain, 2015).

The incidence of pancreatitis varies with the population studied. At Parkland Hospital, with a predominant Mexican-American population, acute pancreatitis complicated approximately 1 in 3300 pregnancies (Ramin, 1995). From other reviews, the incidence is 1 case in 3500 to 6000 pregnancies (Eddy, 2008; Hacker, 2015; Hernandez, 2007).

In nonpregnant patients, acute pancreatitis is almost equally associated with gallstones and alcohol abuse. During pregnancy, however, cholelithiasis is almost always the predisposing condition. Other causes are hyperlipidemias, usually hypertriglyceridemia; hyperparathyroidism; congenital ductal anomalies; recent ERCP; some drugs; and rarely autoimmune pancreatitis (Conwell, 2018; Tang, 2018). Nonbiliary pancreatitis occasionally develops postoperatively, or it is associated with trauma, drugs, or some viral infections. Certain metabolic conditions, including acute AFLP and familial hypertriglyceridemia, also predispose to pancreatitis (Nelson, 2013). Cases of acute and chronic pancreatitis have been linked to numerous mutations of the cystic fibrosis transmembrane conductance regulator gene (Chang, 2015).

Diagnosis

Acute pancreatitis incites incapacitating epigastric pain, nausea and vomiting, and abdominal distention. Patients are usually distressed and have low-grade fever, tachycardia, hypotension, and abdominal tenderness. As many as 10 percent have sepsis, which causes endothelial activation and can lead to acute respiratory distress syndrome (Chap. 50, p. 887).

Serum lipase measurements are preferred for diagnosis, however, amylase levels also can be used. In 173 pregnant women with pancreatitis, the mean amylase value approximated 2000 IU/L, and the mean lipase value approached 3000 IU/L (Table 58-5). *Importantly, the degree of enzyme elevation and disease severity do not reliably correlate.* By 48 to 72 hours amylase levels may return to normal despite other evidence for continuing pancreatitis. Serum lipase activity typically remains increased with continued inflammation. Leukocytosis is usually found, and 25 percent of patients have hypocalcemia. Elevated serum bilirubin and aspartate transaminase levels may signify concomitant gallstone disease.

TABLE 58-5. Laboratory Values in 173 Pregnant Women with Acute Pancreatitis

Analyte	Mean	Range	Normal
Serum amylase (IU/L)	1980	111–8917	28–100
Serum lipase (IU/L)	3076	36–41,824	7–59
Total bilirubin (mg/dL)	1.7	0.1–8.71	0.2–1.3
Aspartate transaminase (U/L)	115	11–1113	10–35
Leukocytes (per μL)	10,700	1000–27,200	3900–10,700

From Ramin, 1995; Tang, 2010; Turhan, 2010.

Several prognostic scoring systems are used to classify pancreatitis severity. However, the Ranson criteria and the Apache II scoring system may be less relevant for pregnancy. In contrast, the Atlanta Classification incorporates the degree of organ failure as a measure of severity and may be more applicable in pregnancy (Cain, 2015; Conwell, 2018). With this last tool, *mild disease* lacks organ failure or systemic complications. *Moderately severe disease* shows organ failure lasting <48 h, with or without local or systemic complications. *Severe disease* is defined by persistent single- or multi-organ failure (Banks, 2013).

Management

Medical treatment mirrors that for nonpregnant patients. This includes analgesics, intravenous hydration, and measures to decrease pancreatic secretion by interdiction of oral intake. Nasogastric suction does not improve outcomes of mild to moderate disease. In a series by Ramin and colleagues (1995), all 43 affected pregnant women responded to conservative treatment and were hospitalized for a mean of 8.5 days. If bacterial superinfection, necrotizing pancreatitis, sepsis, or cholangitis is found, broad-spectrum antimicrobials are administered. If common duct stones are found, ERCP is indicated.

Enteral feeding may be helpful once pain improves and associated ileus resolves. For women with more severe pancreatitis and prolonged disease course, total enteral nutrition using nasojejunal feeding is superior to TPN (Cain, 2015; Conwell, 2018). Cholecystectomy is considered after inflammation subsides because women with gallstone pancreatitis carry a greater risk of recurrent inflammation (Cain, 2015). Juo and coworkers (2018) reported that a third of women with biliary pancreatitis not treated with cholecystectomy were readmitted, and 30 percent of these had recurrent pancreatitis. Of the initial group, those who instead did undergo cholecystectomy had only a 5-percent readmission rate.

Pregnancy Outcomes

Increasing severity of pancreatitis is associated with adverse maternal and fetal outcomes (Tang, 2018). In one review of 101 pancreatitis cases, Eddy and coworkers (2008) found a 30-percent preterm delivery rate, and 11 percent were delivered before 35 weeks' gestation. There were also 4 percent stillbirths. There were two pancreatitis-related maternal deaths. Importantly, almost a third of women had recurrent pancreatitis during pregnancy. In another study of 342 pregnancies complicated by pancreatitis, preterm delivery and fetal mortality rates were comparable to the data from Eddy (Hacker, 2015).

■ Pancreatic Transplantation

Few reports describe pregnancy following pancreas transplantation. Of 44 pregnancies in 73 women following pancreas-kidney transplantation, outcomes are encouraging, and vaginal delivery has been described (Mastrobattista, 2008). Although the incidence of hypertension, preeclampsia, preterm delivery, and fetal-growth restriction are high, there was only one perinatal death. Four rejection episodes developed during pregnancy and were treated successfully. Pancreatic islet autotransplantation and at least three subsequent successful pregnancies have been reported (Jung, 2007).

CHAPTER 59

Hematological Disorders

Pregnant women are susceptible to several hematological abnormalities that may affect any woman of childbearing age. These include chronic disorders such as hereditary anemias, immunological thrombocytopenia, and hematological malignancies. Other disorders arise from pregnancy-induced demands. Two are iron deficiency and megaloblastic anemias. Pregnancy may also unmask underlying hematological conditions. Importantly, pregnancy induces physiological changes that often confuse diagnosis and assessment of these disorders (Chap. 4, p. 60).

ANEMIAS

Definition and Incidence

Normal values for concentrations of many cellular elements during pregnancy are listed in the Appendix (p. 1227). The Centers for Disease Control and Prevention (1998) defined anemia in iron-supplemented pregnant women using a cutoff of the 5th percentile, which is 11 g/dL in the first and third trimesters and 10.5 g/dL in the second trimester. Notably, these were not based on a U.S. population. Table 59-1 describes the distribution of hematocrit values of 480 iron-sufficient women at Parkland Hospital (Zofkie, 2020). Using these data, values below 30 percent seem reasonable to define anemia.

The modest fall in hemoglobin and hematocrit values during pregnancy stems from a relatively greater expansion of plasma volume compared with red cell volume (Georgieff, 2020). The disproportion between the rates at which plasma and erythrocytes add to the maternal circulation is greatest during the second trimester. Late in pregnancy, plasma expansion essentially ceases, while hemoglobin mass continues to accrue.

The causes of more common anemias encountered in pregnancy are listed in Table 59-2. Their frequency is dependent on

TABLE 59-1. Hematocrit Values in Pregnancy

	Percent		
	5th percentile	50th percentile	75th percentile
1st trimester	33.0	37.5	41.2
2nd trimester	30.5	35.7	39.2
Predelivery	30.7	36.5	40.5

Hemolytic anemias

multiple factors such as geography, ethnicity, socioeconomic level, nutrition, preexisting iron status, and prenatal iron supplementation (American College of Obstetricians and Gynecologists, 2021). In the United States, the prevalence of anemia in pregnancy is 3 to 38 percent (Centers for Disease Control and Prevention, 1989).

Initial evaluation of a pregnant woman with moderate anemia includes measurements of hemoglobin, hematocrit, red cell indices, and serum iron or ferritin levels; careful examination of a peripheral blood smear; and a sickle-cell preparation if the woman has African lineage (Appendix p. 1227).

Effects on Pregnancy Outcomes

Anemia is associated with several adverse pregnancy outcomes (American College of Obstetricians and Gynecologists, 2021; Rahmati, 2020). Most anemia studies during pregnancy describe large populations and nutritional anemias. In a Canadian study, 12 percent of more than 500,000 women had mild anemia defined by a hemoglobin concentration of 9.0 to 10.9 g/dL (Smith, 2019). These women had a 2.5-fold increased risk for blood transfusions. With moderate anemia, incidences of fetal-growth restriction, low 5-minute Apgar score, and perinatal mortality were increased. Ray and coworkers (2020) reported similar results. Correction of iron-deficiency anemia results in a lower transfusion rate with delivery (Ibinosa, 2020).

A seemingly paradoxical finding is that healthy pregnant women with higher hemoglobin concentrations also are at greater risk for adverse perinatal outcomes (von Tempelhoff, 2008). This may result from lower than average plasma volume expansion of pregnancy concurrent with normal red cell mass accrual. Scanlon and associates (2000) studied the relationship between maternal hemoglobin levels and rates of preterm or growth-restricted newborns. Women whose hemoglobin concentration was three standard deviations *above* the mean at 12 or 18 weeks' gestation had a 1.3- to 1.8-fold greater incidence of fetal-growth restriction. Placental weight correlates negatively with maternal hemoglobin concentration (Larsen, 2016). These findings have led some to the illogical conclusion that withholding iron to cause iron-deficiency anemia will improve pregnancy outcomes (Ziaei, 2007).

Iron-deficiency Anemia

The two most common causes of anemia during pregnancy and the puerperium are iron deficiency and acute blood loss (Vandevijvere, 2013). In a typical singleton gestation, the maternal need for iron averages nearly 1000 mg (Chap. 4, p. 60). Multifetal gestational requirements are considerably higher (Ru, 2016). These amounts exceed the iron stores of most women and result in iron-deficiency anemia unless supplementation is provided.

In the third trimester, additional iron is needed to augment maternal hemoglobin levels and for transport to the fetus. Because the amount of iron diverted to the fetus is similar in a normal and in an iron-deficient mother, the newborn of a severely anemic mother does not suffer from iron-deficiency anemia. Neonatal iron stores are related to maternal iron status and to timing of cord clamping.

Iron deficiency often manifests as an appreciable drop in hemoglobin concentration. Classic morphological evidence is erythrocyte hypochromia and microcytosis (Fig. 59-1). These may be less prominent in the pregnant woman. A mean corpuscular volume <80 fL is classically seen (Appendix, p. 1227) (James, 2021). Serum ferritin levels normally decline during pregnancy, and levels below 10 to 15 mg/L confirm iron-deficiency anemia. In addition, *hepcidin* levels drop in pregnancy. This hormone inhibits iron transport by binding to the iron-export channel ferroportin.

Routinely in pregnancy, daily oral supplementation with 30 to 60 mg of elemental iron and 400 μg of folic acid is recommended (World Health Organization, 2016). For iron-deficiency anemia, resolution and restitution of iron stores can be accomplished with simple iron salts that provide approximately 200 mg daily of *elemental iron*. These include ferrous sulfate, fumarate, or gluconate. If a woman cannot take oral iron preparations, parenteral therapy is given. Although both are administered intravenously, ferrous sucrose is safer than iron dextran (Auerbach, 2020; Pavord, 2020).

Moderate iron-deficiency anemia responds to adequate iron therapy, and the hematological response is an elevated

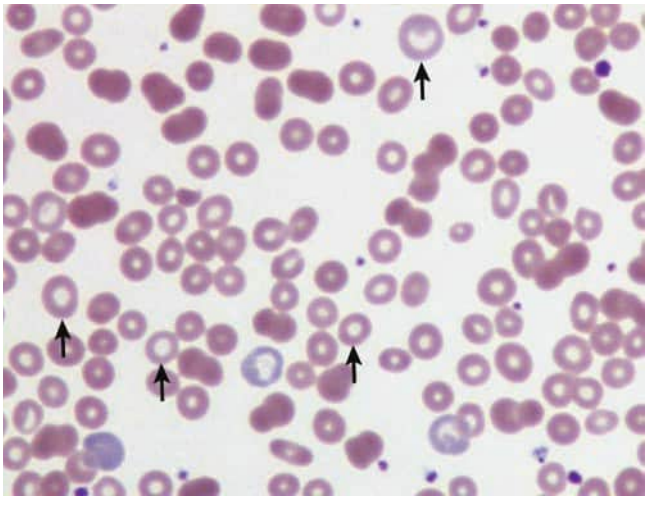

FIGURE 59-1 In this peripheral blood smear, iron-deficiency anemia is reflected by scattered microcytic and hypochromic red cells (*arrows*). (Reproduced with permission from Dr. Siayareh Rambally.)

reticulocyte count. In gravidas, the rise of hemoglobin concentration or hematocrit is typically slower than in nonpregnant women due to the larger plasma volumes of pregnancy. Hemoglobin and ferritin levels show equivalent rises in women treated with either oral or parenteral iron therapy (Breymann, 2017; Daru, 2016; Neogi, 2019).

Anemia from Acute Blood Loss

In early pregnancy, anemia caused by acute blood loss is common with abortion, ectopic pregnancy, and hydatidiform mole. Postpartum, anemia commonly stems from obstetrical hemorrhage. Massive hemorrhage demands immediate treatment and is described in Chapter 44 (p. 771). If a moderately anemic woman—defined by a hemoglobin value of approximately 7 g/dL—is hemodynamically stable, is able to ambulate without adverse symptoms, and is not septic, then blood transfusions are not indicated. Instead, oral iron therapy is provided for at least 3 months.

Anemia of Chronic Disease

Diseases associated with chronic inflammation can cause mild to moderate anemia. Anemia stems from several cytokines produced by inflammatory cells. These restrict erythropoiesis and shorten red cell lifespan. Hepcidin levels are elevated with chronic inflammation, and this inhibits iron-exporting activity from enterocytes (Ross, 2017). Anemia is usually characterized by slightly hypochromic and microcytic erythrocytes, low transferrin saturation, and a high serum ferritin level (Ganz, 2019). Along with iron deficiency, it is the most common form of anemia worldwide.

During pregnancy, women with chronic disorders may develop anemia for the first time. In those with preexisting anemia, it may worsen as plasma volume expands. Frequent causes include chronic renal insufficiency, inflammatory bowel disease, and connective tissue disorders. Others are granulomatous infections and malignant neoplasms.

Chronic renal insufficiency is the most common disorder that we have encountered during pregnancy as a cause of this anemia type. Some cases are accompanied by erythropoietin deficiency. During pregnancy in women with mild chronic renal disease, the degree of red cell mass expansion is inversely related to renal impairment (Chap. 56, p. 1004). At the same time, plasma volume expansion usually is normal, and thus anemia severity intensifies (Cunningham, 1990).

For treatment, adequate iron stores must be ensured. *Recombinant erythropoietin*, with or without intravenous iron, has been used to treat anemia stemming from chronic disease (Ganz, 2019). In pregnancies complicated by chronic renal insufficiency, recombinant erythropoietin is usually considered when the hematocrit approximates 20 percent (Cyganek, 2011). One side effect is hypertension, which is already prevalent in women with renal disease. Red cell aplasia and antierythropoietin antibodies also have been reported (McCoy, 2008).

Megaloblastic Anemia

Folic Acid Deficiency

Megaloblastic anemias are characterized by blood and bone marrow abnormalities from impaired DNA synthesis. This leads to large cells with arrested nuclear maturation, whereas the cytoplasm matures more normally. Worldwide, the pregnancy prevalence of this anemia varies considerably but is low in the United States.

Megaloblastic anemia developing during pregnancy almost always results from folic acid deficiency. In the past, this condition was called *pernicious anemia of pregnancy*. It usually is found in women who do not consume fresh green leafy vegetables, legumes, or animal protein. As folate deficiency and anemia worsen, anorexia often intensifies and further aggravates the dietary deficiency. Other causes are malabsorption syndromes that include tropical sprue, extensive jejunal resection, gastrectomy, and Crohn disease; hemolytic anemias; malignancy; and some antifolate drugs (Hoffbrand, 2018).

Nonpregnant women need 50 to 100 μg of folic acid daily. During pregnancy, requirements rise, and 400 μg/d is recommended. The earliest biochemical evidence is low plasma folic acid concentrations (Appendix, p. 1227). Early morphological changes usually include hypersegmented neutrophils and macrocytic erythrocytes. As the anemia worsens, peripheral nucleated erythrocytes appear, and bone marrow examination discloses megaloblastic erythropoiesis. Anemia may then become severe, and thrombocytopenia, leukopenia, or both may develop. The fetus and placenta effectively extract folate from maternal circulation, and the fetus is not anemic despite severe maternal anemia.

For treatment, 5 to 15 mg of oral folic acid is provided with iron, and a nutritious diet is encouraged (Hoffbrand, 2018). At 4 to 7 days of treatment, the reticulocyte count is higher, and leukopenia and thrombocytopenia are corrected.

For anemia prevention, a diet should contain sufficient folic acid. Moreover, the role of folate deficiency in the genesis of neural-tube defects is well studied (Chap. 15, p. 276).

Vitamin B_{12} Deficiency

With pregnancy, vitamin B_{12} levels are lower than nonpregnant values because levels of binding proteins, namely, the transcobalamins decline. However, in most gravidas, megaloblastic anemia is rarely from vitamin B_{12} deficiency. Of predisposing conditions, vitamin B_{12} deficiency in pregnancy is more likely encountered following gastric resection. Women who have undergone total gastrectomy require 1000 μg of intramuscular vitamin B_{12} (cyanocobalamin) monthly. Those with a partial gastrectomy usually do not need supplementation, but adequate serum vitamin B_{12} levels should be ensured (Appendix, p. 1230). Other causes of megaloblastic anemia from vitamin B_{12} deficiency include Crohn disease, ileal resection, some drugs, and bacterial overgrowth in the small bowel (Hoffbrand, 2018). *Addisonian pernicious anemia* results from absent intrinsic factor that is requisite for dietary vitamin B_{12} absorption. This autoimmune disorder usually has its onset after age 40 years, which accounts for its uncommon occurrence in pregnancy (Govindappagari, 2019).

Hemolytic Anemia

Several conditions accelerate erythrocyte destruction. Hemolysis may be a primary disorder, and sickle-cell disease and

hereditary spherocytosis are examples. In others, hemolysis complicates an underlying condition such as systemic lupus erythematosus or preeclampsia. Microangiopathic hemolytic anemia from malignancy has been reported in pregnancy (Happe, 2016).

Autoimmune Hemolysis

The cause of aberrant antibody production is unknown. Typically, both the direct and indirect antiglobulin (Coombs) tests are positive. Anemias caused by these factors may be due to warm-active autoantibodies (80 to 90 percent), cold-active antibodies, or a combination. These syndromes may also be classified as primary (idiopathic) or secondary due to underlying diseases or other factors. Examples of the secondary group include lymphomas and leukemias, connective tissue diseases, infections, chronic inflammatory diseases, and drug-induced antibodies (Knuesel, 2018). *Cold-agglutinin disease* may be induced by infectious etiologies such as *Mycoplasma pneumoniae* or Epstein-Barr viral mononucleosis. Hemolysis and positive antiglobulin test results may be the consequence of either immunoglobulin M (IgM) or immunoglobulin G (IgG) antierythrocyte antibodies. When thrombocytopenia is comorbid, it is termed *Evans syndrome* (Wright, 2013).

In pregnancy, hemolysis can be markedly accelerated. Low-dose rituximab (Truxima)—100mg weekly for 4 weeks—coupled with prednisone, is first-line treatment (Luzzatto, 2018). Coincidental thrombocytopenia usually corrects with therapy. Transfusion of red cells is complicated by antierythrocyte antibodies, but warming the donor cells to body temperature may decrease their destruction by cold agglutinins. In rare cases, the fetus may be involved (Maroto, 2020).

Drug-induced Hemolysis

These hemolytic anemias must be differentiated from other causes of autoimmune hemolysis. In most cases, hemolysis is mild and resolves with drug withdrawal. Subsequently, avoiding the drug is preventive. One mechanism is hemolysis induced through drug-mediated immunological injury to red cells. If bound to a red cell protein, the drug may act as a high-affinity hapten to which antidrug antibodies attach. An example is IgM antipenicillin or anticephalosporin antibodies. Garratty and colleagues (1999) described seven women with severe Coombs-positive hemolysis stimulated by cefotetan given as prophylaxis for obstetrical procedures. Alpha-methyldopa can cause similar hemolysis (Grigoriadis, 2013). Some other drugs, which include probenecid, quinidine, and rifampin, act as low-affinity haptens and adhere to cell membrane proteins. A frequent mechanism for drug-induced hemolysis relates to a congenital erythrocyte enzymatic defect, such as glucose-6-phosphate dehydrogenase deficiency (p. 1052).

Pregnancy-associated Hemolysis

Unexplained severe hemolytic anemia can develop during early pregnancy and resolves within months postpartum. Clear immune mechanisms or red cell defects are not contributory. Because the fetus–neonate also may demonstrate transient hemolysis, an immunological cause is suspected. Maternal corticosteroid treatment is often—but not always—effective (Kumar, 2001). We have cared for a woman who during each pregnancy developed severe hemolysis with anemia that responded to prednisone. Her fetuses were not affected, and hemolysis abated spontaneously after delivery.

In some cases, hemolysis is induced by conditions unique to pregnancy. Mild microangiopathic hemolysis with thrombocytopenia is relatively common with severe preeclampsia and eclampsia (Cunningham, 2015; Kenny, 2015). This HELLP (hemolysis, elevated liver enzyme levels, low platelet count) syndrome is discussed in Chapter 40 (p. 699). Another example is acute fatty liver of pregnancy, which causes moderate to severe hemolytic anemia (Chap. 58, p. 1033).

Paroxysmal Nocturnal Hemoglobinuria

Although commonly regarded as a hemolytic anemia, this hemopoietic stem cell disorder is characterized by formation of defective platelets, granulocytes, and erythrocytes. Paroxysmal nocturnal hemoglobinuria is acquired and arises from one abnormal clone of cells, much like a neoplasm. In contrast, one mutated X-linked gene responsible for this condition is termed *PIG-A* because it codes for phosphatidylinositol glycan protein A. Resultant abnormal anchor proteins of the erythrocyte and granulocyte membrane make these cells unusually susceptible to lysis by complement. A serious complication is thrombosis, which is heightened in the hypercoagulable state of pregnancy.

Chronic hemolysis has an insidious onset, and its severity ranges from mild to lethal. Hemoglobinuria develops at irregular intervals and is not necessarily nocturnal. Hemolysis may be initiated by transfusions, infections, or surgery. Almost 40 percent of patients suffer venous thromboembolism (VTE) and may also experience renal failure, hypertension, and Budd-Chiari syndrome. To counter the VTE risk, prophylactic anticoagulation is recommended (Luzzato, 2018). The preferred treatment is eculizumab (Soliris), an antibody that inhibits complement activation (Kelly, 2015; Stefanovic, 2019). The drug is apparently safe in pregnancy (Sarno, 2019). Median survival after diagnosis of the syndrome is 10 years, and bone marrow transplantation is the definitive treatment.

During pregnancy, paroxysmal nocturnal hemoglobinuria can be serious and unpredictable. Complications may affect up to three fourths of affected women, and the maternal mortality rate in the past was 10 to 20 percent (de Guibert, 2011). Complications more often develop postpartum, and half of affected women develop VTE. Kelly and coworkers (2015) described 75 pregnancies in 61 affected women treated with eculizumab. They described no maternal deaths, but the stillbirth rate was 4 percent. Miyasaka and associates (2016) found similar results.

Bacterial Toxins

The most fulminant acquired hemolytic anemia encountered during pregnancy is caused by the exotoxin of *Clostridium perfringens* or by group A β-hemolytic streptococcus (Chap. 50, p. 890). In additional, endotoxin of gram-negative bacteria, that is, lipopolysaccharide, may be accompanied by hemolysis and mild to moderate anemia (Cox, 1991). For example, anemia often accompanies acute pyelonephritis. With normal erythropoietin production, red cell mass is restored following infection resolution (Cavenee, 1994; Dotters-Katz, 2013).

Inherited Erythrocyte Membrane Defects

The normal erythrocyte is a flexible biconcave disc that allows numerous cycles of reversible deformations. Several genes encode erythrocyte structural membrane proteins and intraerythrocytic enzymes. Various mutations can destabilize the lipid bilayer. The loss of lipids from the cell membrane causes a surface area deficiency and poorly deformable erythrocytes that undergo hemolysis (Iolascon, 2019). Anemia severity depends on the degree of rigidity. Erythrocyte morphology similarly is dependent on these factors, and these disorders are usually named after the most dominant red cell shape. Three examples are *hereditary spherocytosis*, *pyropoikilocytosis*, and *ovalocytosis*.

Hemolytic anemias that compose this group of inherited membrane defects are among the most common complicating pregnancy. Mutations are usually an autosomally dominant, variably penetrant α- and β-spectrin deficiency. Others are dominant or recessive gene mutations that result from deficiency of ankyrin, band 3, 4.1, and 4.2, or combinations of these (Luzzato, 2018; Rencic, 2017). The degrees of anemia and jaundice vary, and diagnosis is confirmed by identification of abnormal erythrocytes on peripheral smear and their increased osmotic fragility.

Spherocytic anemias may be associated with a crisis typified by severe anemia from accelerated hemolysis, and it develops in patients with an enlarged spleen. Infection can also accelerate hemolysis or suppress erythropoiesis to worsen anemia. An example of the latter is parvovirus B19 infection (Chap. 67, p. 1191). In severe cases, splenectomy reduces hemolysis, anemia, and jaundice.

In general, women with inherited erythrocyte membrane defects do well during pregnancy. Oral folic acid supplementation of 4 mg daily is given to sustain erythropoiesis. Women with hereditary spherocytosis cared for at Parkland Hospital had hematocrits ranging from 23 to 41 percent, with a mean of 31 (Maberry, 1992). Reticulocyte counts varied from 1 to 23 percent. Among 50 pregnancies in 23 women, eight women miscarried. Four of 42 infants were born preterm, but none was growth restricted. Infection in four women intensified hemolysis, and three of these required transfusions. Similar results were reported by Pajor and colleagues (1993).

Because these disorders are inherited, the newborn may be affected. Preconceptional counseling emphasizes folic acid supplementation and provides an opportunity to discuss prenatal diagnosis. Celkan and Alhaj (2008) report prenatal diagnosis via cordocentesis at 18 weeks' gestation and testing for osmotic fragility. Although fetal anemia is uncommon, newborns with hereditary spherocytosis may manifest hyperbilirubinemia and anemia shortly after birth.

Erythrocyte Enzyme Deficiencies

An intraerythrocytic deficiency of enzymes that permit anaerobic glucose metabolism may cause *hereditary nonspherocytic anemia*. Most of these mutations are autosomal recessive traits. Most episodes of severe anemia with these enzyme deficiencies are induced by drugs or infections.

Pyruvate kinase deficiency has a frequency of 1:10,000 persons and is associated with variable degrees of anemia (Luzzatto, 2018). Recurrent transfusions in homozygous carriers can lead to iron overload, and associated myocardial dysfunction should be monitored (Dolan, 2002). The fetus that is homozygous for this mutation may develop *hydrops fetalis* from anemia and heart failure (Chap. 18, p. 360).

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is complex because there are more than 200 enzyme variants. The most common stem from a base substitution that leads to an amino acid replacement and a broad range of phenotypic severity (Luzzatto, 2018; Puig, 2013). In the homozygous or A variant, both X chromosomes are affected, and erythrocytes are markedly deficient in G6PD activity. Approximately 2 percent of African-American women are affected, and the heterozygous variant is found in 10 to 15 percent. In both cases, random X-chromosome inactivation—*lyonization*—results in variable enzyme activity.

During pregnancy, hemolysis severity in G6PD-deficient heterozygotes or homozygotes is related to enzyme activity. Anemia is usually episodic, but some variants induce chronic nonspherocytic hemolysis. Because young erythrocytes contain more enzyme activity, anemia stabilizes and corrects soon after the inciting cause is resolved.

These women are offered preconceptional counseling to discuss risks of adverse pregnancy outcomes, precipitating factors of hemolysis such as pyelonephritis and pneumonia, and the limited list of safe medications available for treatment during pregnancy. For example, macrodantin is used for pyelonephritis suppression in pregnancy but can induce hemolysis in those with G6PD deficiency. Because fetal and neonatal manifestations are possible, these patients should undergo genetic counseling, with possible partner testing, to assess fetal transmission risk.

■ Aplastic and Hypoplastic Anemia

Aplastic anemia is a grave complication characterized by pancytopenia and markedly hypocellular bone marrow (Young, 2018). The functional defect is a marked decline in the number of committed marrow stem cells. Etiologies are multiple, and the inciting cause can be identified in approximately a third of cases. These include immunological disorders, drugs, other chemicals, infection, irradiation, leukemia, and inherited conditions such as *Fanconi anemia* and *Diamond-Blackfan syndrome* (Green, 2009).

Immunosuppressive therapy is given, and in some nonresponders, eltrombopag (Promacta) is successful (Townsley, 2017; Young, 2018). Definitive treatment is bone marrow transplantation, and approximately three fourths of patients have a good response and long-term survival (Tichelli, 2020). Umbilical cord blood–derived stem cells also can serve as a potential transplant source (Moise, 2005; Pinto, 2008).

Pregnancy

Hypoplastic or aplastic anemia complicating pregnancy is rare. A study of 60 pregnancies complicated by aplastic anemia found that half were diagnosed during pregnancy (Bo, 2016). In another series of 19 pregnancies, the complication rate was 79 percent, but no women died (McGowan, 2019). *Pregnancy-*

induced hypoplastic anemia is rare, and the anemia and other cytopenias improve or remit following delivery or pregnancy termination (Choudhry, 2002; Edahiro, 2020). In some cases, anemia recurs in a subsequent pregnancy.

Diamond-Blackfan anemia is rare form of pure red cell hypoplasia. Approximately 40 percent of cases are familial and have autosomal dominant inheritance (Orfali, 2004). The response to glucocorticoid therapy is usually good. Continuous treatment is necessary, and most become at least partially transfusion dependent (Gansner, 2017). In a study of 64 pregnancies complicated by this syndrome, two thirds had problems related to placental vascular etiologies that included miscarriage, preeclampsia, preterm birth, fetal-growth restriction, or stillbirth (Faivre, 2006).

Gaucher disease is an autosomally recessive lysosomal enzyme deficiency characterized by deficient activity of *acid β-glucosidase*. Affected women have anemia and thrombocytopenia that usually worsens in pregnancy. Elstein and colleagues (1997) described six pregnant women whose disease improved with alglucerase enzyme replacement. Imiglucerase (Cerezyme) is human recombinant enzyme replacement therapy.

The major risks with hypoplastic anemia are hemorrhage and infection. Rates of preterm labor, preeclampsia, fetal-growth restriction, and stillbirth are increased (Bo, 2016). Management depends on gestational age, and supportive care includes continuous infection surveillance and prompt antimicrobial therapy. Granulocyte transfusions are given only during infections. Red cells are transfused to improve symptomatic anemia and routinely to maintain the hematocrit above 20 volumes percent. Platelet transfusions may be needed to control hemorrhage. Mortality rates reported since 1960 have averaged nearly 50 percent but have declined more recently (Giri, 2017).

Bone Marrow Transplantation

Several reports describe successful pregnancies in women who have undergone bone marrow transplantation. In their review, Sanders and coworkers (1996) reported 72 pregnancies in 41 such women. In the 52 pregnancies resulting in a liveborn neonate, almost half were complicated by preterm delivery or hypertension. Data from the National Cancer Institute regarding 102 pregnancies following transplantation showed 71 liveborns, of which 16 were preterm. Of all women, 20 percent had decreased hemopoiesis, and transfusions were required (Giri, 2017). Carter and associates (2006) reported decreased fertility but generally good pregnancy outcomes. Our experiences with a few of these women indicate that they have normal pregnancy-augmented erythropoiesis and total blood volume expansion. In pregnancy, cell-free DNA study results must account for donor DNA contributions (Duque-Afonso, 2018).

POLYCYTHEMIAS

Excessive erythrocytosis during pregnancy is usually secondary and related to chronic hypoxia. Etiologies include maternal congenital cyanotic cardiac disease or a chronic pulmonary disorder. In addition, we have encountered otherwise healthy pregnant women who were heavy smokers, had chronic bronchitis, and had hematocrits ranging from 55 to 60 volumes percent! If polycythemia is severe, the probability of a successful pregnancy outcome is low.

Polycythemia vera is a primary clonal myeloproliferative hemopoietic stem cell disorder characterized by excessive proliferation of erythroid, myeloid, and megakaryocytic precursors. Virtually all patients have a *JAK2* gene mutation (Spivak, 2018). Symptoms are related to greater blood viscosity, and thrombotic complications are common. Treatment of nonpregnant patients is with hydroxyurea or ruxolitinib.

Fetal loss rates are high in women with polycythemia vera, and pregnancy outcome may be improved with aspirin therapy (Bertozzi, 2018; Dewarrat, 2020). Women with a history of VTE are given prophylaxis with low-molecular-weight heparin (Stein, 2019). If cytoreduction is required during pregnancy, interferon alpha may be considered (Kreher, 2014).

HEMOGLOBINOPATHIES

■ Sickle-cell Hemoglobinopathies

Pathophysiology

Hemoglobin A is the most common hemoglobin tetramer and consists of two α- and two β-globin chains. Genes *HBA1* and *HBA2* each code for α-globin, whereas only *HBB* codes for β-globin. Sickle hemoglobin (hemoglobin S) originates from a single β-globin substitution of glutamic acid by valine, which stems from an A-for-T substitution. Hemoglobin C originates from a single β-globin substitution of glutamic acid by lysine, which stems from a T-for-C substitution. Hemoglobinopathies that can result in clinical features of the *sickle-cell syndrome* include sickle-cell anemia (Hb SS); sickle-cell hemoglobin C disease (Hb SC); sickle-cell β-thalassemia disease (either Hb S/B^0 or Hb S/B^+); and sickle-cell E disease (Hb SE). All are associated with higher pregnancy morbidity.

When deoxygenated, red cells containing hemoglobin S undergo sickling, and the hemoglobin aggregates (Fig. 59-2). Constant sickling and unsickling damages the cell membrane, and its shape may become irreversibly sickled. Events that slow

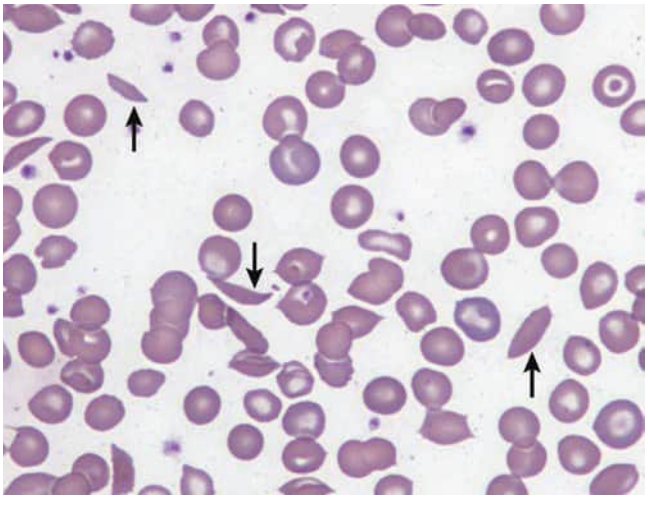

FIGURE 59-2 Peripheral smear of sickle cells (*arrows*) characteristic of sickle-cell anemia. (Reproduced with permission from Dr. Imran Hitto.)

erythrocyte transit through the microcirculation include adhesion to endothelial cells, erythrocyte dehydration, and vasomotor dysregulation.

Clinically, sickling episodes are marked by ischemia and infarction in various organs. The *sickle-cell crisis* produces pain, which is often severe. Aplastic, megaloblastic, sequestration, and hemolytic crises can develop.

Chronic and acute changes from sickling include bony abnormalities such as osteonecrosis of femoral and humeral heads, renal medullary damage, autosplenectomy in homozygous SS patients but splenomegaly in other variants, hepatomegaly, ventricular hypertrophy, pulmonary infarctions, cerebrovascular accidents, leg ulcers, and a propensity for infection and sepsis (Benz, 2018; Ware, 2017). Pulmonary hypertension can develop and is found in 20 percent of adults with SS hemoglobin (Gladwin, 2008). Other sequelae are cerebrovascular aneurysms and sickle-cell vasculopathy (Buonanno, 2016).

Treatment

Good supportive care is essential to prevent mortality. Specific therapies are evolving, and many are still experimental. One treatment is hemoglobin F induction with drugs that stimulate γ-globin synthesis. Remember that hemoglobin F is prominent in fetal life (Chap. 7, p. 129). This induction raises hemoglobin F levels, which inhibits hemoglobin S polymerization. One agent is hydroxyurea, which augments hemoglobin F production and reduces the number of sickling episodes (Tshilolo, 2019). Hydroxyurea is teratogenic in animals. A preliminary 17-year surveillance of antenatally exposed children was reassuring (Ballas, 2009; Briggs, 2017).

Other agents include biologic antibody drugs and l-glutamine (Ataga, 2017, Niihara, 2018; Stefanovic, 2019). Various forms of hemopoietic cell transplantation are emerging as "cures" for sickle-cell syndromes and severe thalassemias (Oringanje, 2013; Kanter, 2021). Last, gene therapy has been accomplished by viral vector–mediated addition of a β-globin gene into stem cells (Harrison, 2019; Ribeil, 2017).

■ Sickle-cell Syndromes During Pregnancy

Pregnancy is a serious burden to women with any major sickle hemoglobinopathy, particularly those with hemoglobin SS (Table 59-3) (Kuo, 2016; Villers, 2008). Maternal mortality rates have improved, but perinatal morbidity and mortality rates remain formidable (Bae, 2021; Oteng-Ntim, 2015). Thus, women with sickle-cell hemoglobinopathies require close prenatal observation. Specifically, any factor that impairs erythropoiesis or increases red cell destruction aggravates the anemia. Prenatal folic acid supplementation with 4 mg daily is needed to support rapid red blood cell turnover.

TABLE 59-3. Pregnancy Morbidity with Hemoglobin SS and SC Disease

Outcome	Odds Ratios	
	Hb SS	Hb SC
Preeclampsia	2–3.1	2.0
Stillbirth	6.5	3.2
Preterm delivery	2–2.7	1.5
Growth restriction	2.8–3.9	1.5
Maternal mortality	11–23	11

From Boafor, 2016; Oteng-Ntim, 2015.

One danger is that a symptomatic woman may categorically be considered to be suffering from a sickle-cell crisis. As a result, serious obstetrical or medical problems that cause pain, anemia, or both may be overlooked. Examples are ectopic pregnancy, placental abruption, pyelonephritis, or appendicitis. Thus, a diagnosis of sickle-cell crisis should be applied only after all other possible causes have been excluded. Pain with sickle-cell syndromes is caused by intense sequestration of sickled erythrocytes and infarction in various organs, particularly bone marrow. These episodes develop acutely, especially late in pregnancy, during labor and delivery, and early in the puerperium.

No randomized trials have evaluated treatment during pregnancy. At minimum, intravenous fluids are given, and opioids are administered promptly for severe pain. Oxygen via nasal cannula may decrease the sickling intensity at the capillary level. We have found that red cell transfusions after the onset of severe pain do not dramatically relieve pain intensity and may not shorten its duration. Conversely, as discussed later, prophylactic transfusions almost always prevent further vaso-occlusive episodes and pain crises. Antenatal epidural analgesia may offer benefits for pain (Verstraete, 2012; Winder, 2011). Long term, affected women can become habituated to narcotics. This problem is highlighted by the elevated rates of neonatal abstinence syndrome, which is a constellation of withdrawal symptoms (Shirel, 2016).

Rates of covert bacteriuria and acute pyelonephritis are elevated substantively, and screening and treatment for bacteriuria are essential. If pyelonephritis develops, sickle cells are extremely susceptible to bacterial endotoxin, which can incite dramatic, rapid red cell destruction and suppress erythropoiesis. Pneumonia, especially due to *Streptococcus pneumoniae,* is common. The Centers for Disease Control and Prevention (2020) recommends specific vaccination for those with sickle-cell disease and all asplenic patients. These are polyvalent pneumococcal, *Haemophilus influenzae* type B, and meningococcal vaccines (Table 10-7, p. 190).

Pulmonary complications are frequent. Of these, *acute chest syndrome* is characterized by pleuritic chest pain, fever, cough, lung infiltrates, hypoxia, and usually bone and joint pain (Vichinsky, 2000). It develops in approximately 6 percent of pregnant women (Inparaj, 2020). In addition to symptoms, radiographs show a new pulmonary infiltrate. The four precipitants are infection, marrow emboli, thromboembolism, and atelectasis (Medoff, 2005). Bacterial or viral infection causes approximately half of cases. When acute chest syndrome develops, the mean duration of hospitalization is 10.5 days. Mechanical ventilation is required in approximately 15 percent, and the mortality rate nears 3 percent (Gladwin, 2008).

For nonpregnant adults, some recommend rapid simple transfusion or exchange transfusions to remove the "trigger" for acute chest syndromes (Ramphul, 2020). In a study of nonpregnant patients, Turner and colleagues (2009) reported that

exchange transfusion offered no increased benefits compared with simple transfusions, and the former were associated with fourfold greater blood usage. These results notwithstanding, the American Society of Hematology *suggests* exchange transfusions instead of simple transfusions. However, they state this recommendation is conditional due to scarce high-quality evidence (Chou, 2020).

Women with sickle-cell disease usually have some degree of *cardiac dysfunction* from ventricular hypertrophy. Chronic hypertension worsens the dysfunction. During pregnancy, the basal hemodynamic state characterized by high cardiac output and increased blood volume is augmented (Veille, 1994). Although most women tolerate pregnancy without problems, complications such as severe preeclampsia or serious infections may result in ventricular failure (Cunningham, 1986). Heart failure caused by pulmonary hypertension also must be considered.

In 4352 pregnancies in women with sickle-cell syndromes, Chakravarty and associates (2008) reported significantly higher pregnancy complication rates. Compared with controls, women with sickling disorders had a 63-percent rate of nondelivery-related admissions. They had a 1.8-fold greater incidence of hypertensive disorders—19 percent; a 2.9-fold higher rate of fetal-growth restriction—6 percent; and a 1.7-fold increased cesarean delivery rate—45 percent.

With hemoglobin SC disease, morbidity and mortality rates are appreciably lower than those from sickle-cell anemia. Indeed, fewer than half of these women have symptoms before pregnancy. In our experiences, affected gravidas suffer attacks of severe bone pain and episodes of pulmonary infarction and embolization more commonly than when not pregnant (Cunningham, 1983). Some adverse pregnancy outcomes are shown in Table 59-3.

Prophylactic Red Cell Transfusions

Chronic transfusion therapy has the most dramatic benefit on maternal morbidity rates (Benites, 2016; Malinowski, 2015; Vianello, 2018). It is problematic for universal application because of complications from multiple transfusions. In an earlier 10-year prospective study at Parkland Hospital, we offered prophylactic transfusions to all pregnant women with sickle-cell syndromes. Transfusions were given throughout pregnancy to maintain the hematocrit above 25 volumes percent and the portion of hemoglobin S below 60 percent (Cunningham, 1979). Maternal morbidity was minimal, and erythropoiesis suppression was not problematic. Their outcomes were compared with historical controls who were not routinely transfused. Overall, maternal morbidity and hospitalization rates were reduced in the transfused group, but perinatal morbidity and mortality rates remained increased because of preterm birth and fetal-growth restriction (Cunningham, 1983).

In a multicenter trial, Koshy and coworkers (1988) randomly assigned 72 pregnant women with sickle-cell syndromes to prophylactic or indicated transfusions. They reported a significant decline in the incidence of painful sickle-cell crises with prophylactic transfusions but no differences in perinatal outcomes. Because of risks inherent with blood administration, they concluded that prophylactic transfusions were not indicated.

A metaanalysis of 12 studies found prophylactic transfusions improved rates of most adverse maternal and neonatal outcomes, including maternal mortality, pulmonary complications, and perinatal mortality (Malinowski, 2015). Undoubtedly, morbidity from multiple transfusions is significant. Up to 10 percent of women had a delayed hemolytic transfusion reaction, and infections are a major concern. Garratty (1997) reviewed 12 studies and found alloimmunization developed in a fourth of women. Last, from liver biopsies in these women, we found no evidence of transfusion-related iron overload, hemochromatosis, or chronic hepatitis (Yeomans, 1990).

Because of what some consider marginal benefits, routine prophylactic transfusions during pregnancy remain controversial (American College of Obstetricians and Gynecologists, 2019b). Current consensus is that their use should be individualized. With such a practice, approximately 60 percent of women will need transfusions during pregnancy (Sharif, 2018).

Fetal Assessment

Perinatal outcomes include increased risks for preterm birth, fetal-growth restriction, and perinatal mortality. Thus, beginning in the mid-second trimester, serial fetal-growth assessment with sonography is reasonable. At 32 to 34 weeks' gestation, weekly antepartum surveillance with biophysical profiles or nonstress test is considered (American College of Obstetricians and Gynecologists, 2019b). Anyaegbunam and colleagues (1991) reported nonreactive stress tests during sickling crises, which resumed reactivity with crisis resolution. They concluded that transient effects of sickle-cell crisis do not compromise umbilical blood flow. Of interest, placentas from sickle-cell pregnancies show abnormalities in 69 percent (Malinowski, 2020).

Labor and Delivery

Management is essentially identical to that for women with cardiac disease (Chap. 52, p. 920). Women are kept comfortable but not oversedated. Conduction analgesia is ideal. Compatible blood should be available. If a difficult vaginal or cesarean delivery is contemplated and the hematocrit is <20 volumes percent, packed erythrocyte transfusions are administered. Vaginal delivery is suitable, and cesarean delivery is reserved for obstetrical indications (Rogers, 2010).

In the puerperium, many clinicians do not recommend combination hormonal contraception because of potential adverse vascular and thrombotic effects. However, one systematic review found that complication rates were not higher with their use in women with sickle-cell syndromes (Haddad, 2012). The Centers for Disease Control and Prevention categorizes combination hormonal contraception, intrauterine devices, implants, and progestin-only methods as having no risk or as having advantages that generally outweigh theoretical or proven risks (Curtis, 2016).

■ Sickle-cell Trait

The frequency of sickle-cell trait among African Americans averages 8 percent. Carriers have occasional hematuria, renal papillary necrosis, and hyposthenuria, which is urine of low

specific gravity (Tsaras, 2009). Sickle trait may be associated with progression of end-stage renal disease in blacks (Olaniran, 2020). Although controversial, sickle-cell trait does not appear to be associated with increased rates of abortion, perinatal mortality, low birthweight, or pregnancy-induced hypertension (Pritchard, 1973; Wellenstein, 2019; Wilson, 2020). In one study of more than 5000 women, the incidence of gestational hypertension was significantly elevated, but that of preeclampsia was not (O'Hara, 2020). Of note, they did not control for chronic hypertension. One unquestioned relationship is the twofold greater incidence of asymptomatic bacteriuria and urinary infection. Sickle-cell trait is not considered a deterrent to pregnancy or to hormonal contraception.

Hemoglobin C and C-β-Thalassemia

Approximately 2 percent of African-Americans are heterozygous for hemoglobin C, but even if homozygous, hemoglobin C is innocuous (Nagel, 2003). Only when coinherited with sickle-cell trait to yield hemoglobin SC is the trait problematic. Pregnancy in women with homozygous hemoglobin CC disease or C-β-thalassemia carries relatively benign associations. Other than mild to moderate anemia, pregnancy outcomes were not abnormal (Maberry, 1990). Supplementation with folic acid and iron is indicated.

Hemoglobin E

Although uncommon in the United States, hemoglobin E is the second most frequent hemoglobin variant worldwide. The heterozygous E trait is common in Southeast Asia. In one study, homozygous hemoglobin E, hemoglobin E plus β-thalassemia, or hemoglobin E trait was identified in 36 percent of Cambodians and 25 percent of Laotians (Hurst, 1983). Homozygosity for hemoglobin E is associated with little or no anemia, hypochromia, marked microcytosis, or erythrocyte targeting. With hemoglobin E trait, another study found no increased pregnancy risks other than asymptomatic bacteriuria between 1073 women and 2146 controls (Kemthong, 2016).

Conversely, doubly heterozygous E-β-thalassemia is a common cause of severe childhood anemia in Southeast Asia (Taher, 2018). In a cohort study of 54 women with singleton pregnancies, a threefold greater risk of preterm birth and fetal-growth restriction was found in affected women (Luewan, 2009). It is unclear if hemoglobin SE disease is ominous during pregnancy.

Hemoglobinopathy in the Newborn

Neonates with homozygous SS, SC, and CC disease can be identified accurately at birth by cord blood electrophoresis. The United States Health Resources and Services Administration (2020) recommends that all newborns be tested for sickle-cell disease. In most states, such screening is mandated by law and performed routinely (Chap. 32, p. 594).

Prenatal Diagnosis

Inheritance is a concern for the fetus whenever a mother and father carry a gene for abnormal hemoglobins that include S, C, and D or for β-thalassemia trait. Sickle-cell anemia results from the inheritance of the gene for S hemoglobin from each parent. In the United States, 1 of 12 African-Americans has sickle-cell trait, which results from inheritance of one gene for hemoglobin S and one for normal hemoglobin A. The computed incidence of sickle-cell anemia among African-Americans is 1 in 576 (1/12 × 1/12 × 1/4 = 1/576). The disease is less common in adults because of earlier mortality. Approximately 1 in 40 African-Americans has the gene for hemoglobin C. Thus, the theoretical incidence for coinheritance of the gene for hemoglobin S and an allelic gene for hemoglobin C in an African-American child is 1 in 2000 (1/12 × 1/40 × 1/4). β-Thalassemia minor affects about 1 in 40, thus S-β-thalassemia also is found in approximately 1 in 2000 (1/12 × 1/40 × 1/4).

Many tests are available to detect sickle-cell disease antenatally. Most are DNA based and use chorionic villus samples or amnionic fluid specimens (American College of Obstetricians and Gynecologists, 2019b). Several mutations that encode hemoglobin S and other abnormal hemoglobins can be detected by targeted mutation analysis and polymerase chain reaction–based techniques (Chap. 18, p. 325).

THALASSEMIA SYNDROMES

Hundreds of mutations affect the genes that control hemoglobin production (Benz, 2018). Some of these impair synthesis of one or more of the normal globin peptides and may result in a clinical syndrome characterized by varying degrees of ineffective erythropoiesis, hemolysis, and anemia. Thalassemias are classified according to the globin that is deficient. The two major forms involve impaired production or instability of α-globin to cause α-thalassemia or of β-globin to cause β-thalassemia. Clinically, these can be divided into transfusion dependent and nontransfusion dependent (Taher, 2018).

Alpha Thalassemias

The two α-globin genes, *HBA1* and *HBA2*, are both found on chromosome 16. Because diploid chromosome sets contains four α-globin genes total, the inheritance of α-thalassemia is more complicated than for β-thalassemia (Piel, 2014). Some of the possible genotypes and phenotypes are shown in Table 59-4. The γ-globin genes are similarly duplicated. Correspondingly, the normal genotype for diploid cells can be expressed as αα/αα and γγ/γγ. Of the two main groups of α-thalassemia determinants, α^0-thalassemia is mutation of both genes from one chromosome (––/αα), whereas α^+-thalassemia is mutation of a single gene from one allele (–α/αα heterozygote) or from both alleles (–α/–α homozygote).

The relative frequency of the different α-thalassemia types varies remarkably among racial groups, and all are encountered in Asians. In those of African descent, although α-thalassemia minor has a frequency approximating 2 percent, hemoglobin H disease is rare and hemoglobin Bart disease is unreported. This is because Asians usually have α^0-thalassemia minor inherited with both gene deletions typically from the

TABLE 59-4. Genotypes and Phenotypes of α-Thalassemia Syndromes

Genotype	Genotype	Phenotype
Normal	αα/αα	Normal
α^+-Thalassemia heterozygote	−α/αα αα/−α	Normal; silent carrier
α^+-Thalassemia homozygote[a]	−α/−α	α-Thalassemia minor—mild hypochromic, microcytic anemia
α^0-Thalassemia heterozygote[b]	−−/αα	
Compound heterozygous α^0/α^+	−−/−α	Hb H (β_4) disease with moderate to severe hemolytic anemia
Homozygous α-thalassemia	−−/−−	Hb Bart (γ_4) disease, hydrops fetalis

[a]More common in African Americans.
[b]More common in Asian Americans.

same chromosome (−−/αα), whereas blacks usually have α^+-thalassemia minor in which one gene is deleted from each chromosome (−α/−α).

Pregnancy

Important obstetrical aspects of some α-thalassemia syndromes depend on the number of gene deletions in a given woman. Clinical severity closely correlates with the degree of impaired α-globin synthesis. The silent carrier state with one gene deletion may be associated with mild microcytic anemia (Andolina, 2020). Deletion of two genes resulting in α-thalassemia minor is characterized by minimal to moderate hypochromic microcytic anemia. This is due to either α^0- or α^+-thalassemia trait, and thus genotypes may be −−/αα or −α/−α, respectively. Differentiation is possible only by DNA analysis (Piel, 2014). Because no other clinical abnormalities accompany either form of α-thalassemia minor, it often goes unrecognized and is usually of no maternal consequence (Hanprasertpong, 2013). The fetus with these forms of thalassemia minor will have hemoglobin Bart (γ_4) at birth, but as its levels drop, it is not replaced by hemoglobin H (β_4). Red cells are hypochromic and microcytic, and the hemoglobin concentration is normal to slightly depressed.

Hemoglobin H disease (β_4) results from the compound heterozygous state for α^0- plus α^+-thalassemia with deletion of three of four alpha genes (−−/−α). With only one functional α-globin gene per diploid genome, the newborn will have abnormal red cells containing a mixture of hemoglobin Bart (γ_4), hemoglobin H (β_4), and hemoglobin A. Of these three, fetal hemoglobin Bart (γ_4) and hemoglobin H (β_4) transport oxygen poorly. The neonate appears normal but soon develops hemolytic anemia as most of the hemoglobin Bart (γ_4) is replaced by hemoglobin H (β_4). In adults, their low hemoglobin A production leads to anemia that is moderate to severe and usually worsens during pregnancy.

Inheritance of all four abnormal α-globin genes causes homozygous α-thalassemia, which is also called Hb Bart disease and alpha thalassemia major. Hemoglobin Bart (γ_4) is predominantly produced. This hemoglobin Bart has an appreciably increased affinity for oxygen, transfers oxygen to end organs poorly, and is incompatible with extended survival. These fetuses are stillborn or are hydropic and usually die soon after birth.

Sonographic measurement of the fetal cardiothoracic ratio at 12 to 13 weeks' gestation can be used to identify affected fetuses (Lam, 1999; Zhen, 2015). Sonographic assessment of myocardial performance—the *Tei index*—in the first half of pregnancy has been evaluated. Changes predate hydrops in affected fetuses (Luewan, 2013). These noninvasive tests may aid pregnancy counseling.

■ Beta Thalassemias

The β-thalassemias stem from impaired β-globin production or α-globin instability. Genes that encode control of β-globin synthesis are in the δγβ-gene cluster on chromosome 11 (Chap. 7, p. 129). More than 150 point mutations in the β-globin gene have been described (Weatherall, 2010). In β-thalassemia, β-globin production is decreased, and excess α-globin precipitate to damage cell membranes. Other forms of β-thalassemias derive from α-globin instability (Kihm, 2002).

The heterozygous trait is β-thalassemia minor, and those most commonly encountered have elevated hemoglobin A_2 levels. This hemoglobin is composed of two α- and two δ-globins, and concentrations are usually more than 3.5 percent. Hemoglobin F—composed of two α- and two γ-globins—also usually has increased concentrations that exceed 2 percent. Some patients with heterozygous β-thalassemia minor do not have anemia, and others have mild to moderate anemia characterized by hypochromia and microcytosis.

Homozygous β-thalassemia—also called β-thalassemia major or Cooley anemia—is a serious and frequently fatal disorder. Hemolysis is intense and leads to severe anemia. Many patients become transfusion dependent, and the subsequent iron load, along with abnormally greater gastrointestinal iron absorption, leads to hemochromatosis, which is fatal in many cases. A heterozygous form of β-thalassemia that clinically manifests as *thalassemia intermedia* produces moderate anemia.

Several treatment schemes treat β-thalassemia. Stem cell transplantation has been used to treat β-thalassemia major (Jagannath, 2014). Preliminary observations indicate that a combination of thalidomide and hydroxyurea—both contraindicated in pregnancy—may be beneficial to boost hemoglobin

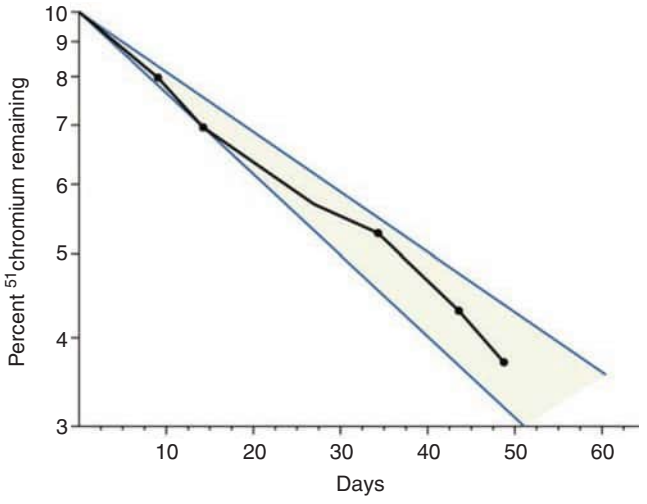

FIGURE 59-3 Erythrocyte-survival times with β-thalassemia minor (*black solid line*) are comparable to those of normal red cells (*shaded area*).

production (Shah, 2020). Inserting a gene with a lentiviral vector into β-globin has been used to transfect harvested bone marrow stem cells (Harrison, 2019). Last, luspatercept—a recombinant fusion protein—may enhance erythroid maturation to reduce transfusion requirements (Cappellini, 2020).

Pregnancy

Iron and folate supplements are given to all affected women. Those with β-thalassemia minor may have mild anemia during pregnancy (Charoenboon, 2016). This is caused by ineffective erythropoiesis and not hemolysis. Shown in Figure 59-3 are comparable red cell survival times in women with β-thalassemia minor compared with those from normally pregnant women. In some women, anemia will worsen because slightly subnormal erythropoiesis accompanies normal plasma volume expansion. Fetal-growth restriction has been associated with thalassemia minor (Vafaei, 2020).

Thalassemia major and some of the other severe forms were uncommonly encountered during pregnancy before the advent of transfusion and iron-chelation therapy. In reviews, 63 pregnancies with such management were reported and suffered no serious complications (Aessopos, 1999; Daskalakis, 1998). Pregnancy is considered reasonably safe if maternal cardiac function is normal. Transfusions are provided throughout pregnancy to maintain the hemoglobin concentration at 10 g/dL. This is coupled with surveillance of fetal growth (American College of Obstetricians and Gynecologists, 2019b).

■ Prenatal Diagnosis

Diagnosis of α-thalassemia major in the fetus can be accomplished by DNA analysis using molecular techniques (Piel, 2014). Fetal diagnosis of hemoglobin Bart (γ_4) has been described using capillary electrophoresis or high-performance liquid chromatography techniques (Sirichotiyakul, 2009). Molecular genetic testing for *HBA1* and *HBA2* identifies 90 percent of deletions and 10 percent of point mutations in affected individuals (Galanello, 2011b).

Because β-thalassemia major is caused by numerous mutations, prenatal diagnosis is difficult. For a given individual, targeted mutation analysis requires prior identification of the familial mutation. The analysis is done using chorionic villus sampling and other techniques discussed in Chapter 17 (p. 344). Noninvasive testing using cell-free fetal DNA for β-thalassemia diagnosis has been described (Xiong, 2015; Zhang, 2019). Preimplantation genetic testing allows for identification of affected offspring prior to blastocyst transfer.

PLATELET DISORDERS

■ Thrombocytopenia

Platelet abnormalities are common and may precede pregnancy, develop coincidentally during pregnancy, or be induced by pregnancy. Thrombocytopenia—defined by a platelet count <150,000/μL—is identified in nearly 10 percent of gravidas (American College of Obstetricians and Gynecologists, 2019c). Of these cases, 75 percent are *gestational thrombocytopenia.* The remainder is due to other causes, and HELLP syndrome is a common one (Eslick, 2020). Thrombocytopenia may be inherited or idiopathic, acute or chronic, and primary or associated with other disorders (Table 59-5). Of recent importance is thrombocytopenia in pregnancy complicated by COVID-19 infection (Tang, 2020; Zitiello, 2020).

■ Gestational Thrombocytopenia

In two studies of pregnant women, platelet counts falling below the 2.5th percentile were 116,000 and 123,000/μL (American

TABLE 59-5. Some Causes of Thrombocytopenia in Pregnancy

Gestational thrombocytopenia: 75 percent

Aplastic anemia
Genetic causes
COVID-19

APS = antiphospholipid syndrome; DIC = disseminated intravascular coagulopathy; HELLP = hemolysis, elevated liver enzyme levels, low platelet count; MTP = massive transfusion protocol.
From American College of Obstetricians and Gynecologists, 2019c; Cooper, 2019; Tang, 2020.

College of Obstetricians and Gynecologists, 2019c). Approximately 1 percent have values <100,000/μL. Bleeding is only encountered with drastically lower values. It seems reasonable that a platelet count of <80,000/μL should trigger an evaluation for etiologies other than incidental or gestational thrombocytopenia, which is unlikely to have a platelet count <50,000/μL.

Platelet counts decline normally across pregnancy (Fig. 4-7, p. 62). With gestational thrombocytopenia, the platelet concentration nadir is usually evident in the third trimester and is thought to stem from hemodilution. The normal increased splenic mass of pregnancy also may contribute (Maymon, 2006; Reese, 2018).

Inherited Thrombocytopenias

Bernard-Soulier syndrome and *Glanzmann thrombasthenia* lack a platelet membrane glycoprotein, which leads to severe dysfunction (Grainger, 2018). Moreover, women exposed to fetal platelets carrying this glycoprotein can develop antibodies against this fetal GPIb/IX antigen to cause alloimmune fetal thrombocytopenia (Poon, 2018). In 30 pregnancies in 18 women from one review, the primary postpartum hemorrhage rate was 33 percent, and half of women with bleeding required blood transfusion (Peitsidis, 2010). The reviewers also described six cases of neonatal alloimmune thrombocytopenia and two perinatal deaths. Close monitoring throughout pregnancy and 6 weeks postpartum is critical to avoid potential life-threatening hemorrhage (Prabu, 2006).

May-Hegglin anomaly is an autosomal dominant disorder characterized by thrombocytopenia, giant platelets, and leukocyte inclusions. In one review of 26 studies containing 75 pregnancies, there were four cases of postpartum hemorrhage, 34 cases of neonatal thrombocytopenia, and two fetal deaths (Hussein, 2013).

Immune Thrombocytopenic Purpura

The primary form—also termed *idiopathic thrombocytopenic purpura (ITP)*—is usually caused by a cluster of IgG antibodies directed against one or more platelet glycoproteins. Antibody-coated platelets are destroyed prematurely in the reticuloendothelial system, especially the spleen (Baucom, 2019; Cooper, 2019). With ITP, platelet counts range from 10,000 to 100,000/μL (George, 2014). Although not proven, ITP is probably mediated by autoantibodies directed at platelet-associated immunoglobulins—PAIgG, PAIgM, and PAIgA.

ITP classification is shown in Table 59-6 (Rodeghiero, 2009). In adults, it usually is a chronic disease that rarely resolves spontaneously. Secondary forms of immune-mediated chronic thrombocytopenia appear in association with systemic lupus erythematosus, lymphomas, leukemias, and several systemic diseases. Approximately 2 percent of thrombocytopenic patients have positive serological tests for lupus, and in some cases, levels of anticardiolipin antibodies are high. Last, approximately 10 percent of patients with human immunodeficiency virus (HIV) have associated thrombocytopenia.

TABLE 59-6. Classification of Immune Thrombocytopenia (ITP)

Etiology	
Primary ITP: acquired immune-mediated disorder characterized by isolated thrombocytopenia in the absence of obvious initiating or underlying cause	
Secondary ITP: thrombocytopenia due to underlying cause/drug exposure	
Duration	
Newly diagnosed: persistent 3–12 months	
Chronic: 12 months or more	

Pregnancy

Pregnancy does not raise the risk of relapse or worsen active disease. The estimated incidence of ITP complicating pregnancy approximates 1 case in 10,000 births (Care, 2018). However, it is not unusual for women who have been in clinical remission for several years to have recurrent thrombocytopenia during pregnancy. Although this may be from closer surveillance, hyperestrogenemia is also implicated.

Therapy is considered if the woman has symptomatic bleeding and the platelet count is below 30,000/μL. The corrected target level is 50,000/μL (American College of Obstetricians and Gynecologists, 2019c). Primary treatment is corticosteroids, intravenous immune globulin (IVIG), or both (Cooper, 2019). Initially, prednisone, 1 mg/kg daily, helps suppress the phagocytic activity of the splenic monocyte–macrophage system. IVIG given in a total dose of 2 g/kg over 2 to 5 days also is effective.

Some immunomodulating agents are avoided in pregnancy due to teratogenicity risks. Azathioprine (Imuran) and rituximab (Truxima), however, which are used in nonpregnant persons with ITP, have been used for other conditions in pregnancy. Last, the thrombopoietin-receptor agonists romiplostim (Nplate) and eltrombopag (Promacta) have stimulated responses in some patients (Patras, 2020; Rosa María, 2020).

Prospective observations from the UK Obstetric Surveillance System (UKOSS) of 107 pregnancies were described by Care and associates (2018). Postpartum hemorrhage occurred in half, and in 20 percent it was severe. No neonate needed therapy for thrombocytopenia, and no cases of intracranial hemorrhage were noted. Comont and coworkers (2018) reported on 50 pregnancies in 39 women with ITP. Half had a platelet count <50,000/μL, but 84 percent were treated. They concluded that a third of these women were overtreated.

In pregnant women with no response to corticosteroid or IVIG therapy, open or laparoscopic splenectomy may be effective. In late pregnancy, cesarean delivery may be necessary for surgical exposure. Improvement usually follows splenectomy in 1 to 3 days and peaks at approximately 8 days.

Fetal and Neonatal Effects

Pregnancy complications that are increased with ITP include stillbirth, fetal loss, and preterm birth (Wyszynski, 2016). Platelet-associated IgG antibodies cross the placenta, and fetal death from hemorrhage occurs occasionally. Studies that included more than 800 neonates born to women with ITP cite an intracranial hemorrhage rate <1 percent (American College of Obstetricians and Gynecologists, 2019c). Hemorrhage was not associated with route of delivery.

Investigators concur that fetal and maternal platelet counts lack strong correlation (George, 2009; Hachisuga, 2014). Because of this, maternal IgG free platelet antibody levels and platelet-associated antibody levels have been evaluated to predict fetal platelet counts. Again, however, little concurrence with these was found. Measuring fetal platelet counts by direct sampling is not recommended (American College Obstetricians and Gynecologists, 2019c).

Alloimmune Thrombocytopenia

Disparity between maternal and fetal platelet antigens can stimulate maternal production of antiplatelet antibodies. Such platelet alloimmunization can be severe, and its pathophysiology mirrors that caused by red cell antigens. This is discussed in Chapter 18 (p. 352).

■ Thrombocytosis

Also called *thrombocythemia*, thrombocytosis generally is defined as persistent platelet counts >450,000/μL. Common causes of *secondary* or *reactive thrombocytosis* are infection, iron deficiency, trauma, inflammatory diseases, and malignant tumors (Tefferi, 2019). Platelet counts seldom exceed 1 million/μL in these secondary disorders, and prognosis depends on the underlying disease. Instead, *primary* or *essential thrombocytosis* accounts for most cases in which platelet counts exceed 1 million/μL. It is a clonal disorder often due to an acquired mutation in the *JAK2* gene (Spivak, 2018). Thrombocytosis usually is asymptomatic, but arterial and venous thromboses may develop, and thrombosis is associated with pregnancy complications (Rabinerson, 2007; Randi, 2014). First-line treatment is aspirin and possibly hydroxyurea.

Normal pregnancies have been described in women whose mean platelet counts were >1.25 million/μL. However, in a report of 40 pregnancies in 16 women with essential thrombocythemia, almost half had a spontaneous abortion, fetal demise, or preeclampsia (Niittyvuopio, 2004). In 63 pregnancies in 36 women cared for at the Mayo Clinic, a third had a miscarriage, but other pregnancy complications were uncommon (Gangat, 2009). In this observational study, aspirin therapy was associated with a significantly lower abortion rate than that in untreated women—1 versus 75 percent, respectively. Suggested treatments during pregnancy include aspirin, low-molecular-weight heparin, and interferon α (Finazzi, 2012; Vantroyen, 2002). Interferon α therapy during pregnancy was successful in a review of 11 women. One women had transient blindness at midpregnancy when her platelet count was 2.3 million/μL (Delage, 1996).

THROMBOTIC MICROANGIOPATHIES

Although not a primary platelet disorder, some degree of thrombocytopenia accompanies the thrombotic microangiopathies, which include *thrombotic thrombocytopenic purpura (TTP)* and *hemolytic uremic syndrome (HUS).* These are characterized by thrombocytopenia, microangiopathic hemolysis, and microvascular thrombosis (Konkle, 2018). Their similarities to HELLP syndrome allude to their obstetrical ramifications.

■ Etiopathogenesis

Although different causes account for the variable findings within these syndromes, clinically, they frequently are indistinguishable. Inherited or idiopathic TTP is thought to be caused by antibodies to or a plasma deficiency of ADAMTS13 (Konkle, 2018). This endothelium-derived metalloprotease cleaves von Willebrand factor (vWF) to decrease its activity. Conversely, HUS is usually from endothelial damage incited by viral or bacterial infections and is seen primarily in children (George, 2014). Secondary thrombotic microangiopathies are the most common—94 percent (Bayer, 2019). A substantial number of all cases are pregnancy related. Other common causes are malignancies, drugs, transplantations, and autoimmune diseases. COVID-19 infection has been reported to precipitate TTP (Futterman, 2020; Makatsariya, 2020).

With TTP, intravascular platelet aggregation stimulates a cascade that leads to end-organ failure. There is endothelial activation and damage, but it is unclear whether this is a consequence or a cause. Elevated levels of unusually large multimers of vWF are identified with active TTP. Various defects in the *ADAMTS13* gene create differing clinical presentations. In another mechanism, antibodies raised against ADAMTS13 neutralize its action to cleave vWF multimers during an acute episode. The result is microthrombi of hyaline material containing platelets and fibrin within arterioles and capillaries. When sufficient in number or size, these aggregates produce ischemia or infarction.

■ Manifestations

Thrombotic microangiopathies are characterized by thrombocytopenia, fragmentation hemolysis, and organ dysfunction. TTP has the pentad of thrombocytopenia, hemolytic anemia, fever, renal impairment, and neurological abnormalities. HUS typically has more profound renal involvement and fewer neurological aberrations (Gaggl, 2018).

Thrombocytopenia is usually severe, but fortunately, even with very low platelet counts, spontaneous severe hemorrhage is uncommon. Microangiopathic hemolysis is associated with moderate to marked anemia, and erythrocyte transfusions are frequently necessary. The blood smear shows erythrocyte fragmentation and schizocytosis. Reticulocytes and nucleated red blood cells counts are increased, lactate dehydrogenase (LDH) levels are high, and haptoglobin concentrations are decreased (Konkle, 2018). Consumptive coagulopathy, although common, is usually subtle and clinically insignificant.

■ Treatment

The cornerstone of treatment for TTP is plasmapheresis with fresh-frozen plasma replacement along with glucocorticoids. Plasma exchange removes inhibitors and replaces the ADAMTS13 enzyme (George, 2014; Scully, 2019). Treatment with caplacizumab (Cablivi), the anti-vWF immunoglobulin, inhibits the interaction between ultra-large vWF multimers and platelets (Peyandi, 2016). These treatments have remarkably improved outcomes in patients with these formerly fatal syndromes. Red cell transfusions are imperative for life-threatening anemia.

Treatment is usually continued until the platelet count is normal for 2 days. Unfortunately, relapses are common. Additionally, long-term sequelae such as renal impairment can develop (Dashe, 1998; Vesely, 2015). Treatment for pregnancy-associated HUS, which is complement mediated, is eculizumab (Soliris), the anti-C5 humanized monoclonal antibody (Fakhouri, 2016; Gupta, 2020).

Pregnancy

As shown in the Appendix (p. 1228), ADAMTS13 enzyme activity declines across pregnancy by up to 50 percent (Sánchez-Luceros, 2004). Levels drop even further with preeclampsia, and especially HELLP syndrome. This is consonant with prevailing opinions that TTP is more commonly seen during pregnancy. In the Parkland Hospital experience, 11 pregnancies were complicated by these syndromes among nearly 275,000 gravidas—a frequency of 1 in 25,000 (Dashe, 1998).

Some of the disparately higher incidence in pregnancy reported by others may be from the inclusion of women with severe preeclampsia and eclampsia (Hsu, 1995; Magann, 1994). Differences that usually allow appropriate diagnosis are listed in Table 59-7. For example, moderate to severe hemolysis is a rather constant feature of thrombotic microangiopathies. This is seldom severe with preeclampsia, even when complicated by HELLP syndrome (Chap. 40, p. 699). Moreover, although hyaline microthrombi are seen in the liver with thrombotic microangiopathy, hepatocellular necrosis and elevated serum hepatic transaminase levels, which are characteristic of preeclampsia, are not a common feature (Ganesan, 2011; Sadler, 2010).

The diagnosis of thrombotic microangiopathies, rather than severe preeclampsia, should be clear before initiating therapy. Unfortunately, recall that determination of ADAMTS13 enzyme activity may be difficult to interpret with HELLP syndrome (Franchini, 2007). *Plasmapheresis is not indicated for preeclampsia-eclampsia complicated by hemolysis and thrombocytopenia.* Importantly, delivery is imperative to reverse the preeclampsia syndrome, but thrombotic microangiopathy is not improved by delivery (Dashe, 1998; Letsky, 2000).

TABLE 59-7. Some Differential Factors between HELLP Syndrome and Thrombotic Microangiopathies[a]

	HELLP Syndrome	Thrombotic Microangiopathies
Thrombocytopenia	Mild/mod.	Mod./severe
Microangiopathic hemolysis (schizocytosis)	Mild	Severe
ADAMTS13 deficiency	Mild/mod.	Severe
DIC	Mild	Mild
Transaminitis (AST, ALT)	Mod./severe	None/mild
Treatment	Delivery	Plasmapheresis

[a]Includes thrombotic thrombocytopenia purpura (TTP) and hemolytic uremic syndrome (HUS).
ADAMTS13 = ADAM metallopeptidase with thrombospondin type 1 motif, 13; AST = aspartate transaminase; ALT = alanine transaminase; DIC = disseminated intravascular coagulopathy; HELLP = hemolysis, elevated liver enzyme levels, low platelet count; Mod. = moderate.

Thrombotic microangiopathy was previously fatal in up to half of mothers. However, during the past two decades, and coincidental with plasmapheresis and plasma exchange, maternal survival rates have improved dramatically (Go, 2018; Gupta, 2020). Hunt and associates (2013) reported that TTP accounted for 1 percent of maternal deaths in the United Kingdom from 2003 to 2008. In a systematic review of 60 cases of pregnancy-associated HUS, two mothers died (Gupta, 2020).

Microangiopathic syndromes are usually recurrent and frequently unassociated with pregnancy. For example, seven of the 11 women described earlier at Parkland Hospital had recurrent disease either when not pregnant or within the first trimester of a subsequent pregnancy. George (2009) reported recurrent TTP in only five of 36 subsequent pregnancies. In 17 women with nonpregnant atypical HUS, recurrence developed in five of 32 pregnancies.

Long-term Prognosis

Women who are diagnosed with thrombotic microangiopathy during pregnancy are at risk for serious long-term complications (Gaggl, 2018; George, 2018). The relapse rate is as high as 40 percent in nonpregnant patients (Konkle, 2018). The described Parkland experience included a mean 9-year surveillance period (Dashe, 1998). These women had multiple recurrences; renal disease requiring dialysis, transplantation, or both; severe chronic hypertension; and transfusion-acquired infection. Two women died remote from pregnancy—one from dialysis complications and one from transfusion-acquired HIV infection. In the review by Gupta (2020) cited earlier, 15 percent of mothers with atypical HUS had long-term renal failure. In 19 women with primary atypical HUS, eight progressed to end-stage renal disease (Timmermans, 2020).

INHERITED COAGULATION DEFECTS

Hemophilias A and B

Obstetrical hemorrhage may infrequently be the consequence of an inherited defect in a protein that controls coagulation (Majluf-Cruz, 2020). Hemophilia and von Willebrand disease are examples.

Hemophilia A is an X-linked recessively transmitted disorder characterized by a marked deficiency of factor VIII. Severity reflects plasma factor levels and is categorized as mild—levels of 6 to 30 percent; moderate—2 to 5 percent; or severe—less than 1 percent (Arruda, 2015). It is rare among women compared with men, in whom the heterozygous state is responsible for the disease. Heterozygous women have diminished factor VIII levels, but almost invariably, the homozygous state is requisite for hemophilia A. In a few instances, it appears in

women spontaneously from a newly mutated gene. Pregnancy-associated acquired hemophilia A from antibodies may result in severe bleeding-related morbidity (Tengborn, 2012). *Christmas disease* or *hemophilia B* is caused by severe deficiency of factor IX and has similar genetic and clinical features.

Pregnancy

The risk of obstetrical bleeding with hemophilia is directly related to factor VIII or IX levels. Affected women have a range of activity that is determined by random X-chromosome inactivation—lyonization—although activity is expected to average 50 percent (Letsky, 2000). Levels below 10 to 20 percent pose hemorrhage risks. If levels fall to near zero, this risk is substantial. Pregnancy does afford some protection, however, because concentrations of both these clotting factors rise appreciably during normal pregnancy (Appendix, p. 1228). Treatment with desmopressin can stimulate factor VIII release. Risks are further reduced by avoiding lacerations, minimizing episiotomy use, and maximizing postpartum uterine contractions. Operative vaginal delivery and cesarean delivery pose bleeding risks.

A few articles describe pregnancy courses. Kadir and colleagues (1997) reported that 20 percent of carriers had postpartum hemorrhage. Guy and associates (1992) reviewed five pregnancies in women with hemophilia B, and in all, outcomes were favorable. They recommended factor IX administration if levels are below 10 percent. Desmopressin in selected cases has reduced obstetrical bleeding complications (Trigg, 2012). If a male fetus has hemophilia, the risk of hemorrhage increases after delivery in the neonate. This is especially true if circumcision is attempted.

Related to preconceptional counseling, most women with hemophilia A or B carry one affected allele and the other X chromosome is normal. These individuals will have all sons affected by the disease, and half of her daughters will be carriers. Rarely, a woman may carry two abnormal alleles, in which case all daughters will be carriers and all of her sons will inherit the disease. Prenatal diagnosis of hemophilia is possible in some families using chorionic villus biopsy (Chap. 17, p. 346). Preimplantation genetic testing for hemophilia was reviewed by Lavery (2009).

Factor VIII or IX Inhibitors

Rarely, antibodies directed against factor VIII or IX are acquired and may lead to life-threatening hemorrhage. Patients with hemophilia more commonly develop antibodies, and their acquisition in patients without hemophilia is extraordinary. It has been identified rarely in women during the puerperium (Santoro, 2009). The prominent clinical feature is severe, protracted, repetitive hemorrhage from the reproductive tract starting a week or so after an apparently uncomplicated delivery (Gibson, 2016). The activated partial thromboplastin time is markedly prolonged. Treatment has included multiple blood-component transfusions, immunosuppressive therapy, and attempts at various surgical procedures, especially curettage and hysterectomy. A recombinant activated factor VII (NovoSeven) stops bleeding in up to 75 percent of patients with these inhibitors (Arruda, 2015; Gibson, 2016).

Von Willebrand Disease

At least 20 heterogeneous clinical disorders involve aberrations of factor VIII complex and platelet dysfunction and collectively are termed *von Willebrand disease (vWD)*. These abnormalities are the most frequently inherited bleeding disorders, and their prevalence is as high as 1 to 2 percent (Arruda, 2015; Punt, 2020). Most von Willebrand disease variants are inherited as autosomal dominant traits. Types I and II are the most common, and type I accounts for 75 percent. Type III, which is the most severe, is a recessive trait. Although most cases of acquired vWD develop after age 50 years, some have been reported in pregnant women (Lipkind, 2005).

Pathogenesis

The *von Willebrand factor (vWF)* is a series of large, plasma multimeric glycoproteins that form part of the factor VIII complex. It is essential for normal platelet adhesion to subendothelial collagen and formation of a primary hemostatic plug. It also plays a major role in stabilizing the coagulant properties of factor VIII. Factor VIII, a glycoprotein, is synthesized by the liver. The von Willebrand precursor, which is present in platelets and plasma, is instead synthesized by endothelium and megakaryocytes. The von Willebrand factor antigen (vWF:Ag) is the antigenic determinant measured by immunoassays.

Symptomatic women typically present with easy bruising, epistaxis, mucosal hemorrhage, heavy menses, and excessive bleeding with trauma or surgery. The classic autosomal dominant forms usually cause symptoms in the heterozygous state. With vWD, laboratory features often include a prolonged bleeding time, prolonged partial thromboplastin time, decreased vWF antigen levels, decreased factor VIII immunological and coagulation-promoting activity, and inability of platelets from an affected person to react to various stimuli.

Although most patients with vWD have heterozygous variants and associated minor bleeding complications, the disease can be severe. Moreover, homozygous offspring develop serious clotting dysfunction. Chorionic villus sampling with DNA analysis to detect the missing genes has been described, but the specific genetic mutation must be known. Some authorities recommend cesarean delivery to avoid trauma to a possibly affected fetus if the mother has severe disease.

Pregnancy

During normal pregnancy, maternal levels of both factor VIII and vWF antigen increase substantively (Appendix, p. 1228). Because of this, pregnant women with vWD often develop normal levels of factor VIII coagulant activity and vWF antigen, although their measured bleeding time still may be prolonged (Delbrück, 2019). If factor VIII activity is very low or if there is bleeding, treatment is recommended. Desmopressin by infusion transiently increases factor VIII and vWF levels (Arruda, 2015). With significant bleeding, 15 or 20 units of cryoprecipitate are transfused every 12 hours. Alternatively, factor VIII concentrates (Alphanate, Humate-P) that contain high-molecular-weight vWF multimers may be given. Lubetsky and colleagues (1999) described continuous infusion with Humate-P in a woman during a vaginal delivery. According to Chi and

coworkers (2009), conduction analgesia can be provided safely if coagulation defects have corrected or if hemostatic agents are administered prophylactically.

Pregnancy outcomes in women with vWD are generally good, but postpartum hemorrhage is common. In one systematic review, with more than 800 deliveries, the postpartum hemorrhage incidence was 33 percent (Punt, 2020). In a database review of more than 2200 deliveries complicated by vWD, this incidence was only about 5 percent (O'Brien, 2020). From two reviews, postpartum hemorrhage may be primary and at the time of delivery, or it may have a delayed onset (Makhamreh, 2021a,b).

■ Other Factor Deficiencies

In general, the activity of most procoagulant factors rises across pregnancy (Appendix, p. 1228). *Factor VII deficiency* is a rare autosomal recessive disorder. Levels of this factor increase during normal pregnancy, but these may rise only mildly in women with factor VII deficiency (Fadel, 1989). A systematic review of 94 births found no difference in postpartum hemorrhage rates with or without prophylaxis with recombinant factor VIIa (Baumann Kreuziger, 2013).

Factor X or *Stuart-Prower factor* deficiency is rare and inherited as an autosomal recessive trait. Factor X levels typically rise by 50 percent during normal pregnancy. Despite this, adverse pregnancy outcome are common. Spiliopoulos and coworkers (2019) reported 31 pregnancies in 19 women. They described a high rate of preterm birth, perinatal mortality, and postpartum hemorrhage. Conversely, Nance and colleagues (2012) described 24 pregnancies, of which 18 resulted in a healthy baby. Treatment is with plasma-derived factor X, fresh-frozen plasma, or prothrombin complex concentrates.

Factor XI deficiency is inherited as an autosomal recessive trait in most families. It manifests as severe disease in homozygotes but only as a minor defect in heterozygotes. It is most prevalent in Ashkenazi Jews and is rarely seen in pregnancy. In one review of 105 pregnancies from 33 affected women, 70 percent had an uneventful pregnancy and delivery (Myers, 2007). Authors recommended peripartum treatment with factor XI concentrate for cesarean delivery and advised against epidural analgesia unless factor XI is given. From another review, factor XI levels and bleeding severity correlated poorly in women with severe deficiency (Martin-Salces, 2010). Wiewel-Verschueren and associates (2016) performed a systematic review of 27 studies with 372 women and reported that 18 percent had postpartum hemorrhage.

Factor XII deficiency is another autosomal recessive disorder that rarely complicates pregnancy. A greater incidence of thromboembolism is encountered in nonpregnant patients with this deficiency.

Factor XIII deficiency is an autosomal recessive trait and may be associated with maternal intracranial hemorrhage (Bouttefroy, 2020). In their review, Kadir and associates (2009) cited an increased risk of recurrent miscarriage and placental abruption. It has also been reported to cause umbilical cord bleeding (Odame, 2014). Treatment is fresh frozen plasma. Naderi and colleagues (2012) described 17 successful pregnancies in women receiving weekly prophylaxis with factor XIII concentrate.

Fibrinogen abnormalities—either qualitative or quantitative—also may cause coagulation abnormalities. Autosomally inherited abnormalities usually involve the formation of a functionally defective fibrinogen—commonly referred to as *dysfibrinogenemia*. Familial *hypofibrinogenemia* and sometimes *afibrinogenemia* are infrequent recessive disorders. Our experience suggests that hypofibrinogenemia represents a heterozygous autosomal dominant state. The thrombin-clottable protein level in these patients typically ranges from 80 to 110 mg/dL when nonpregnant. Cai and coworkers (2018) described successful outcomes in affected women in whom fibrinogen or plasma infusions were given throughout pregnancy.

THROMBOPHILIAS

Several important regulatory proteins act as inhibitors at strategic sites in the coagulation cascade to maintain blood fluidity. Inherited deficiencies of these inhibitory proteins are caused by gene mutations. Because they may be associated with recurrent thromboembolism, they are collectively referred to as *thrombophilias.* These are discussed in Chapter 55 (p. 976) and reviewed by the American College of Obstetricians and Gynecologists (2020).

CHAPTER 60

Diabetes Mellitus

According to the Centers for Disease Control and Prevention (2020), nearly 27 million adults in the United States have been diagnosed with diabetes. Another 7.3 million are suspected to be undiagnosed, and an estimated 88 million have prediabetes. Reasons for these substantial rates include an aging population, which is more likely to develop type 2 diabetes; population growth within minority groups at particular risk for type 2 diabetes; and a dramatic rise in obesity rates. In 2019, almost three in 10 women were considered obese prior to becoming pregnant (Driscoll, 2020). The strong relationship between diabetes and the current obesity epidemic in the United States underlines the critical need for diet and lifestyle interventions to change the trajectory of both.

TYPES OF DIABETES

In nonpregnant individuals, the type of diabetes is based on its presumed pathogenesis and its manifestations. Absolute insulin deficiency, which generally is autoimmune in etiology, characterizes *type 1 diabetes*. In contrast, insulin resistance, relative insulin deficiency, or elevated glucose production characterizes *type 2 diabetes* (Table 60-1). Both types are generally preceded by a period of abnormal glucose homeostasis often referred to as prediabetes. Pancreatic β-cell destruction can begin at any age, but type 1 diabetes is clinically apparent most often before age 30. Type 2 diabetes usually develops with advancing age but is increasingly identified in younger obese adolescents. Etiological overlap in diabetes subtypes is well established and has led to the proposal of a single classification system centered on β-cell function along with the concept of individualized treatment strategies (World Health Organization, 2020). Other forms of diabetes include *maturity-onset diabetes of the young (MODY)*. The more common MODY type is in obese adolescents (TODAY Study Group, 2021). The less common form is an autosomal dominant condition and characterized by mild diabetes diagnosed in adolescence or young adulthood (Udler, 2020).

Classification During Pregnancy

Diabetes is the most common medical complication of pregnancy. Women can be separated into those diagnosed with diabetes before pregnancy—*pregestational* or *overt diabetes*, and those diagnosed during pregnancy—*gestational diabetes*.

The proportion of pregnancies complicated by diabetes more than doubled between 1994 and 2008, after which rates have leveled (Deputy, 2018; Jovanovič, 2015). In 2018, 7.6 percent of pregnant women in this country had some form of diabetes (Martin, 2019). Prevalence is highest among non-Hispanic

TABLE 60-1. Etiological Classification of Diabetes Mellitus

Type 1: β-Cell destruction, usually absolute insulin deficiency
Immune-mediated
Idiopathic

Type 2: Ranges from predominantly insulin resistance to predominantly an insulin secretory defect with insulin resistance

Other types
Genetic mutations of β-cell function: MODY 1–6, others
Genetic defects in insulin action
Genetic syndromes: Down, Klinefelter, Turner, others
Diseases of the exocrine pancreas: pancreatitis, cystic fibrosis
Endocrinopathies: Cushing syndrome, pheochromocytoma, others
Drug or chemical induced: glucocorticosteroids, thiazides, β-adrenergic agonists, others
Congenital infections: rubella, cytomegalovirus, coxsackievirus

Gestational diabetes (GDM)

MODY = maturity-onset diabetes of the young.
Adapted from American Diabetes Association, 2020; Powers, 2018.

blacks, Mexican-Americans, Puerto Rican-Americans, and Native Americans (Powers, 2018).

White Classification

Until the mid-1990s, the classification system of Priscilla White (1978) for diabetic pregnant women was the linchpin of management. Today, the White classification is used less often but still provides simple, useful information on pregnancy risks and prognosis (Bennett, 2015). Because most currently cited literature also contains data from these older classifications, the one previously recommended by the American College of Obstetricians and Gynecologists (1986) is shown in Table 60-2.

The American College of Obstetricians and Gynecologists (2019a) no longer recommends the White classification. The current focus is whether diabetes *antedates* pregnancy or is first diagnosed *during* pregnancy. Many now recommend the system proposed by the American Diabetes Association (Table 60-3).

PREGESTATIONAL DIABETES

Considering the previously mentioned high percentage of undiagnosed diabetes, many women identified with gestational diabetes likely have previously unrecognized type 2 diabetes. Indeed, 5 to 10 percent of women with gestational diabetes are diagnosed with overt diabetes immediately after pregnancy.

Diagnosis

Women with high plasma glucose levels, glucosuria, and ketoacidosis present no diagnostic challenge. Women with a random plasma glucose level >200 mg/dL plus classic signs and symptoms such as polydipsia, polyuria, and unexplained weight loss, those with a fasting glucose level >125 mg/dL, or those with a first-trimester glycosylated hemoglobin (HbA_{1c}) level of ≥6.5 percent are considered by the American Diabetes Association

TABLE 60-2. Modified White Classification Scheme Used from 1986 Through 1994 for Diabetes Complicating Pregnancy

		Plasma Glucose Level		
Class	**Onset**	**Fasting**	**2-Hour Postprandial**	**Therapy**
A_1	Gestational	<105 mg/dL	<120 mg/dL	Diet
A_2	Gestational	>105 mg/dL	>120 mg/dL	Insulin
Class	**Age of Onset (yr)**	**Duration (yr)**	**Vascular Disease**	**Therapy**
B	Over 20	<10	None	Insulin
C	10 to 19	10 to 19	None	Insulin
D	Before 10	>20	Benign retinopathy	Insulin
F	Any	Any	Nephropathy[a]	Insulin
R	Any	Any	Proliferative retinopathy	Insulin
H	Any	Any	Heart	Insulin

[a]When diagnosed during pregnancy: proteinuria ≥500 mg/24 hr before 20 weeks' gestation.

TABLE 60-3. Proposed Classification System for Diabetes in Pregnancy

Gestational diabetes: diabetes diagnosed during pregnancy that is not clearly overt (type 1 or type 2) diabetes

Type 1 Diabetes:
Diabetes resulting from β-cell destruction, usually leading to absolute insulin deficiency
a. Without vascular complications
b. With vascular complications (specify which)

Type 2 Diabetes:
Diabetes from inadequate insulin secretion in the face of increased insulin resistance
a. Without vascular complications
b. With vascular complications (specify which)

Other types of diabetes: genetic in origin, associated with pancreatic disease, drug-induced, or chemically induced

Data from American Diabetes Association, 2017a; Powers, 2018.

(2019) and the World Health Organization (2019) to have overt diabetes first detected in pregnancy.

Women with only minimal metabolic derangement may be more difficult to identify. To diagnose overt diabetes in pregnancy, the International Association of Diabetes and Pregnancy Study Groups (IADPSG) Consensus Panel (2010) recognizes the threshold values found in Table 60-4 for fasting or random plasma glucose and HbA_{1c} levels at prenatal care initiation. The American Diabetes Association (2020) and the World Health Organization (2019) now also consider a plasma glucose level >200 mg/dL measured 2 hours after a 75-g oral glucose load to be diagnostic. No consensus has been reached as to whether such testing should be universal or limited to those women classified as high risk.

Regardless, a presumed diagnosis of overt diabetes in pregnancy based on these thresholds should be confirmed postpartum. Risk factors for impaired carbohydrate metabolism in pregnant women include a strong familial history of diabetes, prior delivery of a large newborn, persistent glucosuria, or unexplained fetal losses.

Harm in Pregnancy

With overt diabetes, the embryo, fetus, and mother frequently experience serious complications directly attributable to diabetes (Egan, 2020). Many of these complications might be prevented each year by preconceptional care for improved glycemic control (Peterson, 2015). Using HbA_{1c} values as objective risk quartiles, Finneran and Kiefer (2020) reported that glycemic control throughout pregnancy and a late-pregnancy HbA_{1c} level <6.5 percent leads to reduced rates of adverse obstetrical and neonatal outcomes. The likelihood of successful outcomes with overt diabetes, however, is not simply related to glucose control. The degree of underlying cardiovascular or renal disease may be more important. Thus, advancing stages of the White classification, seen in Table 60-2, are inversely related to favorable pregnancy outcomes. Shown in Table 60-5 are data that chronicle the adverse pregnancy outcomes with overt diabetes, and many are described next (Battarbee, 2020b).

Fetal Effects

Spontaneous Abortion

Up to 25 percent of overtly diabetic mothers have an early miscarriage, and poor glycemic control is an associated factor. In one study, those whose HbA_{1c} concentrations were >12 percent or whose preprandial glucose concentrations persisted above 120 mg/dL had an elevated miscarriage risk (Galindo, 2006). In a large Chinese population-based study, those with a history of diabetes had an increased risk of miscarriage, and the risk rose 8 percent for each 20-mg/dL incremental rise in fasting glucose (Wei, 2019). In 89 pregnancies in women with the monogenic form of MODY, only women with the causative *glucose kinase (GCK)* mutation were more likely to miscarry (Bacon, 2015). Another analysis of 128 GCK-MODY pregnancies showed that the observed miscarriage rate was comparable to the background rate (Dickson, 2019). These women have hyperglycemic variability that can be difficult to control.

Preterm Delivery

Overt diabetes is an undisputed risk factor for preterm birth. In an analysis of more than 500,000 pregnancies in Ontario,

TABLE 60-4. Diagnosis of Overt Diabetes in Pregnancy[a]

Measure of Glycemia	Threshold
Fasting plasma glucose	At least 7.0 mmol/L (126 mg/dL)
Hemoglobin A_{1c}	At least 6.5%
Random plasma glucose	At least 11.1 mmol/L (200 mg/dL) plus confirmation

[a]Apply to women without known diabetes antedating pregnancy. The decision to perform blood testing for evaluation of glycemia on all pregnant women or only on women with characteristics indicating a high risk for diabetes is based on the background frequency of abnormal glucose metabolism in the population and on local circumstances.
Data from International Association of Diabetes and Pregnancy Study Groups Consensus Panel, 2010.

TABLE 60-5. Selected Maternal and Perinatal Outcomes in Percent in Women with Gestational and Overt Diabetes Compared with Nondiabetic Women[a]

Factor	Normal 182,464[b] (%)	GDM 10,549[b] (%)	Overt DM 2993[b] (%)
Maternal			
Chronic HTN	1.5	5.0	11.5
Renal disease	0.5	0.6	2.7
Gestational HTN	8.0	12.9	22.9
Chorioamnionitis	4.1	4.0	5.2
Cesarean birth	42	59	69
Neonatal			
RDS	3.8	4.7	11.0
Ventilation	2.8	3.1	7.0
NICU admit	12.8	19.8	41.9
Macrosomia	7.7	18.1	29.9
Death[c]	0.2	0.1	0.4

[a]Unless specified, all comparisons $p < 0.001$.
[b]Number of women in group.
[c]$p < 0.05$.
DM = diabetes mellitus; GDM = gestational diabetes mellitus; HTN = hypertension; NICU = neonatal intensive care unit; RDS = respiratory distress syndrome.

almost 20 percent of women with diabetes were delivered preterm compared with 5.6 percent of women without diabetes, obesity, or hypertension (Berger, 2020). More than 60 percent were indicated preterm births, that is, due to obstetrical or medical complications. Notably, more than 37 percent of women with diabetes and chronic hypertension delivered preterm. In a review of California births, 19 percent of women with pregestational diabetes delivered before 37 weeks' gestation compared with 9 percent of controls (Yanit, 2012). In a study from the United Kingdom, the preterm delivery rate was 42 percent for 8690 type 1 diabetic women and 3 percent for those with type 2 diabetes (Murphy, 2021).

Malformations

The incidence of major malformations in fetuses of women with type 1 diabetes approximates 11 percent and is at least double the rate in fetuses of nondiabetic mothers (Jovanovič, 2015). This risk is present for all women with pregestational diabetes, including those with type 2 disease (Tinker, 2020). Congenital anomalies constitute almost half of perinatal deaths in diabetic pregnancies.

Cardiovascular malformations account for more than half of the anomalies, and Table 60-6 lists selected malformations reported by the National Birth Defects Prevention Study (Tinker, 2020). In a study of more than 2 million births in Canada, the risk of an isolated cardiac defect was fivefold higher in women with type 1 diabetes compared with nondiabetic mothers (Liu, 2013). The *caudal regression sequence*, described in Chapter 15 (p. 280), is a rare malformation that, according to the National Birth Defects Prevention Study, is 80 times more likely in women with pregestational diabetes.

TABLE 60-6. Selected Congenital Malformations in Pregnancies Complicated by Overt Diabetes

Birth Defect	OR (95% CI)
Cardiovascular	
Fallot tetralogy	5.3 (3.5–8.0)
AV septal defect	10.5 (6.2–17.9)
Aortic coarctation	4.5 (2.8–7.1)
Neural-tube defect	
Anencephaly	3.5 (1.9–6.4)
Encephalocoele	5.4 (2.5–11.7)
Hydrocephaly	8.2 (5.0–13.5)
Cleft palate	4.3 (2.9–6.5)
Esophageal	3.4 (1.9–6.1)
Hypospadias	2.8 (1.7–4.8)
Renal	8.1 (3.9–16.9)
Sacral agenesis	80.2 (46.1–139.3)

CI = confidence interval; OR = odds ratio.

Poorly controlled diabetes, both preconceptionally and early in pregnancy, is thought to underlie this elevated risk for major malformation. In one study of mothers with type 1 diabetes, a periconceptional HbA_{1c} <6.5 percent carried a twofold risk for a fetal major cardiac defect, and a HbA_{1c} >9 percent carried a sixfold risk (Ludvigsson, 2018). Others cite similar frequencies (Murphy, 2021). Figure 60-1 shows the association between HbA_{1c} levels and fetal congenital malformation rates in a Parkland Hospital cohort of women with overt diabetes (Martin, 2021).

The etiological mechanisms that explain this link include excess production of toxic superoxide radicals, altered cell signaling pathways, upregulation of some genes by hyperglycemia, and

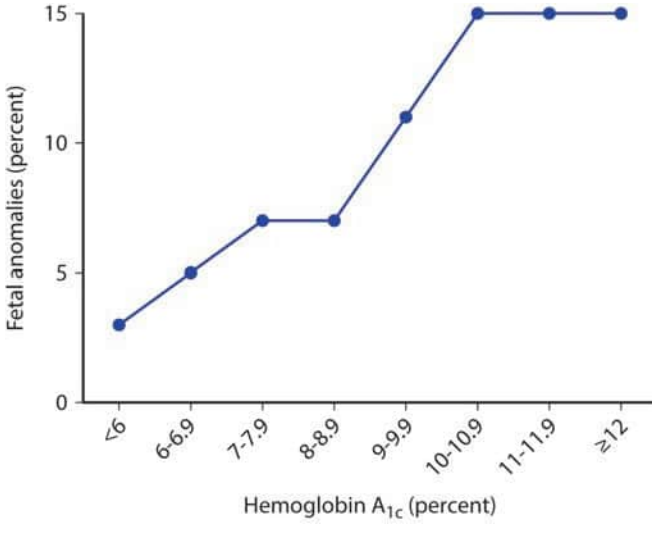

FIGURE 60-1 Association between fetal malformation rates and HbA_{1c} values determined at initiation of prenatal care in 1573 pregnancies in women with pregestational diabetes.

activation of programmed cell death (Basu, 2018; Reece, 2012). One review of potential molecular mechanisms suggests that cellular responses to oxidative stress represent possible therapeutic targets to prevent diabetes-induced embryopathy (Yang, 2015).

Altered Fetal Growth

Diminished fetal growth may result from congenital malformations or from substrate deprivation due to advanced maternal vascular disease. That said, fetal overgrowth is more typical of pregestational diabetes. Maternal hyperglycemia prompts fetal hyperinsulinemia, and this in turn stimulates excessive somatic growth. Except for the brain, most fetal organs are affected by the macrosomia that characterizes the fetus of diabetic women. Newborns are described as anthropometrically different from other large-for-gestational age (LGA) neonates (Catalano, 2003; Durnwald, 2004). Specifically, those whose mothers are diabetic have excessive fat deposition on the shoulders and trunk, which predisposes to shoulder dystocia or fetopelvic disproportion (Fig. 60-2).

The incidence of macrosomia rises significantly when mean maternal blood glucose concentrations chronically exceed 130 mg/dL (Hay, 2012). In addition, the overall birthweight distribution of neonates of diabetic mothers is skewed toward consistently heavier birthweights. In one sonographic study, the macrosomia rates for Nordic women with type 1, type 2, or gestational diabetes were 35, 28, and 24 percent, respectively (Hammoud, 2013). Moreover, the abdominal circumference grew disproportionately larger in the diabetic groups. Analysis of head circumference/abdominal circumference (HC/AC) ratios shows that this disproportionate growth occurs mainly in diabetic pregnancies that ultimately yield macrosomic newborns.

Unexplained Fetal Demise

The risk of fetal death is three to four times higher in women with pregestational diabetes (Gardosi, 2013; Patel, 2015). In the United Kingdom study of more than 17,000 pregnancies in women with pregestational diabetes, the stillbirth incidence was similar in those with type 1 or type 2 diabetes—10.4 versus 13.5 per 1000 live and stillbirths, respectively (Murphy, 2021). Stillbirth without an identifiable cause is a phenomenon relatively limited to pregnancies complicated by overt diabetes. These stillbirths are "unexplained" because common factors such as obvious placental insufficiency, placental abruption, fetal-growth restriction, or oligohydramnios are not identified. These fetuses are typically LGA and die before labor, usually later in the third trimester.

FIGURE 60-2 This 6050-g macrosomic neonate was born to a woman with gestational diabetes.

These unexplained stillbirths are usually associated with poor glycemic control. In one study, suboptimal glycemic control was identified in two thirds of unexplained stillbirths between 1990 and 2000 (Lauenborg, 2003). Fetuses of diabetic mothers also often have elevated lactic acid levels. Salvesen and colleagues (1992, 1993) analyzed fetal blood samples and reported that mean umbilical venous blood pH was lower in diabetic pregnancies and was significantly related to fetal insulin levels. These findings support a hypothesis that hyperglycemic-mediated chronic aberrations in oxygen and fetal metabolite transport may underlie these unexplained fetal deaths (Pedersen, 1977).

Maternal ketoacidosis also can cause fetal death (Bryant, 2017). Moreover, stillbirths from placental insufficiency occur with increased frequency in women with overt diabetes and are usually associated with severe preeclampsia. In the prior cited California study, the fetal death risk was sevenfold higher in women with hypertension and pregestational diabetes compared with the threefold increased risk associated with diabetes alone (Yanit, 2012). Stillbirth rates are also elevated in women with advanced diabetes and vascular complications.

Hydramnios

Diabetic pregnancies are often complicated by excess amnionic fluid. In one sonographic study, 18 percent of 314 pregnancies complicated by pregestational diabetes were found to have hydramnios in the third trimester, which was defined as an amnionic fluid index (AFI) >24 cm. Women with elevated HbA_{1c} values in the third trimester were more likely to have hydramnios (Idris, 2010). In a similar study, poor maternal glucose control was associated with macrosomia and hydramnios (Vink, 2006). A likely—albeit unproven—explanation is that fetal hyperglycemia causes fetal polyuria (Chap. 14, p. 256). In a study from Parkland Hospital, Dashe and coworkers (2000) found that the AFI parallels the amnionic fluid glucose level among women with diabetes.

Neonatal Effects

Before tests of fetal health and maturity became available, delivery before term was deliberately selected for women with diabetes to avoid unexplained stillbirth. Although this practice has been largely abandoned, a higher frequency of preterm delivery in women with diabetes persists. One analysis of early-term delivery ($37^{0/7}$ to $38^{6/7}$ weeks) showed a 13-percent reduction in such deliveries in women with diabetes between 2005 and 2011 (Little, 2015). Most indicated deliveries are prompted by advanced diabetes with superimposed preeclampsia.

Although modern neonatal care has reduced neonatal death rates due to immaturity, neonatal *morbidity* due to preterm birth continues to be a serious consequence. In one Neonatal Research Network study of 10,781 extremely preterm neonates, those born to diabetic women treated with insulin prior

to pregnancy were at greater risk for necrotizing enterocolitis and late-onset sepsis than similarly aged neonates of mothers without diabetes (Boghossian, 2016).

Respiratory Distress Syndrome

Gestational age rather than overt diabetes is likely the most significant factor associated with respiratory distress syndrome (Chap. 34, p. 615). Indeed, in one analysis of 19,399 very-low-birthweight neonates delivered between 24 and 33 weeks' gestation, rates of respiratory distress syndrome in newborns of diabetic mothers were not higher compared with rates in neonates of nondiabetic mothers (Bental, 2011). Diabetes does not appear to alter the beneficial effects of antenatal corticosteroids to hasten lung maturity (Battarbee, 2020a).

Hypoglycemia and Hypocalcemia

Newborns of a diabetic mother experience a rapid drop in plasma glucose concentration after delivery. This is attributed to the hyperplasia of fetal β-islet cells that is induced by chronic maternal hyperglycemia. Low glucose concentrations—defined as <45 mg/dL—are particularly common in newborns of women with unstable glucose concentrations during labor (van Kempen, 2020). Preliminary observations showed that early-term fetuses exposed to antenatal corticosteroids have a high rate of hypoglycemia (Gupta, 2020). Frequent blood glucose measurements in the newborn and active early feeding practices can mitigate this complication.

Hypocalcemia is defined as a total serum calcium concentration <8 mg/dL in term newborns. Early-onset hypocalcemia is one of the potential metabolic derangements in neonates of diabetic mothers. Its cause is unclear. Theories include altered magnesium–calcium economy, asphyxia, and preterm birth. In one randomized study, 137 pregnant women with type 1 diabetes were managed with strict versus customary glucose control (DeMarini, 1994). Almost a third of neonates in the customary control group developed hypocalcemia compared with only 18 percent of those in the strict-control group.

Hyperbilirubinemia and Polycythemia

The pathogenesis of hyperbilirubinemia in neonates of diabetic mothers is uncertain. A major contributing factor is newborn polycythemia, which raises the bilirubin load (Chap. 33, p. 606). Polycythemia is thought to be a fetal response to relative hypoxia. According to Hay (2012), the sources of this fetal hypoxia are hyperglycemia-mediated elevations in maternal affinity for oxygen and fetal oxygen consumption. Together with insulin-like growth factors, this hypoxia leads to elevated fetal erythropoietin levels and red cell production.

Cardiomyopathy

Newborns of pregestational and gestational diabetic pregnancies frequently have hypertrophic cardiomyopathy. This remodeling can be associated with cardiac dysfunction (Aguilera, 2020; Depla, 2021). Huang and coworkers (2013) propose that pathological ventricular hypertrophy in neonates born to women with diabetes is due to insulin excess. In severe cases, this cardiomyopathy may lead to obstructive cardiac failure. In one study, the fetuses of 26 women with pregestational diabetes underwent serial echocardiographic evaluation. In the first trimester, fetal diastolic dysfunction was already evident in some. In the third trimester, the fetal interventricular septum and right ventricular wall were thicker in fetuses of diabetic mothers (Russell, 2008). Others report similar observations (Aguilera, 2020). Most affected newborns are asymptomatic following birth, and hypertrophy usually resolves in the months after delivery. Any long-term adverse sequelae remain to be determined (Depla, 2021).

Long-term Cognitive Development

Intrauterine metabolic conditions are linked to neurodevelopment in offspring. In a study of more than 700,000 Swedish men, the intelligence quotient of those whose mothers had diabetes during pregnancy averaged 1 to 2 points lower (Fraser, 2014). DeBoer and associates (2005) demonstrated impaired memory performance at age 1 year in infants of diabetic mothers. Results from the Childhood Autism Risks from Genetics and the Environment (CHARGE) study indicated that autism spectrum disorders or developmental delay also were more common in children of diabetic women (Krakowiak, 2012). Adane and colleagues (2016) confirmed a consistent relationship between maternal diabetes and diminished cognitive and language development in studies of younger children but not older children. Because interpreting effects of the intrauterine environment on neurodevelopment is confounded by postnatal factors, the link between maternal diabetes, glycemic control, and long-term neurocognitive outcome remains unconfirmed.

Inheritance

The risk of developing type 1 diabetes if either parent is affected is 3 to 5 percent. Type 2 diabetes has a much stronger genetic component. If both parents have type 2 diabetes, the risk of their offspring developing it approaches 40 percent (Powers, 2018). Both types of diabetes develop after a complex interplay between genetic predisposition and environmental factors. Type 1 diabetes is prompted by environmental triggers such as infection, diet, or toxins and is heralded by the appearance of islet-cell autoantibodies in genetically vulnerable people (Pociot, 2016).

■ Maternal Effects

Diabetes and pregnancy can interact to an extent that maternal welfare can be jeopardized. With the possible exception of diabetic retinopathy, however, the long-term course of diabetes does not appear to be affected by pregnancy.

In one analysis of more than 800,000 pregnancies, the 1125 mothers with type 1 diabetes had greater risks for hypertension and respiratory complications than nondiabetic gravidas (Jovanovič, 2015). The 10,126 mothers with type 2 diabetes had an elevated risk for hypertension, infection, depression, and cardiac or respiratory complications compared with nondiabetic gravidas.

Maternal death is uncommon, but rates in women with diabetes are still higher than those in unaffected gravidas. In one analysis of 972 women with type 1 diabetes, the maternal mortality rate was 0.5 percent. Deaths stemmed from diabetic ketoacidosis, hypoglycemia, hypertension, and infection (Leinonen, 2001).

Preeclampsia

Pregnancy-associated hypertension is the complication that most often forces preterm delivery in diabetic women. The incidence of chronic and gestational hypertension—and especially preeclampsia—is remarkably increased (Chap. 40, p. 690). In one metaanalysis of 92 studies, women with pregestational diabetes had a nearly fourfold higher pooled relative risk for preeclampsia (Bartsch, 2016). In the prior cited California study, preeclampsia developed three to four times more often in women with overt diabetes. Moreover, those diabetics with coexistent chronic hypertension were almost 12 times more likely to develop preeclampsia (Yanit, 2012).

Women with type 1 diabetes in more advanced White classes typically exhibit preexisting vascular complications and nephropathy. These women are more likely to develop preeclampsia (Fig. 60-3). This rising risk may be related to oxidative stress, which plays a key role in the pathogenesis of diabetic complications and preeclampsia. With this in mind, the Diabetes and Preeclampsia Intervention Trial (DAPIT) randomly assigned 762 women with type 1 diabetes to antioxidant vitamin C and E supplementation or placebo in the first half of pregnancy (McCance, 2010). Preeclampsia rates were not improved except in the few with a low antioxidant status at baseline.

Preventively, low-dose aspirin prophylaxis is recommended in women at high risk of preeclampsia, which includes those with type 1 or type 2 diabetes (Chap. 40, p. 705). An 81-mg oral daily dose is initiated between 12 and 28 weeks' gestation and is continued until delivery (American College of Obstetricians and Gynecologists, 2020a).

Diabetic Nephropathy

Diabetes is the leading cause of end-stage renal disease in the United States (Chap. 56, p. 1003). Clinically detectable nephropathy begins with microalbuminuria, recognized as 30 to 300 mg of protein in a 24-hour urine collection specimen. This may manifest as early as 5 years after diabetes onset. Macroalbuminuria—more than 300 mg in a 24-hour collection specimen—develops in patients destined to have end-stage renal disease. Hypertension almost invariably develops during this period, and renal failure ensues typically in the next 5 to 10 years. The incidence of overt proteinuria is nearly 30 percent in individuals with type 1 diabetes and ranges from 4 to 20 percent in those with type 2 diabetes (Reutens, 2013). Regression is common, presumably from improved glucose control.

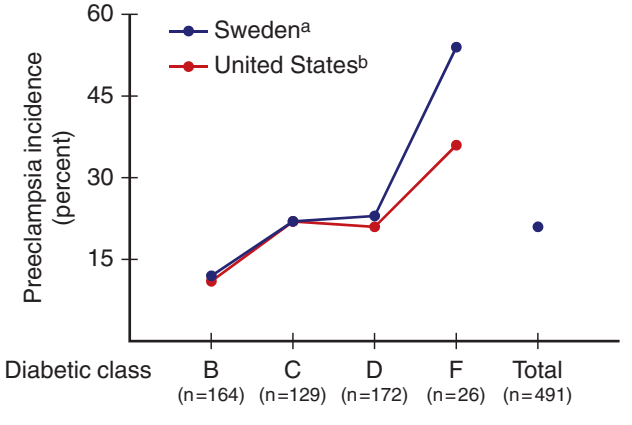

FIGURE 60-3 Incidence of preeclampsia in 491 women with type 1 diabetes stratefied by diabetic class in Sweden and the United States. (Data from Hanson[a], 1993; Sibai[b], 2000.)

Approximately 5 percent of gravidas with overt diabetes already have renal involvement (American College of Obstetricians and Gynecologists, 2020c). As many as 40 percent of these will develop preeclampsia (Vidaeff, 2008). In addition, Ambia and associates (2020) reported that the rates of preterm delivery, preeclampsia, and fetal-growth restriction were significantly higher in diabetic women with proteinuria >300 mg/d compared with rates in diabetic gravidas whose 24-hour protein excretion was <300 mg/d.

In general, pregnancy does not appear to worsen diabetic nephropathy. In one prospective study of 43 women with diabetes, diabetic nephropathy did not progress through 12 months after delivery (Young, 2012). Most of these women had only mild renal impairment. Conversely, pregnant women with moderate to severe renal impairment may have accelerated progression of their disease (Vidaeff, 2008). As in women with glomerulopathies, hypertension or substantial proteinuria before or during pregnancy is a major predictive factor for ultimate progression to renal failure in women with diabetic nephropathy.

Diabetic Retinopathy

Retinal vasculopathy is a highly specific complication of both type 1 and type 2 diabetes. In the United States, diabetic retinopathy is the most important cause of visual impairment in working-aged adults. The first and most common visible lesions are small microaneurysms followed by blot hemorrhages that form when erythrocytes escape from the aneurysms. These areas leak serous fluid that creates hard exudates. Such features are termed *background* or *nonproliferative retinopathy*.

With increasingly severe retinopathy, the abnormal vessels of background eye disease become occluded. This leads to retinal ischemia and infarctions that appear as *cotton wool exudates.* These are considered *preproliferative retinopathy.* In response to ischemia, neovascularization begins on the retinal surface and out into the vitreous cavity. Vision is obscured when these vessels bleed. Laser photocoagulation before hemorrhage reduces the rate of visual loss progression and blindness by half. The procedure may be performed during pregnancy when indicated.

In one study of nearly 500 pregnancies in women with type 1 diabetes, a third had prepregnancy retinopathy and 16 percent of these showed worsening (Bourry, 2021). Almost 25 percent of those without prepregnancy retinopathy developed disease during pregnancy. Fortunately, development of sight-threatening retinopathy was rare, and only 4 percent of patients followed postpartum had progression of disease.

Another group of investigators evaluated 80 women with type 2 diabetes and identified retinopathy, mostly mild, in 14 percent during early pregnancy (Rasmussen, 2010). Progression was identified in 14 percent.

Other risk factors that have been associated with progression of retinopathy include hypertension, higher levels of insulin-like growth factor 1, placental growth factor, and macular edema identified in early pregnancy (Huang, 2015; Vestgaard, 2010). The American Academy of Ophthalmology (2019)

recommends that pregnant women with overt diabetes should be offered retinal assessment after the first prenatal visit. Subsequent eye examinations depend on severity of retinopathy and level of glucose control. Currently, most agree that laser photocoagulation and good glycemic control during pregnancy minimize the potential for deleterious effects of pregnancy.

Ironically, "acute" rigorous metabolic control during pregnancy has been linked to acute worsening of retinopathy. In a study of 201 women with retinopathy, almost 30 percent suffered eye disease progression during pregnancy despite intensive glucose control (McElvy, 2001). That said, Wang and coworkers (1993) observed that although retinopathy worsened during the critical months of rigorous glucose control, long-term progression of eye disease actually slowed.

Diabetic Neuropathy

Peripheral, symmetrical sensorimotor diabetic neuropathy is uncommon in pregnant women. However, one form of this, *diabetic gastropathy*, can be troublesome during pregnancy. It causes nausea and vomiting, nutritional problems, and difficult glucose control. Affected women are advised that this complication is associated with a high risk of morbidity and poor perinatal outcome (Kitzmiller, 2008). Treatment with metoclopramide and dopamine D2 receptor antagonists is sometimes successful. Gastric neurostimulators have shown success during pregnancy (Fuglsang, 2015). Treatment of *hyperemesis gravidarum* can be challenging, and we routinely provide insulin initially by continuous infusion for diabetic women who are admitted with this condition (Chap. 57, p. 1015).

Diabetic Ketoacidosis

This serious complication develops in approximately 1 percent of diabetic pregnancies and is most often encountered in women with type 1 diabetes (Ehrmann, 2020). It is increasingly being reported in women with type 2 or even those with gestational diabetes (Bryant, 2017; Sibai, 2014). Diabetic ketoacidosis (DKA) may develop with hyperemesis gravidarum, infection, insulin noncompliance, insulin pump failures, β-mimetic drugs given for tocolysis, and corticosteroids given to induce fetal lung maturation. DKA results from an insulin deficiency combined with an excess in counter-regulatory hormones such as glucagon. This leads to gluconeogenesis and ketone body formation. The ketone body β-hydroxybutyrate is synthesized at a much greater rate than acetoacetate, which is preferentially detected by commonly used ketosis-detection methods. Thus, serum or plasma assays for β-hydroxybutyrate more accurately reflect true ketone body levels.

The maternal mortality rate with DKA is <1 percent, but perinatal mortality rates associated with a single episode of DKA may reach 35 percent (Bryant, 2017; Guntupalli, 2015). Noncompliance is a prominent factor, and this and DKA were historically considered prognostically bad signs in pregnancy (Pedersen, 1974). Importantly, pregnant women usually develop DKA at lower blood glucose thresholds than when nonpregnant. In a study from Parkland Hospital, the mean glucose level for pregnant women with DKA was 380 mg/dL, and the mean HbA_{1C} value was 10 percent (Bryant, 2017). Euglycemic ketoacidosis during pregnancy also is possible but is rare (Sibai, 2014; Smati, 2020).

One management protocol for diabetic ketoacidosis is shown in Table 60-7. An important cornerstone of management is

TABLE 60-7. Management of Diabetic Ketoacidosis During Pregnancy

Laboratory Assessment
Obtain arterial blood gases to document degree of acidosis present; measure glucose, creatinine, ketones, and electrolyte levels at 1- to 2-hour intervals
Insulin
Low-dose, intravenous Loading dose: 0.2–0.4 U/kg Maintenance: 2–10 U/hr
Fluids
Isotonic sodium chloride for 3L, then 0.45% saline Total replacement in first 12 hours of 4–6 L 1 L in first hour 500–1000 mL/hr for 2–4 hours 250 mL/hr until 80 percent replaced
Glucose
Begin 5-percent dextrose in 0.45% saline when glucose plasma level reaches 250 mg/dL (14 mmol/L)
Potassium
If initially normal or reduced, an infusion rate up to 15–20 mEq/hr may be required; if elevated, wait until levels decrease into the normal range, then add to intravenous solution in a concentration of 20–30 mEq/L
Bicarbonate
Add one ampule (44 mEq) to 1 L of 0.45 normal saline if serum pH is <7.1

Data from Bryant, 2017; Powers, 2018; Sibai, 2014.

vigorous rehydration with crystalloid solutions of normal saline or Ringer lactate.

Infections

The rates of many infections are higher in diabetic pregnant women. Common ones include candidal vulvovaginitis, bacterial urinary and respiratory tract infections, and puerperal pelvic sepsis. However, in one study of more than 1250 diabetic gravidas screened before 16 weeks' gestation, rates of bacterial vaginosis or vaginal colonization with *Candida* or *Trichomonas* species were not increased (Marschalek, 2016).

In one population-based study of almost 200,000 pregnancies, the risk of asymptomatic bacteriuria in women with diabetes was increased twofold (Sheiner, 2009). Another study found positive urine culture results in 25 percent of diabetic women (Alvarez, 2010). In a 2-year analysis of pyelonephritis in pregnant women at Parkland Hospital, 5 percent with diabetes developed pyelonephritis compared with 1.3 percent without diabetes (Hill, 2005). Rates of urinary tract infections can be minimized by screening and eradicating asymptomatic bacteriuria (Chap. 56, p. 995).

Last, Johnston and colleagues (2017) reported that 16.5 percent of women with pregestational diabetes had postoperative wound complications following cesarean delivery. Prevention options are described in Chapter 30 (p. 550).

Preconceptional Care

Because of the close relationship between pregnancy complications and maternal glycemic control, efforts to achieve glucose targets are typically more aggressive during pregnancy. Unfortunately, nearly half of pregnancies in the United States are unplanned, and diabetic women frequently begin pregnancy with suboptimal glucose control (Finer, 2016; Kim, 2005). Management preferably should begin before pregnancy and then include specific goals during each trimester.

To minimize early pregnancy loss and congenital malformations, the National Preconception Health and Healthcare Initiative Clinical Workgroup established values for optimal glycemic control before conception (Frayne, 2016). This was defined as a HbA_{1c} level <6.5 percent in women with pregestational diabetes. The American Diabetes Association (2017b) has also defined optimal preconceptional glucose control in those using insulin. Reflective values are self-monitored preprandial glucose levels of 70 to 100 mg/dL, peak 2-hour postprandial values of 100 to 120 mg/dL, and mean daily glucose concentrations <110 mg/dL.

In one prospective population-based study of 933 pregnant women with type 1 diabetes, the risk of congenital malformations was not demonstrably higher with HbA_{1c} levels <6.9 percent compared with the risk in more than 70,000 nondiabetic gravidas (Jensen, 2010). However, a substantial fourfold greater risk for malformations was found for HbA_{1c} levels >10 percent (see Fig. 60-1). Another study found fewer adverse outcomes with improved HbA_{1c} values from conception to midpregnancy (Davidson, 2020).

If indicated, evaluation and treatment for diabetic complications such as retinopathy or nephropathy should be instituted before pregnancy. Last, folate, 400 μg/d orally, is given periconceptionally and during early pregnancy to decrease the risk of neural-tube defects (Egan, 2020).

First-trimester Care

Careful monitoring of glucose control is essential. For this reason, we routinely hospitalize women with overt diabetes during early pregnancy to initiate an individualized glucose control program and provide education. This also affords an opportunity to assess the extent of diabetic vascular complications and precisely establish gestational age. The checklist provided by the Society for Maternal-Fetal Medicine (2020) is helpful. Some initial evaluations done at Parkland Hospital include assessment of 24-hour urine protein excretion and serum creatinine level, retinal examination, and echocardiogram if chronic hypertension is comorbid.

First-trimester screening for aneuploidy may include measurement of maternal serum pregnancy-associated plasma protein A (PAPP-A), β-human chorionic gonadotropin (hCG), and ultrasound measurement of fetal nuchal translucency (Chap. 17, p. 333). Noninvasive prenatal testing with cell-free DNA also is suitable. Although initially thought not to be different in women with pregestational diabetes, one analysis of more than 100 insulin-treated women identified reductions in median PAPP-A and β-hCG levels compared with gravidas without diabetes (Gurram, 2014). Not surprisingly, they detected no difference in nuchal translucency measurements. When calculating aneuploidy risks in women with diabetes, these differences should be considered.

Insulin Treatment

The gravida with overt diabetes is best treated with insulin. Although oral hypoglycemic agents have been used successfully for gestational diabetes (p. 1083), these agents are not currently recommended for overt diabetes, despite some controversy (American College of Obstetricians and Gynecologists, 2020c). In an international, placebo-controlled trial including 502 insulin-treated women with type 2 diabetes, adjunctive metformin therapy was associated with improved glycemic control, reduced maternal weight gain, lower cesarean delivery rate, and less neonatal adiposity (Feig, 2020). Importantly, the proportion of small-for-gestational age newborns was higher in the insulin plus metformin group, but the rate of composite serious neonatal outcomes was not increased compared with those receiving insulin plus placebo.

Maternal glycemic control can usually be achieved with multiple daily insulin injections and adjustment of dietary intake. Table 60-8 lists the action profiles of common short- and long-acting insulins (Powers, 2018). Subcutaneous insulin infusion by a calibrated pump does not yield better pregnancy outcomes compared with multiple daily injections. However, an infusion pump is a safe alternative in appropriately selected patients (Farrar, 2016). With the advent of sensor-augmented insulin pumps and closed-loop insulin delivery systems, improved glycemic control with either manual or computer-generated insulin adjustments based on continuous glucose monitoring is now possible (Bergenstal, 2021; Stewart, 2016). In one study of insulin pump use in women with type 1 diabetes, total daily insulin doses declined in the first trimester but later rose more than threefold. Postprandial glucose elevations prompted most of the required daily-dose increases (Roeder, 2012). If a

TABLE 60-8. Action Profiles of Commonly Used Insulins

Insulin Type	Onset	Peak (hr)	Duration (hr)
Short-acting (SC)			
Lispro	<15 min	0.5–1.5	2–4
Glulisine	<15 min	0.5–1.5	2–4
Aspart	<15 min	0.5–1.5	2–4
Regular (SC)	30–60 min	2–3	3–6
Regular inhaled	30–60 min	2–3	3
Long-acting (SC)			
Degludec	1–9 hr	—	<12
Detemir	1–4 hr	Minimal[a]	12–24
Glargine	1–4 hr	Minimal[a]	20–24
NPH	1–4 hr	4–10	10–16

[a]Minimal peak activity.

continuous-infusion insulin pump is elected, initiation prepregnancy may help avoid hypoglycemia and ketoacidosis risks associated with the device's learning curve (Sibai, 2014).

Monitoring

Self-monitoring of capillary glucose levels using a glucometer is recommended because this involves the woman in her own care (Dong, 2020). The American Diabetes Association (2017b) recommends fasting and postprandial glucose monitoring, and Table 60-9 lists glucose goals recommended in pregnancy. Currently not standard care, one study showed that longitudinal HbA_{1c} values could be used for risk stratification (Finneran, 2020). Advances in noninvasive glucose monitoring will undoubtedly render intermittent capillary glucose monitoring obsolete. Subcutaneous continuous glucose monitoring devices have shown that pregnant women with diabetes experience significant periods of daytime hyperglycemia and nocturnal hypoglycemia that are undetected by traditional monitoring (Combs, 2012). Such glucose monitoring systems, coupled with a continuous insulin pump, offer the potential of an "artificial pancreas" to avoid hypo- or hyperglycemia during pregnancy (Bergenstal, 2021).

Diet

Nutritional planning includes appropriate weight gain through carbohydrate and caloric modifications based on height, weight, and degree of glucose intolerance (American Diabetes Association, 2017b; Egan, 2020). The mix of carbohydrate, protein, and fat is adjusted to meet the metabolic goals and individual patient preferences. A minimum of 175 g/d of carbohydrates ideally is provided. In one analysis of more than 200 obese pregnant women with glucose intolerance, a lower carbohydrate intake, particularly late in pregnancy, was associated with lower fat mass in offspring at birth (Renault, 2015). Allotted carbohydrates are distributed throughout the day in three small- to moderate-sized meals and two to four snacks. Weight loss is not recommended, but modest caloric restriction may be appropriate for overweight or obese women. An ideal dietary composition is 55 percent carbohydrate, 20 percent protein, and 25 percent fat, of which <10 percent is saturated fat.

TABLE 60-9. Self-Monitored Capillary Blood Glucose Goals

Specimen	Level (mg/dL)
Fasting	≤95
Premeal	≤100
1-hr postprandial	≤140
2-hr postprandial	≤120
0200–0600	≥60
Mean (average)	100
Hemoglobin A_{1c}	≤6%

Hypoglycemia

Diabetic control can be unstable in the first half of pregnancy, and the incidence of hypoglycemia peaks during the first trimester. One study found hypoglycemic events—blood glucose values <40 mg/dL—in 37 of 60 women with type 1 diabetes. A fourth of these were considered severe because the women were unable to treat their own symptoms and required assistance from another person (Chen, 2007). *Caution is recommended when attempting to achieve euglycemia in women with recurrent episodes of hypoglycemia.*

From one Cochrane database review, loose glycemic control, defined as fasting glucose values >120 mg/dL, was associated with greater risks for preeclampsia, cesarean delivery, and birthweight >90th percentile compared with women with tight or moderate control (Middleton, 2016). With *very* tight control, defined by fasting values <90 mg/dL, no obvious benefits were gained, but the number of cases of hypoglycemia increased.

■ Second-trimester Care

Maternal serum alpha-fetoprotein determination at 16 to 20 weeks' gestation is used in association with targeted sonographic examination to detect neural-tube defects and other anomalies (Chap. 17, p. 338). These serum levels may be lower in diabetic pregnancies, and interpretation is altered accordingly. Because the incidence of congenital cardiac anomalies shown in Table 60-6 is increased fivefold in mothers with diabetes, fetal echocardiography is an important part of second-trimester sonographic evaluation (Society for Maternal-Fetal Medicine, 2020). Dashe and coworkers (2009) cautioned that detection of fetal anomalies in obese diabetic women is more difficult than in similarly sized women without diabetes.

Regarding second-trimester glucose control, normoglycemia with self-monitoring continues to be the goal. After the first trimester's glucose instability, a stable period ensues. This is then followed by higher insulin requirements. These stem from the enhanced peripheral resistance to insulin that is related to pregnancy and is described in Chapter 4 (p. 57).

Although most women with pregestational diabetes require a higher total daily insulin dose with advancing gestational age, a small proportion will experience a reduction in their daily dose later in pregnancy. The significance of this drop remains uncertain. One Australian study evaluated women with falling

insulin requirements (FIR), defined as a ≥15 percent drop in the peak total daily insulin dose after 20 weeks' gestation (Padmanabhan, 2017). In 158 women with type 1 and type 2 diabetes and FIR, the risk for a composite of adverse outcomes indicative of placental insufficiency was fourfold greater than in those without FIR. The composite primary outcome included preeclampsia, fetal-growth disorders, delivery before 30 weeks' gestation, placental abruption, and fetal death before 20 weeks. FIR was more common in women with type 1 diabetes.

Third-trimester Care and Delivery

During the past several decades, the threat of late-pregnancy stillbirth in women with diabetes prompted recommendations for various fetal surveillance programs beginning in the third trimester. Such protocols include fetal movement counting, periodic fetal heart rate monitoring, intermittent biophysical profile evaluation, and contraction stress testing (Chap. 20, p. 384). None of these techniques has been subjected to prospective randomized clinical trials, and their primary value seems related to their low false-negative rates. The American College of Obstetricians and Gynecologists (2020c, 2021) suggests initiating such testing at 32 to 34 weeks' gestation. With reassuring testing and no other complications, delivery is anticipated between $39^{0/7}$ and $39^{6/7}$ weeks.

At Parkland Hospital, women with diabetes are seen in a specialized Maternal–Fetal Medicine clinic every 2 weeks. During these visits, glycemic control records are evaluated, and insulin doses are adjusted. Women are routinely instructed to perform fetal kick counts beginning early in the third trimester. At 34 weeks' gestation, admission to our High-Risk Pregnancy Unit is offered to all insulin-treated women. Approximately half of these women choose admission. While in the hospital, they continue daily fetal movement counts and undergo fetal heart rate monitoring three times a week. With no other complications, delivery at Parkland is typically planned for 38 weeks.

At the University of Alabama at Birmingham, weekly antenatal testing is initiated no later than 34 weeks' gestation. Twice-weekly testing is reserved for those with poorly controlled diabetes or supervening medical or obstetrical complications. Delivery is planned for 39 weeks' gestation in those with good glycemic control and reassuring antenatal testing. Earlier delivery is planned for those with poor glycemic control or significant comorbidities.

For vaginal delivery, labor induction may be attempted when the fetus is not excessively large and the cervix is considered favorable (Chap. 26, p. 486). Cesarean delivery at or near term has frequently been used to avoid the traumatic birth of a large fetus in a woman with diabetes. In women with more advanced diabetes, especially those with vascular disease, the reduced likelihood of successful labor induction remote from term has also contributed to an increased cesarean delivery rate.

In an analysis of pregnancy outcomes of diabetic women from University of Alabama at Birmingham according to the White classification, the rates of cesarean delivery and preeclampsia escalated with White class (Bennett, 2015). In another study, a HbA_{1c} level >6.4 percent at delivery was independently associated with urgent cesarean delivery (Miailhe, 2013). This suggests that tighter glycemic control during the third trimester might reduce late fetal compromise and cesarean delivery for fetal indications. Many of these women have undergone prior cesarean delivery. Somewhat related to this, the cesarean delivery rate for women with overt diabetes has remained at approximately 80 percent for the past 40 years at Parkland Hospital.

Reducing or withholding the dose of long-acting insulin on the day of delivery is recommended. Regular insulin should be used to meet most or all of the insulin needs of the mother during this time, because insulin requirements typically drop markedly after delivery. During labor, continuous insulin infusion by calibrated intravenous pump is most satisfactory (Table 60-10). The woman should be adequately hydrated intravenously and given glucose in sufficient amounts to maintain euglycemia. Capillary or plasma glucose levels are checked hourly during active labor, and regular insulin is administered accordingly.

Puerperium

Often, many diabetic women may require virtually no insulin for the first 24 hours or more postpartum. Subsequently, insulin requirements may fluctuate markedly during the next few days. Infection must be promptly detected and treated. When appropriate, oral agents can be restarted. For type 2 diabetic women who will be transitioned to oral agents, this can be done on postoperative day 1.

Counseling in the puerperium should include a discussion of birth control. Effective contraception is especially important in women with overt diabetes to allow optimal glucose control before subsequent conception (Chap. 38, p. 664).

GESTATIONAL DIABETES

In the United States in 2016, almost 6 percent of pregnancies were complicated by gestational diabetes (Deputy, 2018). Worldwide, its prevalence differs according to race, ethnicity, age, and body composition and by screening and diagnostic criteria. As discussed in the following sections, several persisting controversies pertain to the diagnosis and treatment of gestational diabetes.

TABLE 60-10. Insulin Management for Labor Induction or Scheduled Cesarean Delivery

Give evening dose insulin.
Withhold morning dose.
Infuse intravenous normal saline at 100–125 mL/hr.
Regular insulin is infused at 1–1.25 units/hr if glucose levels >100 mg/dL.
Measure glucose levels hourly.
With active labor or if glucose levels are >70 mg/dL, change from intravenous saline to 5% dextrose given at 100–150 mL/hr with a target glucose level of ~100mg/dL.

The word *gestational* implies that diabetes is induced by pregnancy—ostensibly because of exaggerated physiological changes in glucose metabolism (Chap. 4, p. 57). Gestational diabetes is defined as carbohydrate intolerance of variable severity with its onset or first recognition during pregnancy (American College of Obstetricians and Gynecologists, 2019a). This definition applies whether or not insulin is used for treatment and undoubtedly includes some women with previously unrecognized overt diabetes.

The term *gestational diabetes* aims to communicate the need for enhanced surveillance during pregnancy and to stimulate further testing postpartum. The most important perinatal correlate is excessive fetal growth, which may result in both maternal and fetal birth trauma. The likelihood of fetal death with appropriately treated gestational diabetes is not different from that in the general population. More than half of women with gestational diabetes ultimately develop overt diabetes in the ensuing 20 years. Moreover, mounting evidence implicates long-range complications that include obesity and diabetes in their offspring.

Screening and Diagnosis

Despite almost 50 years of research, there is still no agreement on the optimal screening method for gestational diabetes. The difficulty in achieving consensus is underscored by the controversy following publication of the single-step approach shown in Table 60-11, which assesses the glucose values following a 75-g oral glucose load. This strategy is espoused by the International Association of Diabetes and Pregnancy Study Groups Consensus Panel (2010) and was greatly influenced by results of the Hypoglycemia and Pregnancy Outcomes (HAPO) study, described subsequently. Although the American Diabetes Association (2019) supports this new scheme, the American College of Obstetricians and Gynecologists (2019a) continues to recommend a two-step approach to screen and then diagnose gestational diabetes. Similarly, the National Institutes of Health (NIH) Consensus Development Conference in 2013 concluded that evidence is insufficient to adopt a one-step approach.

The recommended two-step approach begins with either universal or risk-based selective screening using a 50-g, 1-hour oral glucose challenge test. Participants in the Fifth International Workshop Conferences on Gestational Diabetes endorsed use of *selective screening* criteria shown in Table 60-12 (Metzger, 1998).

TABLE 60-11. Threshold Values for Diagnosis of Gestational Diabetes with 75-g OGTT

Plasma Glucose	Glucose Concentration Threshold[a]		Above Threshold (%)
	mmol/L	mg/dL	Cumulative
Fasting	5.1	92	8.3
1-hr OGTT	10.0	180	14.0
2-hr OGTT	8.5	153	16.1[b]

[a]One or more of these values from a 75-g OGTT must be equaled or exceeded for the diagnosis of gestational diabetes.
[b]In addition, 1.7% of participants in the initial cohort were unblinded because of fasting plasma glucose levels >5.8 mmol/L (105 mg/dL) or 2-hr OGTT values >11.1 mmol/L (200 mg/dL), bringing the total to 17.8%.
OGTT = oral glucose tolerance test.

TABLE 60-12. Risk-Based Recommended Screening Strategy for Detecting GDM[a]

GDM risk assessment: should be ascertained at the first prenatal visit

Low Risk: Blood glucose testing not routinely required if all the following are present:
- Member of an ethnic group with a low prevalence of GDM
- No known diabetes in first-degree relatives
- Age <25 years
- Weight normal before pregnancy
- Weight normal at birth
- No history of abnormal glucose metabolism
- No history of poor obstetrical outcome

Average Risk: Perform blood glucose testing at 24 to 28 weeks using either:
- Two-step procedure: 50-g oral glucose challenge test (GCT), followed by a diagnostic 100-g OGTT for those meeting the threshold value in the GCT
- One-step procedure: diagnostic 100-g OGTT performed on all subjects

High Risk: Perform blood glucose testing as soon as feasible, using the procedures described above, if one or more of these are present:
- Severe obesity
- Strong family history of type 2 diabetes
- Previous history of GDM, impaired glucose metabolism, or glucosuria
- If GDM is not diagnosed, blood glucose testing should be repeated at 24 to 28 weeks' gestation or at any time symptoms or signs suggest hyperglycemia

[a]Criteria of the Fifth International Workshop-Conference on Gestational Diabetes.
GDM = gestational diabetes mellitus; OGTT = oral glucose tolerance test.

Conversely, the American College of Obstetricians and Gynecologists (2019a) recommends *universal screening* of pregnant women with a protocol that provides a 50-g oral glucose load and that is followed in 1 hour by a laboratory-based blood glucose test. It is suggested that attempts to identify the minority of women who should *not* be screened would add unnecessary complexity. Screening should be performed between 24 and 28 weeks' gestation in those women not known to have glucose intolerance earlier in pregnancy. This *50-g screening test* is followed by a *diagnostic 100-g, 3-hour oral glucose tolerance test (OGTT)* if screening results meet or exceed a predetermined plasma glucose concentration.

For the 50-g screening test, the plasma glucose level is measured 1 hour after a 50-g oral glucose load without regard to the time of day or time of last meal. In an earlier review, the pooled sensitivity for a threshold of 140 mg/dL ranged from 74 to 83 percent depending on 100-g thresholds used for diagnosis (van Leeuwen, 2012). Sensitivity estimates for a 50-g screen threshold of 135 mg/dL improved only slightly to 78 to 85 percent, but specificity dropped from a range of 72 to 85 percent for 140 mg/dL to 65 to 81 percent. Using a threshold of 130 mg/dL marginally improves sensitivity with a further decline in specificity (Donovan, 2013). In the absence of clear evidence supporting one cutoff value over another, the American College of Obstetricians and Gynecologists (2019a) sanctions using any one of these three 50-g screen thresholds. At Parkland Hospital, we continue to use 140 mg/dL as the screening threshold to prompt the 100-g test. The threshold used at the University of Alabama at Birmingham is 135 mg/dL.

Justification for screening and treatment of women with gestational diabetes was strengthened by a randomized treatment trial in 1000 women (Crowther, 2005). Women diagnosed with gestational diabetes after a 75-g OGTT and assigned to receive dietary advice with blood glucose monitoring plus insulin therapy were compared with a cohort assigned to usual prenatal care. The former group had a significantly lower risk of a composite perinatal adverse outcome that included death, shoulder dystocia, bone fracture, and nerve palsy. Macrosomia defined by birthweight ≥4000 g complicated 10 percent of deliveries in the intervention group compared with 21 percent in the routine prenatal care group. Cesarean delivery rates were almost identical in the two study groups.

Slightly different results were reported by the Maternal–Fetal Medicine Units Network randomized trial of 958 women identified with mild gestational diabetes using a two-step screening and diagnosis approach (Landon, 2009). They reported no differences in rates of composite morbidity that included stillbirth, birth trauma, and neonatal hypoglycemia, hyperinsulinemia, and hyperbilirubinemia. Secondary analyses did demonstrate a 50-percent reduction in macrosomia, fewer cesarean deliveries, and a significant decrease in shoulder dystocia rate—1.5 versus 4 percent—in treated versus routine care groups.

Based largely on these two landmark studies, the U.S. Preventive Services Task Force (2021) recommends universal screening in low-risk women after 24 weeks' gestation. However, the Task Force concluded that evidence is insufficient to assess the balance of benefits versus harms of screening before 24 weeks. Earlier screening in obese women did not result in better outcomes (Harper, 2020).

TABLE 60-13. Diagnosis of Gestational Diabetes Mellitus Using Threshold Glucose Values from 100-g Oral Glucose Tolerance Test[a,b]

	NDDG[c]		Carpenter–Coustan[d]	
Time	(mg/dL)	(mmol/L)	(mg/dL)	(mmol/L)
Fasting	105	5.8	95	5.3
1-hr	190	10.6	180	10.0
2-hr	165	9.2	155	8.6
3-hr	145	8.0	140	7.8

[a]The test should be performed when the patient is fasting.
[b]Two or more of the venous plasma glucose concentrations listed are met or exceeded for a positive diagnosis.
[c]Serum glucose level.
[d]Serum or plasma glucose level.
NDDG = National Diabetes Data Group.
Data from American College of Obstetricians and Gynecologists, 2019a; American Diabetes Association, 2019; Ferrara, 2002.

The optimal OGTT to identify gestational diabetes also is debated. Proposed criteria for interpretation of the diagnostic 100-g OGTT are shown in Table 60-13. Criteria for the 75-g OGTT are shown in Table 60-11. A secondary analysis of the Maternal-Fetal Medicine Units Network treatment trial showed that women diagnosed with either the National Diabetes Data Group (NDDG) or the Carpenter-Coustan criteria benefited from treatment (Harper, 2016). However, the number needed to treat to prevent a shoulder dystocia was higher for the Carpenter-Coustan criteria. Others report similar observations (Ghaffari, 2020). At Parkland Hospital, we use the NDDG criteria for diagnosis, whereas Carpenter-Coustan criteria are preferred at the University of Alabama at Birmingham.

Controversies of Screening and Diagnosis

The HAPO study was a 7-year international epidemiological study of 23,325 pregnant women at 15 centers in nine countries analyzing the association of various levels of glucose intolerance during the third trimester with adverse perinatal outcomes (HAPO Study Cooperative Research Group, 2008). Blood glucose levels were stratified into seven categories (Fig. 60-4). These values were then correlated with rates for birthweight >90th percentile, primary cesarean delivery, neonatal hypoglycemia, and cord serum C-peptide levels >90th percentile. Cord serum C-peptide is secreted in equimolar concentrations with insulin and reflects fetal β-islet cell function. Findings generally supported the supposition that increasing plasma glucose levels were associated with increasing adverse outcomes.

The International Association of Diabetes and Pregnancy Study Group

This workshop conference in 2008 concerned the diagnosis and classification of gestational diabetes. After reviewing the results of the HAPO study, a panel developed recommendations for the diagnosis and classification of hyperglycemia during pregnancy.

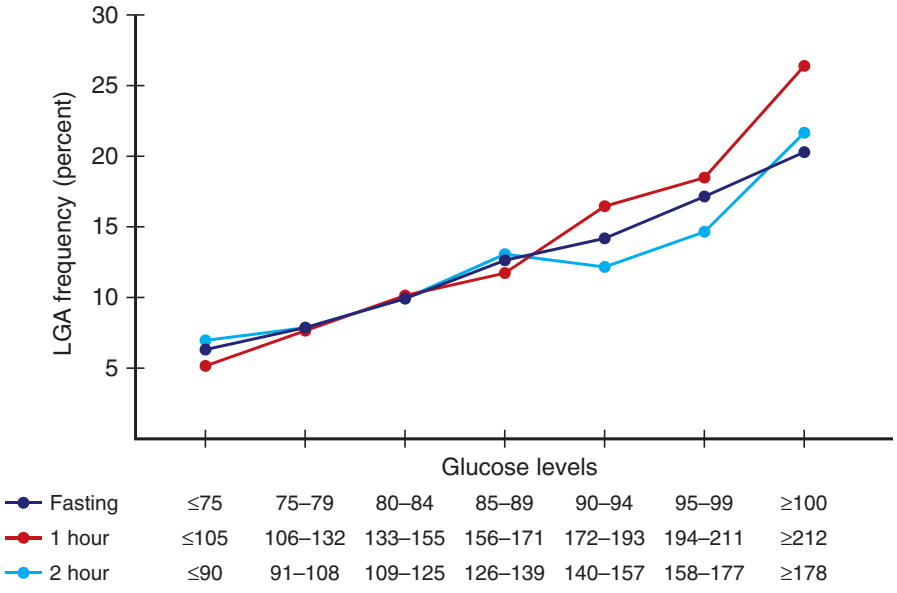

FIGURE 60-4 Hyperglycemia and Adverse Pregnancy Outcome (HAPO) Study. The frequency of newborn birthweight ≥90th percentile for gestational age plotted against glucose levels fasting and at 1- and 2-hr intervals following a 75-g oral glucose load. LGA = large for gestational age. (Reproduced with permission from HAPO Study Cooperative Research Group, Metzger BE, Lowe LP, et al: Hyperglycemia and adverse pregnancy outcomes, N Engl J Med. 2008 May 8;358(19):1991–2002.)

This panel allowed for the diagnosis of overt diabetes during pregnancy as shown in Table 60-4. It also recommended a single-step approach to the diagnosis of gestational diabetes using the 75-g, 2-hour OGTT and thresholds derived using an arbitrary 1.75 odds ratio of outcomes such as LGA birthweight and cord serum C-peptide levels >90th percentile. Only one of these thresholds, shown in Table 60-11, would need to be met or exceeded to make the diagnosis of gestational diabetes.

During their deliberations, the IADPSG estimated that implementation of these recommendations would raise the prevalence of gestational diabetes in the United States to 17.8 percent! Said another way, using this approach, the number of women with mild gestational diabetes would increase almost threefold with no evidence of treatment benefit (Cundy, 2012). Feldman and coworkers (2016) evaluated the implementation of the IADPSG paradigm in a before-after analysis that included more than 6000 women. Compared with a two-step approach, the new strategy was associated with a significant rise in gestational diabetes diagnosis rates but not with reduced macrosomia rates. Remarkably, they identified a higher primary cesarean delivery rate associated with adoption of the IADPSG recommendations. The American Diabetes Association (2013, 2019) initially recommended adopting this new approach, based on benefits inferred from trials in women identified using a two-step approach described earlier. However, it now concludes that data also support a two-step strategy.

NIH Consensus Development Conference

Prompted by these disparate recommendations, the NIH Consensus Development Conference on Diagnosing Gestational Diabetes Mellitus (2013) was convened. The panel found insufficient evidence to adopt the one-step diagnostic process proposed by the IADPSG and recommended continuation of the two-step approach. The Consensus Conference panel did also suggest that further studies resolving the beneficial uncertainties associated with the one-step approach could warrant revision of their conclusions.

A recent trial compared the IADPSG single-step approach to the more traditional two-step approach in almost 24,000 women (Hillier, 2021). Consistent with the IADPSG prediction, the incidence of gestational diabetes was 16.5 percent in those who underwent single-step testing compared with 8.5 percent in women assigned to two-step testing. However, incidences of hypertensive disorders of pregnancy, primary cesarean delivery, LGA newborns, and/or a perinatal composite outcome including measures of birth trauma and perinatal death were not materially different between testing groups. Thus, this large and pragmatic trial does *not* show maternal or perinatal benefit and thus does not justify the increased patient and healthcare costs of broadening the diagnosis of gestational diabetes using the proposed single-step approach (Casey, 2021).

■ Maternal and Fetal Effects

Adverse consequences of gestational diabetes differ from those of pregestational diabetes (see Table 60-5). Similar to women with overt diabetes, adverse maternal effects associated with gestational diabetes include a higher frequency of hypertension and cesarean delivery.

Unlike women with overt diabetes, women with gestational diabetes do not appear to have fetuses with substantially higher rates of anomalies than the general obstetrical population (American College of Obstetricians and Gynecologists, 2019a; Sheffield, 2002). In a study of more than 1 million women from the Swedish Medical Birth Registry, major malformation rates were marginally elevated in fetuses of gestational diabetics compared with those of nondiabetic controls—2.3 versus 1.8 percent (Fadl, 2010).

From this Registry, the stillbirth rate was not higher. Additionally, the stillbirth rate was not increased in an analysis of more than 800,000 pregnancies from 2005 through 2011 (Jovanovič, 2015). That said, women with *elevated* fasting glucose levels have elevated rates of unexplained stillbirths similar to those of women with overt diabetes. This increasing risk with progressive maternal hyperglycemia emphasizes the importance of identifying women with evidence of preexisting diabetes early in pregnancy (see Table 60-4).

Fetal Macrosomia

The primary effect attributed to gestational diabetes is excessive fetal size that is variably defined and discussed in Chapter 47

(p. 832). The perinatal goal is to avoid difficult delivery from macrosomia and concomitant birth trauma associated with shoulder dystocia. In one analysis of more than 80,000 vaginal births in Chinese women, the calculated risk for shoulder dystocia in newborns weighing ≥4200 g was 76-fold greater than the risk in those weighing <3500 g (Cheng, 2013). However, the odds ratio for shoulder dystocia in women with diabetes was <2. Said another way, although gestational diabetes is certainly a risk factor, it accounts for only a small number of pregnancies complicated by shoulder dystocia.

One study identified shoulder dystocia in approximately 4 percent of women with mild gestational diabetes compared with <1 percent of women with a 50-g glucose screen result <120 mg/dL (Landon, 2011). The excessive shoulder and trunk fat that commonly characterizes the macrosomic newborn of a diabetic mother predisposes such neonates to shoulder dystocia or cesarean delivery (Durnwald, 2004; McFarland, 2000). However, one prospective study of fetal adipose measurements demonstrated no differences between measurements in 630 offspring of women with gestational diabetes and 142 without diabetes (Buhling, 2012). The authors attributed this negative finding to successful treatment of gestational diabetes.

Insulin-like growth factors also influence fetal growth. These proinsulin-like polypeptides are produced by virtually all fetal organs and are potent stimulators of cell differentiation and division. Although not a current clinical tool, one study found that maternal insulin-like growth factor 1 levels strongly correlated with birthweight (Luo, 2012). The HAPO Study Cooperative Research Group (2008) also found dramatic elevations in cord serum C-peptide levels associated with rising maternal glucose levels following a 75-g OGTT. C-peptide levels >90th percentile were found in almost a third of newborns in the highest glucose categories. Other factors implicated in macrosomia include epidermal growth factor, fibroblast growth factor, platelet-derived growth factor, leptin, and adiponectin (Grissa, 2010; Loukovaara, 2004; Mazaki-Tovi, 2005).

Maternal body mass index (BMI) is an independent and more substantial risk factor for fetal macrosomia than is glucose intolerance (Ehrenberg, 2004; Mission, 2013). In a secondary analysis of women with either untreated mild gestational diabetes or normal glucose tolerance testing results, higher BMI levels were associated with rising birthweight, regardless of glucose levels (Stuebe, 2012). Another analysis found that gestational diabetes, compared with obesity or gestational weight gain, contributed the least to the population-attributable fraction of LGA neonates (Kim, 2014). The highest fraction of LGA neonates was attributable to maternal obesity plus excessive gestational weight gain. Similarly, Egan and colleagues (2014) found that excessive gestational weight gain is common in women with gestational diabetes and confers an additive risk for fetal macrosomia.

Weight distribution also seems to play a role because the risk of gestational diabetes is greater with maternal truncal obesity. One cohort study found that increased maternal abdominal subcutaneous fat thickness at 18 to 22 weeks' gestation correlated with BMI and was a better predictor of gestational diabetes (Suresh, 2012).

Neonatal Hypoglycemia

Hyperinsulinemia may provoke severe neonatal hypoglycemia within minutes of birth, but only three fourths of these episodes occur in the first 6 hours (Harris, 2012). The definition of neonatal hypoglycemia is debated, and recommended clinical thresholds range from 35 to 45 mg/dL. One NIH workshop conference on the topic supported a threshold of 35 mg/dL in term newborns but cautioned that this practice is not strictly evidence based (Hay, 2009). Treating neonates with glucose levels <47 mg/dL did not improve outcomes compared with treating those with glucose levels <36 mg/dL (van Kempen, 2020).

Newborns described by the HAPO Study Cooperative Research Group (2008) had an incidence of clinical neonatal hypoglycemia that rose with increasing maternal OGTT result values defined in Figure 60-4. The frequency varied from 1 to 2 percent, but it was as high as 4.6 percent in women with fasting glucose levels ≥100 mg/dL. Similarly, an analysis of more than 3000 Korean women who underwent a 50-g OGTT found that neonates born to women with a screening result ≥200 mg/dL were 84 times more likely to have hypoglycemia than those born to women with a result <140 mg/dL (Cho, 2016). The risk of neonatal hypoglycemia correlates with umbilical cord C-peptide levels. The risk also rises with birthweight, independent of a maternal diabetes diagnosis (Mitanchez, 2014).

Management

Women with gestational diabetes can be divided into two functional classes using fasting glucose levels. Pharmacological methods are usually recommended if diet modification does not consistently maintain the fasting plasma glucose levels <95 mg/dL or the 2-hour postprandial plasma glucose <120 mg/dL (American College of Obstetricians and Gynecologists, 2019a). Whether pharmacological treatment should be used in women with lesser degrees of fasting hyperglycemia is unclear. No controlled trials have been done to identify ideal glucose targets for fetal risk prevention. On the other hand, the HAPO Study Cooperative Research Group (2008) did demonstrate increased fetal risk at glucose levels below the threshold used for diagnosis of diabetes. The Fifth International Workshop Conference recommended that fasting capillary glucose levels be kept ≤95 mg/dL (Metzger, 2007).

In their systematic review, Hartling and associates (2013) concluded that treating gestational diabetes resulted in significantly lower incidences of preeclampsia, shoulder dystocia, and macrosomia. For example, the calculated risk ratio was 0.50 for delivering a newborn >4000 g after treatment. These investigators caution that the attributed risk for these outcomes is low, especially when glucose values are only moderately elevated. They were unable to demonstrate an effect on neonatal hypoglycemia or on future metabolic outcomes in the offspring.

Diabetic Diet

Nutritional instructions generally include a carbohydrate-controlled diet sufficient to maintain normoglycemia and avoid ketosis. On average, this includes a caloric intake of 30 to 35 kcal/kg/d. In one study, 152 women with gestational diabetes were randomly assigned to a 40- or a 55-percent daily carbohydrate

diet, and no differences in insulin levels and pregnancy outcomes were found (Moreno-Castilla, 2013). The American College of Obstetricians and Gynecologists (2019a) suggests that carbohydrate intake be limited to 33 to 40 percent of the total daily calories. The remaining calories are apportioned to give 20 percent as protein and 40 percent as fat.

The most appropriate dietary approach for women with gestational diabetes has not been established. One metaanalysis of trials of low-glycemic-index diets found that diets higher in complex carbohydrates and dietary fiber reduced the risk of macrosomia and likelihood of insulin use in women with gestational diabetes (Wei, 2016). However, there clearly are limits to what can be accomplished with various dietary approaches alone. Most and Langer (2012) found that insulin was effective in reducing the risk of excessive birthweight in offspring of obese women with gestational diabetes. Casey and colleagues (2015b) also found that dietary treatment alone for morbidly obese women with mild gestational diabetes did not reduce neonatal fat mass or LGA birthweights.

Exercise

Few trials have evaluated exercise specifically for women with gestational diabetes. The American College of Obstetricians and Gynecologists (2020b) recommends regular physical activity that incorporates aerobic and strength-conditioning exercise during pregnancy and extends this to women with gestational diabetes. Two recent metaanalyses demonstrate that structured exercise programs during pregnancy diminish weight gain during pregnancy and even reduce the risk of developing gestational diabetes (Russo, 2015; Sanabria-Martinez, 2015). Exercise during pregnancy in women with gestational diabetes also lowers glucose levels (Jovanovic-Peterson, 1989).

Glucose Monitoring

Hawkins and associates (2008) compared outcomes in 315 women with diet-treated gestational diabetes who used personal glucose monitors against those of 615 gestational diabetics who were also diet-treated but who underwent intermittent fasting glucose evaluation during weekly obstetrical visits. Women using daily blood-glucose self-monitoring had significantly fewer macrosomic newborns. They also gained less weight after diagnosis than women evaluated during clinic visits only. These findings support the common practice of blood-glucose self-monitoring for women with diet-treated gestational diabetes.

Postprandial surveillance for gestational diabetes is superior to preprandial surveillance (DeVeciana, 1995). The American College of Obstetricians and Gynecologists (2019a) and the American Diabetes Association (2019) recommend glucose assessment four times daily. The first check is performed fasting, and the remainder are done 1 or 2 hours after each meal. At Parkland Hospital in women with diet-treated gestational diabetes, changing to postprandial monitoring significantly reduced weekly maternal weight gain (0.45 lb) compared with preprandial monitoring (0.63 lb).

Insulin Treatment

Historically, insulin has been considered standard therapy in women with gestational diabetes when target glucose levels cannot be consistently achieved through nutrition and exercise. Insulin does not cross the placenta, and tight glycemic control can usually be achieved. Insulin therapy is typically added if fasting levels persist above 95 mg/dL in women with gestational diabetes. The American College of Obstetricians and Gynecologists (2019a) also recommends that insulin be considered in women with 1-hour postprandial levels that persistently exceed 140 mg/dL or those with 2-hour levels >120 mg/dL. Importantly, all of these thresholds are extrapolated from recommendations for managing women with overt diabetes.

The starting insulin dose is typically 0.7 to 1.0 U/kg/d and is given in divided doses (American College of Obstetricians and Gynecologists, 2019a). A combination of intermediate-acting and short-acting insulin may be used, and dose adjustments are based on glucose levels at particular times of the day.

At Parkland Hospital, the starting daily dose is divided so that two thirds is given in the morning before breakfast and one third in the evening before dinner. In the morning dose, one third is regular insulin and two thirds are NPH (neutral protamine Hagedorn) insulin. For the evening dose, one half is regular insulin and the other half is NPH. Insulin instruction for these women is accomplished either in a specialized outpatient clinic or during a short hospital stay.

At the University of Alabama at Birmingham, a basal-bolus approach using insulin glargine with rapid-acting insulin at each meal is preferred. After calculating an initial insulin dose, half is given as long-acting glargine at bedtime, and the other half is administered as rapid-acting insulin split into three doses given before breakfast, lunch, and dinner. As shown in Table 60-8, when using insulin analogues such as insulin aspart and insulin lispro, the more rapid onset of action must be considered during postprandial glucose management.

Oral Hypoglycemic Agents

Insulin is the preferred first-line agent for persistent hyperglycemia in women with gestational diabetes (American College of Obstetricians and Gynecologists, 2019a; American Diabetes Association, 2017b). Both organizations acknowledge that several studies support the safety and efficacy of either metformin (Glucophage) or glyburide (Micronase), which is also called glibenclamide (Feig, 2020; Langer, 2000; Nicholson, 2009). Balsells and coworkers (2015) completed a metaanalyses of trials that compared both agents with insulin or with each other. In the seven trials comparing glyburide with insulin, glyburide was associated with higher birthweight, more macrosomia, and more frequent neonatal hypoglycemia. In the six trials comparing metformin with insulin, metformin was associated with less maternal weight gain, more preterm birth, and less severe neonatal hypoglycemia. Women requiring insulin initiation or insulin addition were considered to have failed treatment. On average, such failures occurred in 6 percent of women treated with glyburide and 34 percent of those treated with metformin. In the two studies directly comparing oral hypoglycemic agents, however, treatment failure rates of both agents were equivalent. Moreover, reminiscent of findings from the trial of adjunctive metformin therapy in women with type 2 diabetes previously described, metformin treatment was associated with less maternal weight gain, lower birthweight, and less macrosomia.

Conversely, in a randomized trial of glyburide treatment as an adjunct to diet therapy in 395 women with mild gestational diabetes, Casey and colleagues (2015a) did not identify any significant improvements in pregnancy outcomes in women treated with adjunctive glyburide.

Concerns have also emerged regarding potential adverse outcomes among women treated with glyburide. First, glyburide crosses the placenta and reaches concentrations in the fetus that are more than two thirds of maternal levels (Caritis, 2013). In a study of more than 9000 women with gestational diabetes treated with either insulin or glyburide, a significant rise in rates of neonatal intensive care unit admission, respiratory distress, and neonatal hypoglycemia was associated with glyburide use (Castillo, 2015).

Similarly, metformin reaches fetal serum concentrations nearly equal to maternal levels. However, in one study of 751 women with gestational diabetes who were randomly assigned to metformin or insulin treatment, short-term perinatal adverse events such as neonatal hypoglycemia, respiratory distress syndrome, phototherapy, or birth trauma did not differ between groups (Rowan, 2008; 2011). The fat distribution in children exposed to metformin showed a tendency toward a more favorable pattern. From a smaller randomized metformin trial, at 18 months, offspring exposed as fetuses to metformin were slightly heavier. However, markers of early motor or language development did not differ compared with those in offspring exposed as fetuses to insulin (Ijäs, 2015).

The Food and Drug Administration has not approved glyburide or metformin use for treatment of gestational diabetes. The American College of Obstetricians and Gynecologists (2019a) recognizes both as reasonable choices for second-line glycemic control in women with gestational diabetes. Because long-term outcomes have not been fully studied, the College recommends disclosure of the limitations in current safety data.

Obstetrical Management

In general, for women with gestational diabetes who do not require insulin, early delivery or other interventions are seldom required. There is no consensus regarding the value or timing of antepartum fetal testing. It is typically reserved for women with pregestational diabetes because of the greater stillbirth risk. The American College of Obstetricians and Gynecologists (2019a, 2020c) endorses fetal surveillance in women with gestational diabetes and poor glycemic control. At Parkland Hospital, women with gestational diabetes are routinely instructed to perform daily fetal kick counts in the third trimester. As previously discussed, insulin-treated women are offered inpatient admission after 34 weeks' gestation. Approximately half of these women accept admission, and antepartum fetal monitoring is performed three times each week.

Women with gestational diabetes and adequate glycemic control are managed expectantly. Elective labor induction to prevent shoulder dystocia compared with spontaneous labor remains controversial. In the truncated GINEXMAL randomized trial of 425 women with gestational diabetes, outcomes of labor induction between 38 and 39 weeks' were compared with expectant management until 41 weeks' gestation (Alberico, 2017). Although underpowered, this trial demonstrated no clinically meaningful difference in the cesarean delivery rate between the induction and expectantly managed groups—12.6 versus 11.8 percent. However, with early labor induction, neonatal hyperbilirubinemia rates were significantly higher, and there was a nonsignificant threefold greater shoulder dystocia rate. In a cohort study of 8392 women with gestational diabetes, routine delivery at 38 or 39 weeks' gestation was associated with a lower rate of cesarean delivery but with an elevated rate of neonatal intensive care unit admission (Melamed, 2016).

The American College of Obstetricians and Gynecologists (2019a) recommends that routine labor induction in women with diet-treated gestational diabetes should not occur before 39 weeks' gestation. As mentioned previously, at Parkland Hospital, those treated with insulin are delivered at 38 weeks' gestation. At the University of Alabama at Birmingham, delivery is carried out after 39 weeks.

Elective cesarean delivery to avoid brachial plexus injuries in overgrown fetuses is another issue. The American College of Obstetricians and Gynecologists (2019b) concludes that data are insufficient to determine whether women with *gestational* diabetes whose fetuses have a sonographically estimated weight ≥4500 g should undergo cesarean delivery to avoid risk of birth trauma. In one systematic review, Garabedian and associates (2010) estimated that as many as 588 cesarean deliveries in women with gestational diabetes and an estimated fetal weight of ≥4500 g would be necessary to avoid one case of permanent brachial plexus palsy. In one analysis of 903 women with gestational diabetes, sonographic estimates of fetal weight within 1 month of delivery typically overdiagnosed fetuses as being LGA. Only 22 percent of women estimated to have an LGA fetus actually delivered an overgrown newborn (Scifres, 2015). Still, the American College of Obstetricians and Gynecologists (2020b) acknowledges that prophylactic cesarean delivery may be considered in diabetic women with an estimated fetal weight ≥4500 g.

Postpartum Evaluation

Recommendations for postpartum evaluation are based on the 50- to 75-percent likelihood that women with gestational diabetes will develop overt diabetes within 15 to 25 years (American Diabetes Association, 2019). The Fifth International Workshop Conference on Gestational Diabetes recommended that women diagnosed with gestational diabetes undergo postpartum evaluation with a 75-g OGTT (Metzger, 2007). These recommendations and the classification scheme of the American Diabetes Association are shown in Table 60-14. However, one study of insurance claim data from 2000 to 2013 showed that only 24 percent of women with a pregnancy complicated by gestational diabetes underwent postpartum screening within a year. Less than half of those underwent a 75-g OGTT (Eggleston, 2016). The American College of Obstetricians and Gynecologists (2019a) recommends either a fasting glucose assessment or a 75-g, 2-hour OGTT at 4 to 12 weeks postpartum for the diagnosis of overt diabetes. The American Diabetes Association (2019) recommends testing every 1 to 3 years in women with a history of gestational diabetes but normal postpartum glucose screening.

Women with a history of gestational diabetes are also at risk for cardiovascular complications associated with dyslipidemia,

TABLE 60-14. Fifth International Workshop-Conference: Metabolic Assessments Recommended After Pregnancy with Gestational Diabetes

Time	Test	Purpose
Postdelivery (1–3 d)	Fasting or random plasma glucose	Detect persistent, overt diabetes
Early postpartum (6–12 wk)	75-g, 2-hr OGTT	Postpartum classification of glucose metabolism
1-yr postpartum	75-g, 2-hr OGTT	Assess glucose metabolism
Annually	Fasting plasma glucose	Assess glucose metabolism
Triennially	75-g, 2-hr OGTT	Assess glucose metabolism
Prepregnancy	75-g, 2-hr OGTT	Classify glucose metabolism
Classification of the American Diabetes Association (2013)		
Normal Values	**Impaired Fasting Glucose or Impaired Glucose Tolerance**	**Diabetes Mellitus**
Fasting <100 mg/dL	100–125 mg/dL	≥126 mg/dL
2 hr <140 mg/dL	2 hr ≥140–199 mg/dL	2 hr ≥200 mg/dL
Hemoglobin A_{1c} <5.7%	5.7–6.4%	≥6.5%

OGTT = oral glucose tolerance test.
Data from American Diabetes Association, 2013, 2017a; Metzger, 2007.

hypertension, and abdominal obesity—the *metabolic syndrome* (Chap. 51, p. 903). In a study of 47,909 parous women, the nearly 5000 women with prior gestational diabetes were 2.6 times more likely to be hospitalized for cardiovascular morbidity (Kessous, 2013). Another study evaluated 483 women between 5 and 10 years after being diagnosed with mild gestational diabetes (Varner, 2017). Investigators found no increased risk for developing metabolic syndrome associated with additional pregnancies. However, risk for subsequent diabetes rose almost fourfold if gestational diabetes complicated at least one subsequent pregnancy.

■ Recurrent Gestational Diabetes

In one large metaanalysis, the pooled gestational diabetes recurrence rate was 48 percent. The same investigative group identified elevated maternal BMI, insulin use, fetal macrosomia, and weight gain between pregnancies as additional risk factors for gestational diabetes recurrence (Schwartz, 2015, 2016).

Lifestyle behavioral changes that include weight control and exercise between pregnancies would seem likely to prevent gestational diabetes recurrence. However, women randomized to an exercise program that started before 14 weeks' gestation in a subsequent pregnancy did not have a lower recurrence rate (Guelfi, 2016). Conversely, Ehrlich and coworkers (2011) found that prepregnancy loss of at least two BMI units was associated with a lower subsequent risk of gestational diabetes in women who were overweight or obese in the first pregnancy.

CHAPTER 61

Endocrine Disorders

Endocrinopathies are closely related to pregnancy for several reasons. One example is the gestational proclivity for prodigious hormone secretion, which is perhaps best illustrated by placental lactogen in diabetes. This is the most common endocrinopathy encountered in pregnancy and discussed in Chapter 57. Pregnancy is also interrelated with some endocrinopathies that are at least partially due to autoimmune dysregulation. Clinical manifestations result from complex interplay among genetic, environmental, and endogenous factors that activate the immune system against targeted cells within endocrine organs. In one extraordinary interaction, studies have implicated maternal organ engraftment by fetal cells transferred during pregnancy. These cells later provoke antibody production, tissue destruction, and autoimmune endocrinopathies.

THYROID DISORDERS

Taken in aggregate, these disorders are common in young women and thus frequently encountered in pregnancy. Maternal and fetal thyroid function are intimately related, and drugs that affect the maternal thyroid affect the fetal gland. Moreover, thyroid autoantibodies are associated with increased rates of early pregnancy wastage. Uncontrolled thyrotoxicosis and untreated hypothyroidism are both associated with adverse pregnancy outcomes. Last, evidence suggests that the severity of some autoimmune thyroid disorders may be ameliorated during pregnancy, only to be exacerbated postpartum.

Thyroid Physiology and Pregnancy

Maternal thyroid changes are substantial, and normally altered gland structure and function can sometimes be confused with thyroid abnormalities. These alterations are discussed in detail in Chapter 4 (p. 71), and normal serum hormone level values are found in the Appendix (p. 1230). First, maternal serum concentrations of thyroid binding globulin are increased concomitantly with total or bound thyroid hormone levels. Second, *thyrotropin*, also called *thyroid-stimulating hormone (TSH)*, plays a central role in screening and diagnosis of many thyroid disorders, but levels change throughout pregnancy. Notably, TSH receptors are cross stimulated, albeit weakly, by massive quantities of human chorionic gonadotropin (hCG) secreted by placental trophoblast. Because TSH does not cross the placenta, it has no direct fetal effects. During the first 12 weeks of gestation, when maternal hCG serum levels are maximal, thyroid hormone secretion is stimulated. The resulting greater serum free thyroxine (T_4) levels act to suppress hypothalamic *thyrotropin-releasing hormone (TRH)* and in turn limit pituitary TSH secretion (Fig. 61-1). Accordingly,

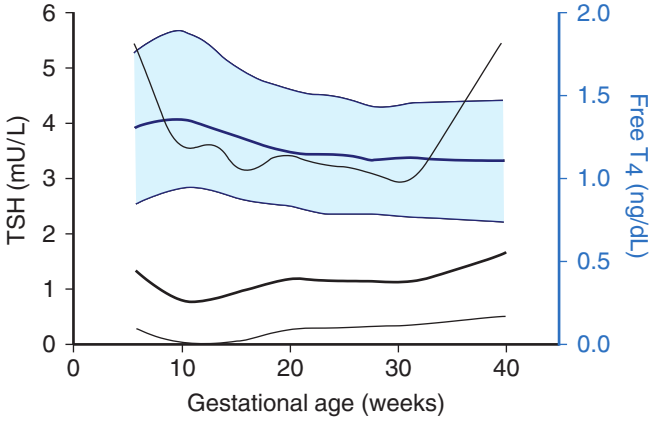

FIGURE 61-1 Gestational-age-specific values for serum thyroid-stimulating hormone (TSH) levels (*black lines*) and free thyroxine (T_4) levels (*blue lines*). Data were derived from 17,298 women tested during pregnancy. For each color, the dark solid lines represent the 50th percentile, whereas the upper and lower light lines represent the 2.5th and 97.5th percentiles, respectively. (Data from Casey, 2005; Dashe, 2005.)

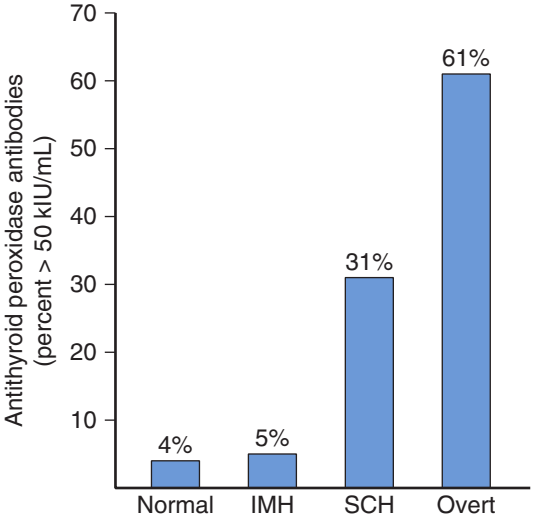

FIGURE 61-2 Incidence of antithyroid peroxidase antibodies in 16,407 women who are normal or euthyroid, in 233 with isolated maternal hypothyroxinemia (IMH), in 598 with subclinical hypothyroidism (SCH), and in 134 with overt hypothyroidism.

TRH is undetectable in maternal serum. Conversely, in fetal serum, beginning at midpregnancy, TRH becomes detectable, but levels are static and do not rise.

Throughout pregnancy, maternal thyroxine is transferred to the fetus (American College of Obstetricians and Gynecologists, 2020). Maternal thyroxine is important for normal fetal brain development, especially before the onset of fetal thyroid gland function (Bernal, 2007; Korevaar, 2016b). Both high and low maternal thyroid function in the first trimester are negatively associated with cortical gray matter volume in childhood (Jansen, 2019). Although the fetal gland begins concentrating iodine and synthesizing thyroid hormone after 12 weeks' gestation, maternal thyroxine contribution remains important. Maternal sources account for 30 percent of thyroxine in fetal serum at term (Thorpe-Beeston, 1991). Still, developmental risks associated with maternal hypothyroidism after midpregnancy remain poorly understood (Morreale de Escobar, 2004; Sarkhail, 2016).

Autoimmunity and Thyroid Disease

Most thyroid disorders are inextricably linked to autoantibodies against nearly 200 thyrocyte components. These antibodies variably stimulate thyroid function, block function, or cause thyroid inflammation that may lead to follicular cell destruction. Often, these effects overlap.

Thyroid-stimulating autoantibodies, also called *thyroid-stimulating immunoglobulins (TSIs)*, bind and activate the TSH receptor to cause thyroid hyperfunction and growth. Although these antibodies are identified in most patients with classic Graves disease, simultaneous production of *thyroid-stimulating blocking antibodies* may blunt this effect (Jameson, 2015).

Thyroid peroxidase (TPO) is a thyroid gland enzyme that normally functions to produce thyroid hormones. *Thyroid peroxidase antibodies* are directed against TPO and are identified in 5 to 15 percent of all gravidas (Fig. 61-2) (Abbassi-Ghanavati, 2010; Casey, 2007; Sarkhail, 2016). TPO antibodies have been associated in some studies with early pregnancy loss and preterm birth (Consortium on Thyroid and Pregnancy, 2019; Plowden, 2017; Thangaratinam, 2011). In another study with more than 1000 pregnant women with TPO antibodies, the risk for preterm birth was not elevated. The risk for placental abruption was greater (Abbassi-Ghanavati, 2010). These women are also at high risk for postpartum thyroid dysfunction and at lifelong risk for permanent thyroid failure (Andersen, 2016; Jameson, 2015).

Fetal Microchimerism

Autoimmune thyroid disease is more common in women than in men. One intriguing explanation for this disparity is fetal-to-maternal cell trafficking (Greer, 2011). Fetal cells are known to enter maternal circulation during pregnancy. When fetal lymphocytes enter maternal circulation, they can live for more than 20 years. Stem cell interchange can lead to engraftment in several maternal tissues and is termed *fetal microchimerism.* In some cases, this may involve the thyroid gland (Bianchi, 2003; Boddy, 2015). A high prevalence of Y chromosome–positive cells has been identified in the thyroid glands of women with Hashimoto thyroiditis—60 percent, or with Graves disease—40 percent (Renné, 2004). In another study of women giving birth to a male fetus, more circulating male mononuclear cells were found in those with Hashimoto thyroiditis (Lepez, 2011). Conversely, for some autoimmune thyroid disorders, fetal microchimerism may actually have a protective role (Cirello, 2015).

Hyperthyroidism

The incidence of thyrotoxicosis or hyperthyroidism in pregnancy varies and complicates between 0.4 and 1.7 percent of births when gestational-age-appropriate TSH threshold values are used (Table 61-1). Because normal pregnancy simulates some clinical findings similar to thyroxine excess, clinically mild thyrotoxicosis may be difficult to diagnose. Suggestive

findings include tachycardia that exceeds that usually seen with normal pregnancy, thyromegaly, exophthalmos, and failure to gain weight despite adequate food intake. Laboratory testing is confirmatory. TSH levels are markedly depressed, while serum free T_4 (fT_4) levels are elevated. Rarely, hyperthyroidism is caused by abnormally high serum triiodothyronine (T_3) levels and called *T_3-toxicosis*.

Thyrotoxicosis and Pregnancy

The overwhelming cause of thyrotoxicosis in pregnancy is Graves disease, an organ-specific autoimmune process associated with thyroid-stimulating TSH-receptor antibodies (De Leo, 2016). These antibodies are specific for Graves hyperthyroidism, and targeted assays have been proposed for diagnosis, management, and prognosis in pregnancies complicated by hyperthyroidism (Alexander, 2017; Barbesino, 2013). With Graves disease, during the course of pregnancy, hyperthyroid symptoms may initially worsen because of hCG stimulation. Symptoms then diminish after a decline in receptor-antibody titers in the second half of pregnancy (Mestman, 2012; Sarkhail, 2016). Levels of blocking antibodies also decline during pregnancy (Amino, 2003).

Treatment

Thyrotoxicosis during pregnancy can nearly always be controlled by thionamide drugs. *Propylthiouracil (PTU)* has been historically preferred because it partially inhibits the conversion of T_4 to T_3 and crosses the placenta less readily than *methimazole*. The latter has also been associated with a rare methimazole embryopathy, characterized by *esophageal* or *choanal atresia* and *aplasia cutis*, a congenital skin defect. In one analysis of Japanese women with first-trimester hyperthyroidism, the risk of major fetal malformation in pregnancies exposed to methimazole was twofold higher than risks with either PTU or potassium iodide use (Yoshihara, 2012, 2015). Specifically, seven of nine cases with aplasia cutis and the only case of esophageal atresia were in the group of methimazole-exposed fetuses. A PTU-associated embryopathy also has been described (Andersen, 2014).

Treatment with PTU is associated with a higher risk for liver injury (Yu, 2020). In 2009, the U.S. Food and Drug Administration issued a safety alert on PTU-associated hepatotoxicity. This warning initially prompted the American Thyroid Association and the American Association of Clinical Endocrinologists (2011) to recommend PTU therapy during the first trimester followed by a switch to methimazole beginning in the second trimester. The obvious disadvantage is that this might lead to poorly controlled thyroid function. More recently, the American Thyroid Association recommends PTU therapy through 16 weeks' gestation but does not make a recommendation regarding switching to methimazole treatment because both agents are associated with adverse effects and the harm from poorer control during the switch is unknown (Alexander, 2017).

Transient leukopenia can be documented in up to 10 percent of women taking antithyroid drugs, but this does not require therapy cessation (American College of Obstetricians and Gynecologists, 2020). In approximately 0.3 percent, however, *agranulocytosis* develops suddenly and mandates drug discontinuance (Thomas, 2013). It is not dose related, and because of its acute onset, routine serial leukocyte counts during therapy are not helpful. *Instead, if fever or sore throat develops, women are instructed to discontinue medication immediately and report for a complete blood count.*

Therapy may have other side effects. First, as noted, hepatotoxicity develops in approximately 0.1 percent of treated women. Serial measurement of hepatic enzyme levels does not prevent fulminant PTU-related hepatotoxicity. Second, an allergic rash may develop in 3 to 5 percent of women taking thionamide drugs (Alexander, 2017). In addition, although approximately 20 percent of patients treated with PTU develop *antineutrophil cytoplasmic antibodies (ANCA)*, only a small percentage of these subsequently develops serious vasculitis (Kimura, 2013). Last, thionamides have the potential to cause fetal complications, but these are uncommon. In some cases, thionamides may even be therapeutic for the fetus. This is because TSH-receptor antibodies cross the placenta and can stimulate the fetal thyroid gland to cause thyrotoxicosis and goiter.

The initial thionamide dose is empirical. For nonpregnant patients, the American Thyroid Association recommends that methimazole be used at an initial higher daily dose of 10 to 20 mg orally followed by a lower maintenance dose of 5 to 10 mg. If PTU is selected, a dose of 50 to 150 mg orally three times daily may be initiated depending on clinical severity. At Parkland Hospital, we usually initially give 300 or 450 mg of PTU daily in three divided doses for pregnant women. Occasionally, daily doses of 600 mg or higher are necessary. We routinely transition women to methimazole after the first trimester. If a switch is deemed appropriate, a dose ratio of 20:1—PTU to methimazole—is recommended (Alexander, 2017). The goal is treatment with the lowest possible thionamide dose to maintain thyroid hormone levels slightly above or in the high normal range, while TSH levels remains suppressed. Serum free T_4 concentrations are measured every 4 to 6 weeks.

Subtotal thyroidectomy can be performed after thyrotoxicosis is medically controlled. This seldom is done during pregnancy but may be appropriate for the very few women who cannot adhere to medical treatment or in whom drug therapy proves toxic (Pearce, 2019; Stagnaro-Green, 2012a). Surgery is best accomplished in the second trimester. Potential drawbacks of thyroidectomy include inadvertent resection of parathyroid glands and injury to the recurrent laryngeal nerve.

Thyroid ablation with therapeutic radioactive iodine is contraindicated in pregnancy (Lee, 2021). These doses may also cause fetal thyroid gland destruction. Thus, when radioactive iodine is given unintentionally, some clinicians recommend abortion. Any exposed fetus must be carefully evaluated, and the incidence of fetal hypothyroidism depends on gestational age and radioiodine dose (Berlin, 2001). Importantly, several cases of inadvertent periconceptional exposure to radioactive iodine have been reported with no obvious ill effects for the offspring (Radacic-Aumiler, 2016; Sadakata, 2014). The International Commission on Radiological Protection recommends that women avoid pregnancy for 6 months after radioablative therapy (Brent, 2008). Moreover, during lactation, the breast also concentrates a substantial amount of iodine. This may pose a neonatal risk due to ^{131}I-containing milk ingestion and maternal risk from significant breast irradiation. To limit the latter, a delay of 3 months after breastfeeding cessation will more reliably ensure complete breast involution.

Pregnancy Outcome

Women with thyrotoxicosis have pregnancy outcomes that largely depend on whether metabolic control is achieved. For example, excess thyroxine may cause miscarriage or preterm birth (Andersen, 2014; Moleti, 2019; Sheehan, 2015). In untreated women or in those who remain hyperthyroid despite therapy, incidences of preeclampsia, heart failure, and adverse perinatal outcomes are higher (Table 61-2). One case-cohort study in the Danish National Birth Cohort found that maternal hyperthyroidism was also a risk for epilepsy and autism spectrum disorders in children (Andersen, 2018).

Fetal and Neonatal Effects

In most cases, the perinate is euthyroid. In some, however, hyper- or hypothyroidism can develop with or without a goiter (Fig. 61-3). Clinical hyperthyroidism develops in up to 1 percent of neonates born to women with Graves disease (Barbesino, 2013; Fitzpatrick, 2010). If fetal thyroid disease is suspected, nomograms exist for sonographically measured thyroid volume (Gietka-Czernel, 2012).

FIGURE 61-3 Term hypothyroid neonate delivered of a woman with a 3-year history of thyrotoxicosis that recurred at 26 weeks' gestation. The mother was given methimazole, 30 mg orally daily, and was euthyroid at delivery.

The fetus or neonate who was exposed to excessive maternal thyroxine may have any of several clinical presentations. First, *goitrous thyrotoxicosis* stems from placental transfer of thyroid-stimulating immunoglobulins. Nonimmune hydrops and fetal demise can complicate fetal thyrotoxicosis (Nachum, 2003; Stulberg, 2000). The best predictor of perinatal thyrotoxicosis is the presence of thyroid-stimulating TSH-receptor antibodies in women with Graves disease (Moleti, 2019; Nathan, 2014). This is especially true if their levels are more than threefold higher than the upper normal limit (Barbesino, 2013). In one study of 72 pregnant women with Graves disease, none of the fetuses in 31 low-risk mothers had a goiter, and all were euthyroid at delivery (Luton, 2005). Low risk was defined as no requirement for antithyroid medications during the third trimester or an absence of antithyroid antibodies. Conversely, in a group of 41 women who either were taking antithyroid medication at delivery or had thyroid-receptor antibodies, 11 fetuses—27 percent—had sonographic evidence of a goiter at 32 weeks' gestation. Seven of these 11 fetuses were determined to be hypothyroid, and the remaining fetuses were hyperthyroid.

Because of these findings, the American Thyroid Association recommends routine evaluation of TSH-receptor antibodies (TRAb) in early pregnancy in women treated with antithyroid medication (Alexander, 2017). In those who have elevated TRAb levels or who continue therapy, repeat testing is recommended between 18 and 22 weeks' gestation. The American College of Obstetricians and Gynecologists (2020), however, does not recommend such testing. If the fetus is thyrotoxic, maternal thionamide drugs are increased even though maternal thyroid function may be within targeted range (Mestman, 2012). If secondary maternal hypothyroidism develops, the fetus can be treated by a reduced maternal antithyroid medication dose and injections of intraamnionic thyroxine if

TABLE 61-2. Pregnancy Outcomes in Women with Overt Thyrotoxicosis

necessary. Although usually short-lived, neonatal thyrotoxicosis may require a short course of antithyroid drug treatment (Levy-Shraga, 2014; Nathan, 2014).

A second fetal presentation is *goitrous hypothyroidism* caused by fetal exposure to maternally administered thionamides (see Fig. 61-3). Despite theoretical neurological implications, reports of adverse fetal effects seem to have been exaggerated. For example, in at least 239 treated thyrotoxic women shown in Table 61-2, evidence of hypothyroidism was found in only four newborns. Furthermore, at least four long-term studies report no abnormal intellectual or physical development of these children (Mestman, 1998). As long as the maternal free thyroxine level remains in the upper therapeutic to mildly thyrotoxic range, the likelihood of fetal hypothyroidism is remote (Moleti, 2019).

A third presentation, *nongoitrous hypothyroidism,* may develop from transplacental passage of maternal TSH-receptor blocking antibodies (Fitzpatrick, 2010). And last, *fetal thyrotoxicosis* after maternal thyroid gland ablation, usually with ^{131}I radioiodine, may result from transplacental thyroid-stimulating antibodies. In one report of early fetal exposure to radioiodine, neonatal thyroid studies indicated transient hyperthyroidism from maternal transfer of stimulating antibodies (Tran, 2010).

Fetal Diagnosis

Evaluation of fetal thyroid function remains controversial. Although the fetal thyroid volume can be measured sonographically in women taking thionamide drugs or in those with thyroid-stimulating antibodies, most investigators do not currently recommend this routinely (Cohen, 2003; Luton, 2005). Fetal hyper- or hypothyroidism may cause hydrops, growth restriction, goiter, or tachycardia, and fetal blood sampling may be appropriate (Brand, 2005). The American Thyroid Association guidelines for management of thyroid disease during pregnancy recommend that umbilical cord blood sampling only be considered when a fetal goiter is detected and the thyroid status of the fetus is unclear (Alexander, 2017). Diagnosis and treatment are considered further in Chapter 19 (p. 370).

Thyroid Storm and Thyrotoxic Heart Failure

Both of these are acute and life-threatening in pregnancy. Thyroid storm is a hypermetabolic state and is rare in pregnancy. In contrast, pulmonary hypertension and heart failure from cardiomyopathy caused by the profound myocardial effects of thyroxine are common in pregnant women (Sheffield, 2004). As shown in Table 61-2, heart failure developed in 8 percent of 90 women with uncontrolled thyrotoxicosis. In a registry of almost 70,000 pregnancies from one province in China, six of 155 (4 percent) women diagnosed with thyrotoxicosis were found to have hyperthyroid heart disease (Shan, 2019).

The pregnant woman with thyrotoxicosis has minimal cardiac reserve, and decompensation is usually precipitated by preeclampsia, anemia, sepsis, or a combination. Fortunately, thyroxine-induced cardiomyopathy and pulmonary hypertension are frequently reversible (Shan, 2019; Sheffield, 2004).

Management

Treatment is similar for thyroid storm and heart failure and should be carried out in an intensive care area that may include special-care units within labor and delivery (American College of Obstetricians and Gynecologists, 2020). Shown in **Figure 61-4** is our stepwise approach to medical management of thyroid storm or thyrotoxic heart failure. An hour or two after initial thionamide administration, iodide is given to inhibit thyroidal release of T_3 and T_4. It can be given intravenously (IV) as sodium iodide or orally as either saturated solution of potassium iodide (SSKI) or Lugol solution. With a history of iodine-induced anaphylaxis, lithium carbonate, 300 mg every 6 hours, is given instead. Most authorities recommend dexamethasone, 2 mg IV every 6 hours for four doses, to further block peripheral conversion of T_4 to T_3. If a β-blocking drug is given to control tachycardia, its effect on heart failure must be considered. Propranolol, labetalol, and esmolol are options. Coexisting severe preeclampsia, infection, or anemia are aggressively managed before delivery is considered.

Hyperemesis Gravidarum

Transient biochemical features of hyperthyroidism may be observed in 2 to 15 percent of women in early pregnancy (Fitzpatrick, 2010). Many women with hyperemesis gravidarum have abnormally high serum T_4 levels and low TSH levels (Chap. 57, p. 1014). This results from TSH-receptor stimulation from hCG. This transient condition is also termed *gestational transient thyrotoxicosis.* Even if associated with hyperemesis, antithyroid drugs are not warranted (American College of Obstetricians and Gynecologists, 2020). The hCG levels do not correlate with T_4 and TSH values, which trend to normal by midpregnancy (Nathan, 2014; Yoshihara, 2015).

Gestational Trophoblastic Disease

The prevalence of T_4 level elevation in women with a molar pregnancy ranges between 25 and 65 percent (Hershman, 2004). As discussed, abnormally high hCG levels lead to overstimulation of the TSH receptor. Because these tumors are now usually diagnosed early, clinically apparent hyperthyroidism is less common. With molar evacuation, serum free T_4 levels usually drop to normal levels rapidly in parallel with declining hCG concentrations.

Subclinical Hyperthyroidism

Third-generation TSH assays with an analytical sensitivity of 0.002 mU/mL permit identification of subclinical thyroid disorders. These biochemically defined extremes usually represent normal biological variations but may herald the earliest stages of thyroid dysfunction. *Subclinical hyperthyroidism* is characterized by an abnormally low serum TSH concentration in concert with normal T_4 hormone levels. Long-term effects of persistent subclinical thyrotoxicosis include osteoporosis, cardiovascular morbidity, and progression to overt thyrotoxicosis or thyroid failure. In one recent metaanalysis of 20 studies, the prevalence of subclinical hyperthyroidism was 1.77 percent in pregnant women (Dong, 2019). Importantly, subclinical hyperthyroidism has not been associated with adverse pregnancy outcomes (Casey, 2006). In separate retrospective analyses of almost 25,000 women who underwent thyroid screening throughout pregnancy, investigators also found no relationship between

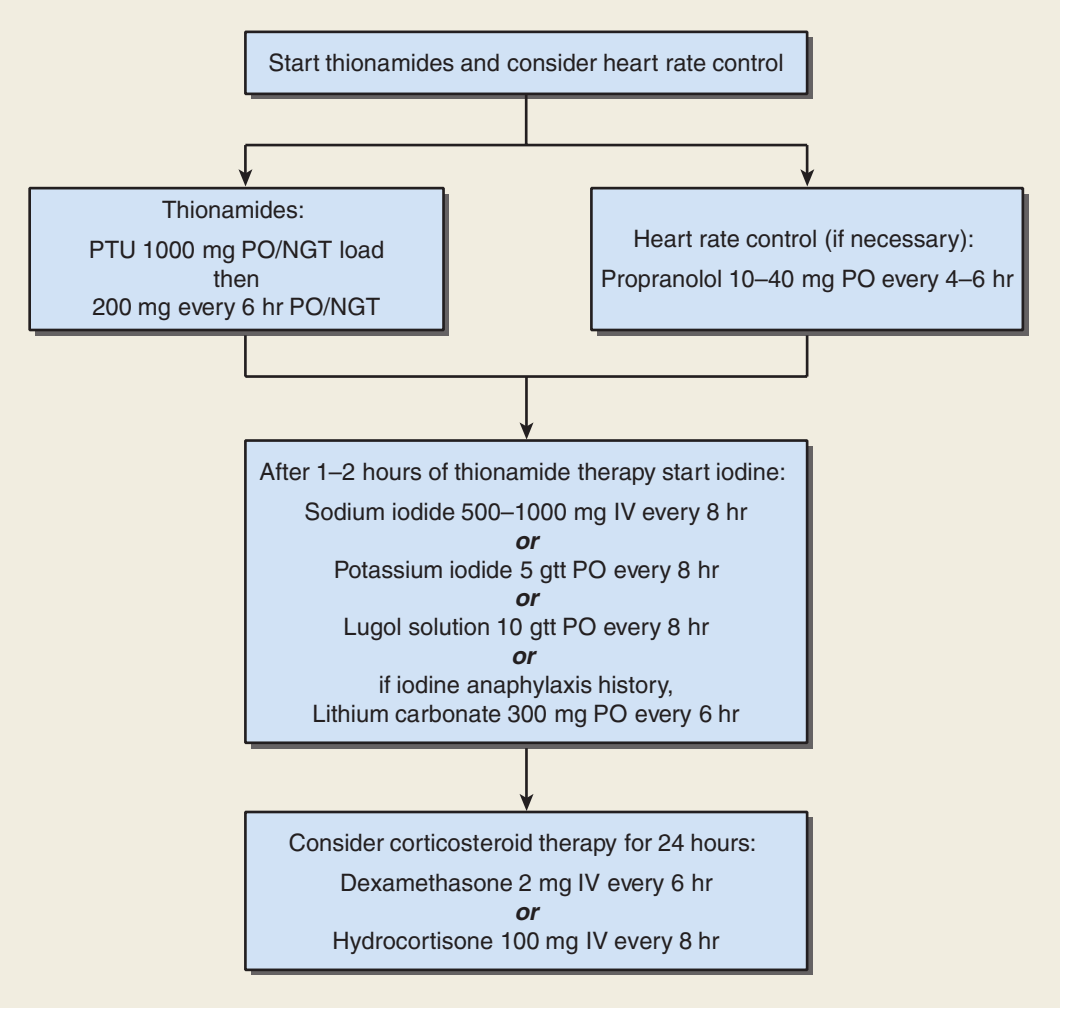

FIGURE 61-4 Parkland Hospital management for thyroid storm or thyrotoxic heart failure. gtt = drops; IV = intravenous; NGT = nasogastric tube; PO = orally; PTU = propylthiouracil.

subclinical hyperthyroidism and preeclampsia or gestational diabetes (Wilson, 2012; Tudela, 2012).

Treatment of subclinical hyperthyroidism is unwarranted in pregnancy because antithyroid drugs may affect the fetus. These women may benefit from periodic surveillance, and approximately half eventually have normal TSH concentrations.

Hypothyroidism

Overt or symptomatic hypothyroidism complicates between 0.2 and 1.2 percent of pregnancies (Andersen, 2016; Casey, 2017). Its insidious, nonspecific clinical findings include fatigue, constipation, cold intolerance, muscle cramps, and weight gain. A pathologically enlarged thyroid gland depends on the etiology of hypothyroidism and is more likely in women in areas of endemic iodine deficiency or those with Hashimoto thyroiditis. Other findings are edema, dry skin, hair loss, and a prolonged relaxation phase of deep tendon reflexes. *Clinical* or *overt hypothyroidism* is confirmed by an abnormally high serum TSH level and an abnormally low T_4 level. *Subclinical hypothyroidism,* discussed later, is defined by an elevated serum TSH level but *normal* serum T_4 concentration (Jameson, 2015). Asymptomatic individuals with high levels of anti-TPO or antithyroglobulin antibodies often are included in the spectrum of subclinical thyroid disease and will also be discussed.

Overt Hypothyroidism and Pregnancy

The most common cause of hypothyroidism in pregnancy is Hashimoto thyroiditis, characterized by glandular destruction from autoantibodies, particularly anti-TPO antibodies. Another cause is postablative Graves disease. Clinical identification of hypothyroidism is especially difficult during pregnancy because many of the signs or symptoms are also common pregnancy itself. Thyroid analyte testing should be performed on symptomatic women, those with a personal or family history of thyroid disease, or those with type 1 diabetes (American College of Obstetricians and Gynecologists, 2020). *Severe hypothyroidism* during pregnancy is uncommon, probably because it is often associated with infertility and higher miscarriage rates (De Groot, 2012).

Treatment

The American College of Obstetricians and Gynecologists (2020) recommends oral replacement therapy for overt hypothyroidism beginning with levothyroxine in doses of 1 to 2 μg/kg/d or approximately 100 μg daily. Women who are athyreotic

after thyroidectomy or radioiodine therapy may require higher doses. Surveillance is with TSH levels measured at 4-week intervals in the first half of pregnancy and at least once in the third trimester. The levothyroxine dose is adjusted by 25- to 50-μg increments until TSH values approximate 2.5 mU/L. Pregnancy is associated with an increased dose requirement in approximately a third of supplemented women (Abalovich, 2010; Alexander, 2004). The greater demand in pregnancy is believed to be related to augmented estrogen production (Arafah, 2001).

Higher dose requirements begin as early as 5 weeks' gestation. Significant hypothyroidism may develop early in women without thyroid reserve, such as those with a previous thyroidectomy, those with prior radioiodine ablation, or those undergoing assisted reproductive techniques (Alexander, 2004; Loh, 2009). Theoretically, an anticipatory 25-percent increase in the levothyroxine dose at pregnancy confirmation will reduce this likelihood. However, one randomized trial compared empiric increases in dose against dose adjustments based on TSH levels and found both equally effective (Sullivan, 2017). Those in the empiric-dosing group had a higher risk of TSH suppression. At Parkland Hospital, all women with hypothyroidism undergo TSH testing at initiation of prenatal care and subsequent indicated dose adjustments. TSH determinations are repeated in each trimester.

Pregnancy Outcome with Overt Hypothyroidism

Observational studies, although limited, indicate that excessive adverse perinatal outcomes are associated with overt T_4 deficiency (Table 61-3). Preterm birth rates also are higher (Sheehan, 2015). With appropriate replacement therapy, however, rates of adverse effects are not increased in most reports (Bryant, 2015; Matalon, 2006; Tan, 2006). In one dissenting study, risks for some pregnancy complications were greater even in women taking replacement therapy (Wikner, 2008). Most experts agree that adequate hormone replacement during pregnancy minimizes the risk of adverse outcomes and most complications.

TABLE 61-3. Pregnancy Complications in 440 Women with Hypothyroidism

Complications	Hypothyroidism (%)	
	Overt (n = 112)	Subclinical (n = 328)
Preeclampsia	32	8
Placental abruption	8	1
Cardiac dysfunction	3	2
Birthweight <2000 g[a,b]	33	32
Stillbirths[c]	9	3[c]

[a]Preterm or term deliveries were the only outcomes reported by Abalovich, 2002.
[b]Low birthweight and stillbirth were outcomes reported by Su, 2011.
[c]One infant died from syphilis.
Data from Abalovich, 2002; Davis, 1988; Leung, 1993; Männistö, 2009; Su, 2011.

Fetal and Neonatal Effects

Undoubtedly, maternal and fetal thyroid abnormalities are related. In both, thyroid function is dependent on adequate iodine intake, and its deficiency early in pregnancy can cause both maternal and fetal hypothyroidism. In one analysis of 4273 mother-child pairs, an association between maternal thyroid function during pregnancy and both neonatal and childhood thyroid function was confirmed (Korevaar, 2016a). As discussed, maternal TSH-receptor-blocking antibodies can cross the placenta and cause fetal thyroid dysfunction. Rovelli and colleagues (2010) evaluated 129 neonates born to women with autoimmune thyroiditis. They found that 28 percent had an elevated TSH level on the third or fourth day of life, and 47 percent of these had TPO antibodies on day 15. Still, autoantibodies were undetectable at age 6 months. In their analysis, Korevaar and coworkers (2016a) concluded that maternal TPO antibodies have no clinically relevant effects on the thyroid function of offspring. Indeed, prevalence of fetal hypothyroidism in women with Hashimoto thyroiditis is estimated to be only 1 case in 180,000 newborns (Brown, 1996).

■ Subclinical Hypothyroidism

Although common in women, the incidence of subclinical hypothyroidism varies depending on age, race, dietary iodine intake, and serum TSH thresholds used (Jameson, 2015). In two large studies totaling more than 25,000 pregnant women screened in the first half of pregnancy, subclinical hypothyroidism was identified in 2.3 percent (Casey, 2005; Cleary-Goldman, 2008). The rate of progression to overt thyroid failure is affected by TSH level, age, other disorders such as diabetes, and presence and concentration of antithyroid antibodies.

Diez and Iglesias (2004) prospectively followed 93 nonpregnant women with subclinical hypothyroidism for 5 years and reported that in a third, TSH values became normal. In the other two thirds, those women whose TSH levels were 10 to 15 mU/L developed overt disease at a rate of 19 cases per 100 patient-years. Those women whose TSH levels were <10 mU/L developed overt hypothyroidism at a rate of 2 cases per 100 patient-years.

Regarding screening for subclinical hypothyroidism in nonpregnant individuals, the U.S. Preventive Services Task Force also reports that nearly all patients who develop overt hypothyroidism within 5 years have an initial TSH level >10 mU/L (Helfand, 2004; Karmisholt, 2008). From one metaanalysis of data from nonpregnant adults with subclinical hypothyroidism, thyroid hormone therapy was not associated with improved general quality of life, thyroid-related symptoms, depression, blood pressure, or other cardiovascular outcomes (Feller, 2018).

In a 20-year follow-up study of 5805 women who were screened in early pregnancy, only 3 percent developed thyroid disease. Of the 224 women identified with subclinical hypothyroidism during pregnancy, 17 percent developed thyroid disease in the next 20 years, and most of these had either TPO or thyroglobulin antibodies during pregnancy (Männistö, 2010). Thus, the likelihood of progression to overt hypothyroidism *during* pregnancy in otherwise healthy women with subclinical hypothyroidism seems remote.

Subclinical Hypothyroidism and Pregnancy

Interest in this subject was heightened 20 years ago by two studies reporting that undiagnosed maternal thyroid hypofunction may impair fetal neuropsychological development (Haddow, 1999; Pop, 1999). Notably, in the Haddow study, many women had both elevated TSH and abnormally low serum free T_4 levels and thus had *overt* hypothyroidism. To evaluate any adverse pregnancy effects, Casey and colleagues (2005) identified subclinical hypothyroidism in 2.3 percent of 17,298 women screened at Parkland Hospital before midpregnancy. These women had small but significantly higher incidences of preterm birth, placental abruption, and neonates admitted to the intensive care nursery compared with euthyroid women. In another study of 10,990 similar women, however, Cleary-Goldman and associates (2008) did not find such associations.

Other studies subsequently confirmed a link between subclinical thyroid function and adverse outcomes (Chen, 2017; Maraka, 2016). One included 24,883 women screened throughout pregnancy and showed an almost twofold greater risk of severe preeclampsia (Wilson, 2012). In an analysis of the latter cohort, a consistent relationship was shown between rising TSH levels and the risk for gestational diabetes (Tudela, 2012). Last, Nelson and associates (2014) found an elevated risk for diabetes and stillbirth.

Lazarus and coworkers (2012) reported the findings of the international multicenter Controlled Antenatal Thyroid Screening (CATS) study. They evaluated prenatal thyroid screening with randomized treatment of both subclinical hypothyroidism and isolated maternal hypothyroxinemia. They found that offspring IQ scores at age 3 years were not superior in the treated cohort. Later evaluation of these offspring through age 9 confirmed that maternal treatment offered no benefit (Hales, 2018). Last, the Maternal-Fetal Medicine Units (MFMU) Network screened more than 97,000 pregnant women for thyroid disorders and reported that 3.3 percent had subclinical hypothyroidism. These 677 women were randomly assigned to thyroxine replacement therapy or placebo. As reported by Casey and colleagues (2017) and shown in Table 61-4, adverse pregnancy outcomes or cognitive development in the offspring at 5 years did not differ between groups. Annual developmental testing scores and behavioral and attention-deficit hyperactivity disorder results also did not differ.

Because of earlier study findings, some professional organizations began to recommend routine prenatal screening and treatment of subclinical hypothyroidism. However, after the CATS and MFMU Network studies, more recent clinical practice guidelines from the Endocrine Society, the American Thyroid Association, and the American Association of Clinical Endocrinologists now uniformly recommended screening only those at greater risk during pregnancy (Alexander, 2017; De Groot, 2012; Garber, 2012). This has been and still is the recommendation of the American College of Obstetricians and Gynecologists (2020).

Isolated Maternal Hypothyroxinemia

Women with low serum free T_4 values but a normal-range TSH level are considered to have *isolated maternal hypothyroxinemia*. Its incidence in two large trials was 1.3 to 2.1 percent (Casey, 2007; Cleary-Goldman, 2008). As shown in Figure 61-2, unlike in subclinical hypothyroidism, these women have a low prevalence of antithyroid antibodies.

Initial studies reported that offspring of women with isolated hypothyroxinemia had neurodevelopmental difficulties (Levie, 2018; Li, 2010; Pop, 1999, 2003). Casey and colleagues

TABLE 61-4. Maternal-Fetal Medicine Unites Network: Pregnancy Outcomes According to Diagnosis and Treatment of Thyroid Disorders[a]

	Subclinical Hypothyroidism		Isolated Hypothyroxinemia	
Outcome	**Thyroxine**	**Placebo**	**Thyroxine**	**Placebo**
Maternal				
EGA at delivery (weeks)	39.1 ± 2.5	38.9 ± 3.1	39.0 ± 2.4	38.8 ± 3.1
Preterm birth <34 weeks	9.1%	10.9%	3.8%	2.7%
Placental abruption	0.3%	1.5%	1.1%	0.8%
Preeclampsia	6.5%	5.9%	3.4%	4.2%
Diabetes	7.4%	6.5%	8.0%	9.2%
Perinatal and Childhood				
Stillbirth	12/1000	21/1000	8/1000	19/1000
Neonatal death	0	3/1000	4/1000	4/1000
NICU admission	8.6%	6.2%	11.8%	11.9%
Birthweight <10th centile	9.8%	8.1%	8.8%	7.8%
IQ median (25th, 75th percentile)	97 (85,105)	94 (85,107)	94 (83,101)	91 (82,101)

[a]For all comparisons, $p > 0.05$.
EGA = estimated gestational age; IQ = intelligence quotient; NICU = neonatal intensive care unit.

(2007), however, found no higher risks in these women for other adverse perinatal outcomes compared with those of euthyroid women. In contrast, a recent individual patient data systematic analysis including 47,045 pregnant women identified a higher risk of preterm birth associated with isolated hypothyroxinemia (Consortium on Thyroid and Pregnancy, 2019).

The aforementioned CATS study, including follow-up of offspring through age 9 years, did not find improved neurodevelopmental outcomes in women with isolated hypothyroxinemia who were then treated with thyroxine (Hales, 2018; Lazarus, 2012). The randomized trial conducted by the MFMU Network also demonstrated no improvement in neurocognitive development with thyroxine treatment during pregnancy (Casey, 2017). This large randomized study also found no higher rates of adverse pregnancy outcomes between groups and found that early thyroxine treatment offered no benefits (see Table 61-4). The American Thyroid Association currently recommends against routine treatment of isolated hypothyroxinemia in pregnancy (Alexander, 2017).

Euthyroid Autoimmune Thyroid Disease

Autoantibodies to TPO and thyroglobulin have been identified in 2 to 17 percent of pregnant women worldwide (Alexander, 2017). Most who test positive for such antibodies, however, are euthyroid. That said, such women carry a two- to fivefold increased risk for early pregnancy loss (Stagnaro-Green, 2004; Thangaratinam, 2011). The presence of thyroid antibodies has also been associated with preterm birth (He, 2012). In a randomized treatment trial of 115 euthyroid women with TPO antibodies, levothyroxine astoundingly reduced the preterm birth rate from 22 to 7 percent (Negro, 2006). In a follow-up trial restricted to women with a TSH <2.5 mU/L, however, levothyroxine treatment had no effect on this risk (Negro, 2016).

In another study, Abbassi-Ghanavati and associates (2010) evaluated pregnancy outcomes in more than 1000 untreated women with TPO antibodies and did not find a higher risk for preterm birth compared with the risk in 16,000 euthyroid women without antibodies. These investigators, however, did find a threefold greater risk of placental abruption in these women. More recently, the Consortium on Thyroid and Pregnancy-Study Group on Preterm Birth (2019) estimated a marginal 1.3-fold increased risk for preterm birth in their meta-analysis of women with TPO antibodies.

As with nonpregnant subjects with TPO antibodies, pregnant women are also at increased risk in later life for progression of thyroid disease and postpartum thyroiditis (Jameson, 2015; Stagnaro-Green, 2012a). Currently, universal screening for the thyroid autoantibodies is not recommended by any professional organization (Alexander, 2017; American College of Obstetricians and Gynecologists, 2020; De Groot, 2012).

Iodine Deficiency

Decreasing iodide fortification of table salt and bread products in the United States during the past 25 years has led to occasional iodide deficiency (Caldwell, 2005; Hollowell, 1998). Importantly, the most recent National Health and Nutrition Examination Survey indicated that, overall, the United States population remains iodine sufficient (Herrick, 2018). However, experts agree that iodine nutrition in vulnerable populations, such as pregnant women, requires continued monitoring. In 2014, the Office of Dietary Supplements of the National Institutes of Health sponsored three workshops to identify information gaps and develop an iodine research agenda. Participants emphasized the gradual decline in median urinary iodine levels in pregnant women and the serious potential effects on developing fetuses (Pearce, 2016).

Dietary iodine requirements are higher during pregnancy due to augmented thyroid hormone production, increased renal losses, and fetal iodine requirements. Adequate iodine is requisite for fetal neurological development beginning soon after conception, and abnormalities vary by the degree of deficiency. For example, Levie and colleagues (2019) demonstrated a positive correlation between maternal urinary iodine/creatinine ratio in the first trimester and offspring nonverbal IQ scores. UNICEF (2018) estimates that nearly 19 million babies born globally every year are at risk of permanent yet preventable brain damage or of reduced cognitive function from iodine deficiency.

Although it is doubtful that *mild deficiency* causes intellectual impairment, supplementation does prevent fetal goiter (Stagnaro-Green, 2012b). In one randomized trial with more than 800 women who had mild deficiency, daily iodine supplementation had no effect on child neurodevelopment at age 5 to 6 years (Gowachirapant, 2017). Supplementation studies conducted in regions with *moderate deficiency* have reported inconsistent findings with regard to psychomotor development (Bell, 2016). Berbel and associates (2009) began daily supplementation in more than 300 pregnant women with moderate deficiency at three time periods. They found improved neurobehavioral development scores in offspring of women supplemented with 200 μg of potassium iodide very early in pregnancy. Similarly, Velasco and coworkers (2009) found improved Bayley Psychomotor Development scores in offspring of women supplemented with 300 μg of iodine daily in the first trimester. In contrast, Murcia and colleagues (2011) identified lower psychomotor scores in 1-year-old infants whose mothers reported daily supplementation of more than 150 μg. *Severe deficiency* is frequently associated with damage typically encountered with *endemic cretinism*, and benefits of universal salt iodization or supplementation have been confirmed (Alexander, 2017).

Regarding daily iodine intake, the Institute of Medicine (2001) recommends 220 μg/d during pregnancy and 290 μg/d during lactation (Chap. 10, p. 185). The American Thyroid Association recommends an average iodine intake of 250 μg/d in all pregnant women and has recommended that 150 μg of iodine be added to prenatal vitamins to achieve this average daily oral intake (Alexander, 2017; Kerver, 2021). In an older study, Leung and coworkers (2011) reported that only half of the prenatal multivitamins in the United States contained iodine. Without evidence of benefit, however, it is hard to justify the cost of iodine supplementation of large numbers of pregnant women in areas with mild iodine deficiency (Pearce, 2016).

Importantly, experts caution against oversupplementation since excessive iodine exposure can lead to subclinical thyroid dysfunction and is associated with increased prevalence of thyroid autoimmunity (Pearce 2016; Shi, 2015). The American Thyroid Association advises against exceeding twice the daily recommended intake of iodine, which is 500 μg/d (Alexander, 2017).

Congenital Hypothyroidism

Universal newborn screening for neonatal hypothyroidism was introduced in 1974 and is now required by law in all states (Chap. 32, p. 594). This develops in approximately 1 in 2000 newborns. The reported incidence has increased during the past few decades and is thought to stem from greater preterm neonate survival rates and methodological shifts in newborn screening (McGrath, 2019). Variation in TSH percentiles according to gestational age at delivery have led some to propose age-adjusted cutoffs to avoid overdiagnosis (Kaluarachchi, 2019). Developmental disorders of the thyroid gland such as agenesis and hypoplasia account for 80 to 90 percent of cases. The remainder may be caused by hereditary defects in thyroid hormone production, but it is estimated that up to 15 percent may have a transient form of the disease (McGrath, 2018; Oron, 2018).

Early and aggressive thyroxine replacement is critical for affected newborns (van Trotsenburg, 2021). In one study of 76 children with congenital hypothyroidism, IQ scores at age 18 years did not differ from those in 40 siblings, provided the initial thyroxine dose was sufficiently high (Aleksander, 2018).

Postpartum Thyroiditis

Transient autoimmune thyroiditis is consistently found in approximately 5 to 10 percent of women during the first year after childbirth (Nathan, 2014; Nguyen, 2019). With an onset within 12 months, postpartum thyroid dysfunction includes hyperthyroidism, hypothyroidism, or both. The propensity for thyroiditis antedates pregnancy and is directly related to increasing serum levels of thyroid autoantibodies. Up to 50 percent of women who have thyroid antibodies in the first trimester will develop postpartum thyroiditis (Stagnaro-Green, 2012a). As mentioned previously, routine thyroid autoantibody testing during pregnancy is currently not recommended (American College of Obstetricians and Gynecologists, 2020).

In clinical practice, postpartum thyroiditis is diagnosed infrequently because it typically develops months after delivery and causes vague symptoms (Nguyen, 2019). The presentation varies, and classically two clinical phases that may develop in succession are recognized. The first and earliest is *destruction-induced thyrotoxicosis* with symptoms from excessive release of hormone from glandular disruption. The onset is abrupt, and a small, painless goiter is common. From many possible symptoms, only fatigue and palpitations are more frequent in thyrotoxic women compared with normal controls. This thyrotoxic phase usually lasts only a few months. Thionamides are ineffective, and if symptoms are severe, a β-blocking agent may be given. The second and usually later phase between 4 and 8 months postpartum is *hypothyroidism* from thyroiditis. Thyromegaly and other symptoms are common and more prominent than during the thyrotoxic phase. Levothyroxine replacement at doses of 25 to 75 μg/d is typically given for 6 to 12 months.

Stagnaro-Green and associates (2011) reported postpartum surveillance results in 4562 Italian gravidas who had been screened for thyroid disease in pregnancy. Serum TSH and anti-TPO antibody levels were measured again at 6 and 12 months. Overall, 169 women (3.9 percent) developed postpartum thyroiditis, and two thirds of these were identified to have hypothyroidism only. The other third were diagnosed with hyperthyroidism. Only 14 percent of all women demonstrated the classic biphasic progression. These findings are consistent with data compiled from 20 other studies between 1982 and 2008 (Stagnaro-Green, 2012a).

Importantly, women who experience either type of postpartum thyroiditis have a 20- to 30-percent risk of eventually developing permanent hypothyroidism, and the annual progression rate is 3.6 percent (Nathan, 2014). Women at greater risk for developing hypothyroidism are those with higher titers of thyroid antibodies and higher TSH levels during the initial hypothyroid phase. Others may develop subclinical disease, but half of those with thyroiditis who are positive for TPO antibodies develop permanent hypothyroidism by 6 to 7 years (Stagnaro-Green, 2012a).

An association between postpartum thyroiditis and postpartum depression has been proposed but remains unresolved (Alexander, 2017). Similarly unsettled is the link between depression and thyroid antibodies. Kuijpens and associates (2001) reported that TPO antibodies were a marker for postpartum depression in euthyroid women. In a randomized trial, however, Harris and coworkers (2002) reported no difference in postpartum depression in 342 women with TPO antibodies who were given either levothyroxine or placebo. Somewhat related, in the MFMU Network randomized trial, women with subclinical hypothyroidism allocated to thyroxine treatment during pregnancy did not experience improvement in their depression (Costantine, 2020).

Nodular Thyroid Disease

Palpable thyroid nodules can be found in up to 5 percent of reproductive-aged women (Angell, 2019). Management of a palpable thyroid nodule during pregnancy depends on gestational age and mass size. Small nodules detected by sensitive sonographic methods are more common during pregnancy in some populations. Kung and associates (2002) used high-resolution sonography and found that 15 percent of Chinese women had nodules larger than 2 mm in diameter. Almost half of cases had multiple masses. The nodules usually enlarged modestly across pregnancy and did not regress postpartum. Biopsy of those measuring >5 mm^3 that persisted at 3 months usually showed nodular hyperplasia, and none was malignant. In most studies, 90 to 95 percent of solitary nodules are benign (Burch, 2016).

Evaluation of thyroid nodules during pregnancy should be similar to that for nonpregnant patients. As discussed in Chapter 49 (p. 875), *radioiodine scanning* in pregnancy is usually not recommended (American College of Obstetricians and Gynecologists, 2020). *Sonographic* examination reliably detects

nodules >5 mm, and their solid or cystic structure also is determined. According to the American Association of Clinical Endocrinologists, sonographic characteristics associated with malignancy include hypoechogenic pattern, irregular margins, and microcalcifications (Gharib, 2016). *Fine-needle aspiration (FNA)* under ultrasound guidance is an excellent assessment method because cytological diagnostic criteria are not substantially influenced by pregnancy (Gharib, 2016). If the FNA biopsy shows a follicular lesion, surgery may be deferred until postpartum.

Evaluation of thyroid cancer involves a multidisciplinary approach (Fagin, 2016). Most thyroid carcinomas are well differentiated and indolent. Messuti and coworkers (2014) provided evidence that persistence or recurrence of these tumors may be more common in pregnant women. For thyroid malignancy diagnosed in the first or second trimester, thyroidectomy may be performed before the third trimester. In women without evidence of an aggressive thyroid cancer or in those diagnosed in the third trimester, surgical treatment can be deferred until the early puerperium (Gharib, 2016) (Chap. 66, p. 1174).

PARATHYROID DISEASE

Parathyroid hormone (PTH) maintains extracellular fluid calcium concentration. This 84-amino-acid hormone acts directly on bone and kidney and indirectly on small intestine to increase serum calcium (Potts, 2015). PTH secretion is regulated by serum ionized calcium concentration through a negative feedback system. *Calcitonin* is a potent parathyroid hormone that acts as a physiological PTH antagonist. The relationships between these hormones, calcium metabolism, and *PTH-related protein (PTH-rP)* produced by fetal tissue are discussed in Chapter 4 (p. 73).

Of fetal demands, calcium requirements reach 300 mg/d in late pregnancy and 30 g for the entire gestation. These needs and greater renal calcium loss from augmented maternal glomerular filtration substantively raise maternal calcium demands. Total serum calcium levels decline with serum albumin concentrations, but ionized calcium levels remain unchanged. Pregnancy is also associated with a twofold rise in serum concentrations of 1,25-dihydroxyvitamin D, which increases gastrointestinal calcium absorption. The effectuating hormone is probably of placental and decidual origin since maternal PTH levels are low normal or decreased during pregnancy (Cooper, 2011). Calcium is actively transported across the placenta and deposited in the developing fetal skeletal system. Fetal calcium homeostasis is maintained through a complex interplay between PTH-rP, PTH, and receptors in the placenta, fetal kidney, and fetal skeleton (Hirai, 2015).

Hyperparathyroidism

Hypercalcemia is caused by hyperparathyroidism or cancer in 90 percent of cases (Potts, 2015). Because many automated laboratory systems include serum calcium measurement, hyperparathyroidism has changed from being a condition defined by symptoms to one that is discovered on routine screening (Pallan, 2012). Hypercalcemia has a reported prevalence of 2 to 3 cases per 1000 women, but some estimate the rate to reach 14 cases per 1000 if asymptomatic women are included. Almost 80 percent are caused by a solitary adenoma, and another 15 percent by hyperfunctioning of all four glands. In the remainder, an associated malignancy is usually obvious. Of note, PTH produced by tumors is not identical to the natural hormone and may not be detected by routine assays.

In most patients with hyperparathyroidism, the serum calcium level is elevated to within only 1 to 1.5 mg/dL above the upper normal limit. This may help to explain why only 20 percent of those who have abnormally elevated levels are symptomatic (Bilezikian, 2004). In a fourth, however, symptoms become apparent when the serum calcium level continues to rise. *Hypercalcemic crisis* manifests as stupor, nausea, vomiting, weakness, fatigue, and dehydration.

Women with symptomatic hyperparathyroidism should be surgically treated (Davis, 2020; Potts, 2015). Indications for parathyroidectomy include a serum calcium level 1.0 mg/dL above the upper normal range, a calculated creatinine clearance <60 mL/min, reduced bone density, or age >50 years (Bilezikian, 2009). Those not meeting these criteria should undergo annual serum calcium and creatinine level measurement and bone density assessment every 1 to 2 years (Pallan, 2012).

Hyperparathyroidism in Pregnancy

In their review, Schnatz and Thaxton (2005) found fewer than 200 reported cases of hyperparathyroidism complicating pregnancy. As in nonpregnant patients, parathyroid adenoma is the most common etiology. Ectopic parathyroid hormone production and rare cases of parathyroid carcinoma have been reported in pregnancy (Montoro, 2000; Saad, 2014). Symptoms of hyperparathyroidism during pregnancy include hyperemesis, generalized weakness, renal calculi, and psychiatric disorders. Occasionally, pancreatitis is the presenting disorder (Hirsch, 2015).

Pregnancy theoretically improves hyperparathyroidism by significantly shunting calcium to the fetus and by augmented renal excretion. When these effects are withdrawn, however, postpartum hypercalcemic crisis is a danger. This life-threatening complication can be seen with serum calcium levels >14 mg/dL, and nausea, vomiting, tremors, dehydration, and mental status changes are symptoms (Malekar-Raikar, 2011).

Early reports described excessive stillbirths and preterm deliveries in pregnancies complicated by hyperparathyroidism. More recent reports, however, describe lower rates of stillbirth, neonatal death, and neonatal tetany (Kovacs, 2011). Other fetal complications include miscarriage, fetal-growth restriction, and low birthweight (Chamarthi, 2011).) One group reported a 30-percent incidence of preeclampsia (Rigg, 2019).

Management in Pregnancy

Surgical removal of a symptomatic parathyroid adenoma is preferable. This should prevent fetal and neonatal morbidities and postpartum parathyroid crises (Kovacs, 2011). In one case series from an Australian referral hospital, 22 pregnancies were managed medically, and six women underwent parathyroidectomy. Preterm delivery was reported in 66 percent of pregnancies managed without surgery, whereas all surgically treated women delivered at term (Rigg, 2019). Elective neck

exploration during pregnancy is usually well tolerated, even in the third trimester (Hirsch, 2015; Stringer, 2017). In at least two cases, a mediastinal adenoma was removed at midpregnancy (Rooney, 1998; Saad, 2014).

Medical management may however be appropriate in asymptomatic pregnant women with mild hypercalcemia (Hirsch, 2015). If so, patients are carefully monitored in the puerperium for hypercalcemic crisis. Initial medical management might include *calcitonin* to decrease skeletal calcium release, or oral phosphate, 1 to 1.5 g daily in divided doses, to bind excess calcium. For women with dangerously elevated serum calcium levels or those who are mentally obtunded with *hypercalcemic crisis*, emergency treatment is instituted. Diuresis with IV normal saline is begun so that urine flow exceeds 150 mL/hr. *Furosemide* is given in conventional doses to block tubular calcium reabsorption. Importantly, hypokalemia and hypomagnesemia should be prevented. Adjunctive therapy includes *mithramycin*, which inhibits bone resorption.

Neonatal Effects

Normally, cord blood calcium levels are higher than maternal levels (Chap. 7, p. 136). With maternal hyperparathyroidism, abnormally elevated maternal and thus fetal levels further suppress fetal parathyroid function. Because of this, newborn calcium levels rapidly drop after birth, and 15 to 25 percent of these neonates develop severe hypocalcemia with or without tetany (Molitch, 2000). Neonatal hypoparathyroidism caused by maternal hyperparathyroidism is usually transient and is treated with calcium and 1,25-dihydroxyvitamin D_3 (calcitriol). The latter will not be effective in preterm infants, however, because the intestinal vitamin D receptor is insufficiently expressed (Kovacs, 2011). Neonatal tetany or seizures should stimulate an evaluation for maternal hyperparathyroidism (Beattie, 2000; Ip, 2003).

■ Hypoparathyroidism

The most common cause of hypocalcemia is hypoparathyroidism that usually follows parathyroid or thyroid surgery. It is estimated that almost 80 percent of cases are attributable to complications of anterior neck surgery (Gafni, 2019). Hypoparathyroidism is characterized by facial muscle spasms, muscle cramps, and paresthesias of the lips, tongue, fingers, and feet. This can progress to tetany and seizures (Potts, 2015). Chronically, hypocalcemic pregnant women may also have a fetus with skeletal demineralization resulting in multiple bone fractures in the neonatal period (Alikasifoglu, 2005).

Maternal treatment includes calcitriol, dihydrotachysterol, or large vitamin D doses of 50,000 to 150,000 U/d; calcium gluconate or calcium lactate in doses of 3 to 5 g/d; and a low-phosphate diet. Fetal risks from large doses of vitamin D have not been established. During treatment, the therapeutic challenge in women with known hypoparathyroidism is management of blood calcium levels. It is possible that the greater calcium absorption typical of pregnancy will result in lower calcium requirements or that the fetal demand for calcium will result in greater need. The goal during pregnancy is to maintain a corrected calcium level in the low normal range.

■ Pregnancy and Lactation-associated Osteoporosis

In most gravidas, even with their remarkably increased calcium requirements, it is uncertain whether pregnancy causes osteopenia. In one study of 200 women, bone density declined during pregnancy (Kraemer, 2011). Women who breastfed, carried twin pregnancies, or had a low body mass index were at higher risk of bone loss. Thomas and Weisman (2006) in their review cite a 3- to 4-percent average reduction in bone mineral density during pregnancy. Lactation also represents a period of negative calcium balance that may be corrected through maternal skeletal resorption. However, data from the Women's Health Initiative found that parity, number of pregnancies, age at first pregnancy, breastfeeding, and duration of breastfeeding were not associated with postmenopausal hip fracture risk or bone density losses (Crandall, 2017).

The most common symptom of this rare disorder of pregnancy-associated osteoporosis is back pain in late pregnancy or postpartum. Other symptoms are hip pain, either unilateral or bilateral, and difficulty in weight bearing until the woman is nearly immobilized (Maliha, 2012). In more than half of women, no apparent reason for osteopenia is found. Some known causes are heparin (unfractionated only), bed rest, and corticosteroid therapy (Cunningham, 2005; Galambosi, 2016). In a few cases, overt hyperparathyroidism or thyrotoxicosis eventually develops.

Treatment is problematic and includes calcium and vitamin D supplementation and pain management. Long-term surveillance of osteopenia indicates that although bone density improves, these women and their offspring may have chronic osteopenia (Carbone, 1995). Related, prenatal supplementation of normal women with cholecalciferol, 1000 IU/d, did not increase offspring bone mineral content, although it did ensure maternal vitamin D repletion (Cooper, 2016). In lactating women with osteoporosis, some advocate cessation of breastfeeding (Zhang, 2017).

ADRENAL GLAND DISORDERS

■ Pheochromocytoma

Pregnancy has profound effects on adrenal cortical secretion. These interrelationships were reviewed by Lekarev and New (2011) and are discussed in detail in Chapter 4 (p. 73). Several adrenal disorders may be encountered in pregnancy.

Of these, pheochromocytomas are chromaffin tumors that secrete catecholamines and usually are located in the adrenal medulla, although 10 percent are located in sympathetic ganglia. They are called the *10-percent tumor* because approximately 10 percent are bilateral, 10 percent are extra adrenal, and 10 percent are malignant. These tumors can be associated with medullary thyroid carcinoma and hyperparathyroidism in some of the autosomally dominant or recessive *multiple endocrine neoplasia syndromes*, as well as in neurofibromatosis and von Hippel-Lindau disease (Neumann, 2018).

Pheochromocytomas complicate approximately 1 per 50,000 pregnancies (Quartermaine, 2018). Notably, they are found in 0.2 to 0.6 percent of hypertensive patients (Lenders, 2019). Symptoms are usually paroxysmal and manifest as hypertensive crisis, seizures, or anxiety attacks. Others are headaches,

sweating, palpitations, chest pain, nausea, vomiting, and pallor or flushing. Hypertension is sustained in 60 percent of patients, but half of these also have paroxysmal crises.

Standard screening is quantification of metanephrines and catecholamine metabolites in a 24-hour urine specimen (Neumann, 2018). Diagnosis is established by measurement of a 24-hour urine collection with at least two of three assays for free catecholamines, metanephrines, or vanillylmandelic acid (VMA). Determination of plasma catecholamine metabolite levels is the most sensitive test, and a pheochromocytoma diagnosis is excluded if they are within normal range (Eisenhofer, 2018). In nonpregnant patients, adrenal localization is usually successful with either computed tomography (CT) or magnetic resonance (MR) imaging. For most cases, preferred treatment is laparoscopic adrenalectomy (Neumann, 2018).

In pregnancy, these tumors are rare but result in dangerous complications. Geelhoed (1983) provided an earlier review of 89 cases in which 43 mothers died. Maternal death was much more common if the tumor was not diagnosed antepartum—58 versus 18 percent. As seen in Table 61-5, maternal mortality rates are now lower but still formidable. In one review of 77 cases, antepartum diagnosis was the most important determinant of maternal mortality risk (Biggar, 2013). However, Salazar-Vega and colleagues (2014) described good outcomes in women diagnosed after delivery.

Diagnosis of pheochromocytoma in pregnancy is similar to that for nonpregnant patients. MR imaging is the preferred technique to locate adrenal and extra-adrenal pheochromocytomas (Fig. 61-5). Importantly, differentiating preeclampsia from the hypertensive crisis caused by pheochromocytoma is essential.

Immediate control of hypertension and symptoms is attained with an α-adrenergic blocking agent such as *phenoxybenzamine*. The dose is 10 to 30 mg, two to four times daily. After α-blockade is achieved, β-blocking drugs such as propranolol may be given for tachycardia. In many cases, surgical exploration and tumor removal are performed during pregnancy, preferably during the second trimester (Biggar, 2013; Dong, 2014). Successful laparoscopic removal of adrenal tumors has become the norm (Miller, 2012; Zuluaga-Gómez, 2012). Donatini and colleagues (2018) described three cases of women with bilateral tumors who had laparoscopic unilateral adrenalectomy of the largest tumor during pregnancy and subsequent contralateral adrenalectomy after delivery to avoid the maternal and fetal effects of adrenal insufficiency. If diagnosed later in pregnancy, either planned cesarean delivery with tumor excision or postpartum resection is appropriate.

Recurrent tumors are troublesome, and even with good blood pressure control, dangerous peripartum hypertension may develop. We have cared for three women in whom recurrent pheochromocytoma was identified during pregnancy. Hypertension was managed with phenoxybenzamine in all three. Two newborns were healthy, but a third was stillborn in a mother with a massive tumor burden who was receiving phenoxybenzamine, 100 mg daily. In all three women, the tumor was resected postpartum.

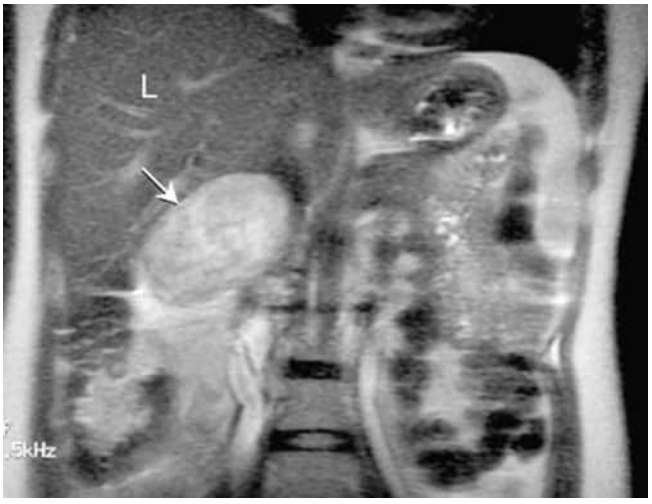

FIGURE 61-5 Coronal magnetic resonance image taken in a 32-week pregnant woman shows a right-sided pheochromocytoma (*arrow*) and its position relative to the liver (*L*) above it.

Maternal death	16	4	12	8
Fetal wastage	26	11	17	17

■ Cushing Syndrome

This syndrome is rare and the female:male ratio is 3:1 (Arit, 2018). Most cases of *Cushing syndrome* are iatrogenic from long-term corticosteroid treatment. Excessive glucocorticoids can also be the result of a pituitary adenoma, adrenal tumor, or bilateral adrenal hyperplasia (Melmed, 2020). *Cushing disease* refers to bilateral adrenal hyperplasia stimulated by corticotropin-producing pituitary adenomas. Corticotropin is also called adrenocorticotropic hormone (ACTH). Most adenomas are microadenomas measuring <1 cm, and half measure <5 mm. Rarely, abnormal secretion of hypothalamic corticotropin-releasing factor may cause corticotropic hyperplasia. Such hyperplasia may also be caused by nonendocrine tumors that produce polypeptides similar to either corticotropin-releasing factor or corticotropin. Less than a fourth of cases of Cushing syndrome are corticotropin independent, and most of these are caused by an adrenal adenoma (Machado, 2018). Tumors are usually bilateral, and half are malignant. Occasionally, associated androgen excess may lead to severe virilization.

The typical cushingoid body habitus is caused by adipose tissue deposition creating *moon facies*, a *buffalo hump*, and *truncal*

obesity. Fatigability and weakness, hypertension, hirsutism, and amenorrhea are each encountered in 75 to 85 percent of nonpregnant patients (Hatipoglu, 2012; Melmed, 2020). Personality changes, easy bruising, and cutaneous striae are common. Up to 60 percent may have impaired glucose tolerance. Diagnosis can be difficult and is suggested by elevated plasma cortisol levels that cannot be suppressed by dexamethasone or by elevated 24-hour urinary free cortisol excretion in three collections (Arit, 2018; Loriaux, 2017). Neither test is totally accurate, and each is more difficult to interpret in obese patients. Serum corticotropin levels and CT and MR imaging are used to localize pituitary and adrenal tumors or hyperplasia.

In pregnancy, diagnosis can be difficult because of pregnancy-induced increases in plasma cortisol, corticotropin, and corticotropin-releasing factor levels. Measurement of urinary free cortisol excretion in a 24-hour collection sample is recommended. With interpretation of results, the normal elevation seen in pregnancy is factored. Because most women have corticotropin-dependent Cushing syndrome, associated androgen excess may cause anovulation, and pregnancy is rare. Caimari and coworkers (2017) identified 263 pregnancies in 220 women with Cushing syndrome in their systematic review. These differ compared with nonpregnant women in that more than half are caused by corticotropin-independent adrenal adenomas (Kamoun, 2014; Lacroix, 2015; Machado, 2018). Approximately 30 percent of cases are from a pituitary adenoma, and 10 percent from adrenal carcinomas. Pregnancy outcomes reviewed by Caimari and associates (2017) in women with Cushing syndrome are listed in Table 61-6.

Long-term medical therapy for Cushing syndrome usually is ineffective, and definitive therapy is resection of the pituitary or adrenal adenoma or bilateral adrenalectomy for hyperplasia (Lacroix, 2015; Machado, 2018). During pregnancy, management of hypertension in mild cases may suffice until delivery. In their review, Lindsay and associates (2005) described primary medical therapy in 20 women with Cushing syndrome. Most were successfully treated with *metyrapone* as an interim treatment until definitive surgery after delivery. A few cases were treated with oral *ketoconazole*. However, because this drug also blocks testicular steroidogenesis, treatment during pregnancy with a male fetus is worrisome. *Mifepristone,* the norethindrone derivative used for abortion and labor induction, has shown promise for treating Cushing disease but should not be used in pregnancy for obvious reasons. Transsphenoidal resection of a pituitary mass or laparoscopic adrenalectomy are considered first-line treatment options in the second trimester (Brue, 2018; Manoharan, 2020). Unilateral adrenalectomy has been safely performed in the early third trimester and can also be curative (Abdelmannan, 2011).

TABLE 61-6. Complications in Pregnancies of Women with Active and Cured Cushing Syndrome

Complication	Incidence (%)	
	Active Disease (n = 214)	Cured (n = 49)

Gestational hypertension	40	2
Preeclampsia	26	2
Cesarean delivery	52	22
Mortality	1	0
Perinatal		
Preterm birth	66	3
Fetal-growth restriction	15	5
Spontaneous abortion	11	6
Stillbirth	6	2
Neonatal death	5	0

Adrenal Insufficiency—Addison Disease

Primary adrenocortical insufficiency is rare because more than 90 percent of total gland volume must be destroyed for symptoms to develop. *Autoimmune adrenalitis* is the most common cause in the developed world, but tuberculosis is a more frequent etiology in resource-poor countries (Arit, 2018; Betterle, 2019; Kamoun, 2014). In the United States, the prevalence in 7.7 million births was 1 case per 10,000 to 20,000 (Schneiderman, 2017). There is an increased incidence of concurrent Hashimoto thyroiditis, primary ovarian insufficiency, type 1 diabetes, and Graves disease. These *polyglandular autoimmune syndromes* also include pernicious anemia, vitiligo, alopecia, nontropical sprue, and myasthenia gravis.

Untreated adrenal hypofunction frequently causes infertility, but with replacement therapy, ovulation is restored. If untreated, women often note weakness, nausea, vomiting, and weight loss. Low levels of plasma cortisol and elevated ACTH levels are generally considered diagnostic (Betterle, 2019). Because serum cortisol levels rise during pregnancy, a short ACTH-stimulation test documenting less than a twofold increase in plasma cortisol in response to infused corticotropin confirms the diagnosis (Manoharan, 2020).

In a large cohort study, 1188 women with Addison disease were compared with more than 11,000 age-matched controls who delivered between 1973 and 2006 (Björnsdottir, 2010). Women diagnosed with adrenal insufficiency within 3 years of delivery were significantly more likely to deliver preterm, to deliver a low-birthweight newborn, and to undergo cesarean delivery. Others have reported similar adverse outcomes (Quartermaine, 2018). Most pregnant women with Addison disease are already taking glucocorticoid and mineralocorticoid replacement drugs. These should be continued, and women are observed for evidence of either inadequate or excessive corticosteroid replacement. A 20- to 40-percent dose increase is usually expected after midpregnancy to mimic the physiological cortisol elevation in pregnancy (Oliveira, 2018). During labor, delivery, and postpartum, or after a surgical procedure, corticosteroid replacement must be increased appreciably to approximate the normal adrenal response. This augmented dose is called a *stress dose*, and one option is hydrocortisone, 100 mg, given IV every 8 hours for 48 hours. Importantly, shock from causes other than adrenocortical insufficiency—for example, hemorrhage or sepsis—must be recognized and treated promptly.

Primary Aldosteronism

Hyperaldosteronism is caused by an adrenal adenoma—Conn syndrome—in approximately 75 percent of cases. Idiopathic bilateral adrenal hyperplasia makes up the remainder, except for rare cases of adrenal carcinoma (Eschler, 2015; Yang, 2020). Findings include hypertension, hypokalemia, and muscle weakness. High serum or urine levels of aldosterone confirm the diagnosis.

In normal pregnancy, as discussed in Chapter 4 (p. 74), progesterone blocks aldosterone action, and this results in very high aldosterone levels (Appendix, p. 1230). Accordingly, the diagnosis of hyperaldosteronism during pregnancy can be difficult. Because renin levels are suppressed in pregnant women with hyperaldosteronism, a plasma aldosterone-to-renin activity ratio may be helpful for diagnosis (Morton, 2015). Hypertension worsens as pregnancy progresses, and medical management includes potassium supplementation and antihypertensive therapy. In many cases, hypertension responds to *spironolactone.* However, β-blocking or calcium channel–blocking drugs may be preferred because of the potential fetal antiandrogenic effects of spironolactone. Mascetti and coworkers (2011) reported successful use of *amiloride* in a pregnant woman. Use of *eplerenone*, a selective aldosterone-receptor antagonist, also has been described (Manoharan, 2020). Laparoscopic tumor resection is considered curative, but the optimal management during pregnancy, either surgical or medical, remains unclear (Eschler, 2015; Morton, 2015).

PITUITARY DISORDERS

Prolactinomas

The pituitary enlarges impressively during pregnancy, predominantly from lactotrophic cellular hyperplasia induced by estrogen (Chap. 4, p. 70). Several pituitary disorders also can complicate pregnancy.

Of these, prolactinomas are tumors that constitute 75 percent of pituitary adenomas in women (Melmed, 2020). They are often found in nonpregnant women since the advent of widely available serum prolactin assays. Serum levels <25 pg/mL are considered normal in nonpregnant women. Adenoma symptoms and findings include amenorrhea, galactorrhea, and hyperprolactinemia. Tumors are classified arbitrarily by their size measured by CT or MR imaging. A microadenoma is ≤10 mm, and a macroadenoma is >10 mm. Treatment for microadenomas is usually with bromocriptine, a dopamine agonist and powerful prolactin inhibitor, which frequently restores ovulation. For suprasellar macroadenomas, most recommend surgical resection before pregnancy is attempted (Araujo, 2015; Melmed, 2020).

In a pooled analysis of more than 750 pregnant women with prolactinomas, only 2.4 percent with *microadenomas* developed symptomatic enlargement during pregnancy (Molitch, 2015). Symptomatic enlargement of *macroadenomas*, however, is more frequent and was found in 21 percent of 238 pregnant women. In another study of 46 women with a macroprolactinoma, 20 percent had tumor growth–related symptoms (Barraud, 2020). Nonfunctioning adenomas can also cause symptoms of pituitary expansion in pregnancy (Lambert, 2017).

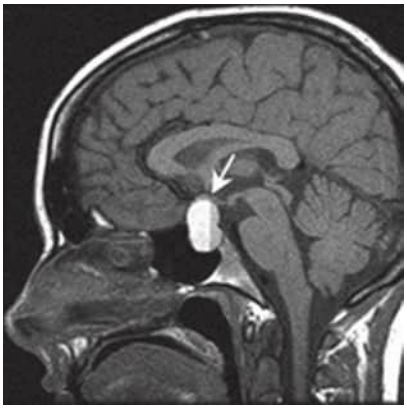

FIGURE 61-6 Magnetic resonance imaging of a pituitary adenoma. This sagittal T1-weighed image demonstrates a fluid-fluid level, consistent with intratumoral hemorrhage (*arrow*). (Reproduced with permission from Dr. Toral Patel.)

Pregnant women with microadenomas should be queried regularly for headaches and visual symptoms. Those with macroadenomas are followed more closely and have visual field testing each trimester. CT or MR imaging is recommended only if symptoms develop (Fig. 61-6). Serial serum prolactin levels serve little use because of normal rises during pregnancy (Appendix, p. 1231). Symptomatic tumor enlargement should be treated immediately with a dopamine antagonist. The safety of bromocriptine in pregnancy is well established. The safety profile is less well known for cabergoline. This drug is increasingly used in nonpregnant women because it is better tolerated and more effective. Cabergoline is generally considered safe for use in pregnancy (Huang, 2019; O'Sullivan, 2020). Surgery is recommended for women with no response, including those with pituitary apoplexy (Barraud, 2020).

Acromegaly

This is caused by excessive growth hormone, usually from an acidophilic or a chromophobic pituitary adenoma. In normal pregnancy, pituitary growth hormone levels decline as placental epitopes are secreted. Diagnosis is suggested by elevated insulin growth factor 1 (IGF-1) serum levels. Levels are more indicative in the first half of pregnancy because IGF-1 concentrations rise in normal pregnancy after midpregnancy (Abucham, 2017; Melmed, 2020). Definitive diagnosis may best be postponed until after delivery. Fewer than 100 cases of acromegaly have been reported during pregnancy (Cheng, 2012; Dias, 2013). Pregnancy is rare in women with acromegaly because half are hyperprolactinemic and anovulatory. During pregnancy, affected women are at marginally greater risk for gestational diabetes and hypertension (Dias, 2013; Jallad, 2018).

Management is similar to that for prolactinomas, and women are monitored for symptoms of tumor enlargement. Dopamine agonist therapy is less effective than for prolactinomas. Transsphenoidal resection, generally considered first-line treatment outside of pregnancy, may be necessary for symptomatic tumor enlargement during pregnancy (Motivala, 2011). Guven and associates (2006) reported a case of pituitary apoplexy necessitating emergent transsphenoidal adenoma resection and

cesarean delivery at 34 weeks' gestation. Successful treatment of pregnant women with the somatostatin-receptor ligand *octreotide* and with the growth hormone analogue *pegvisomant* has been reported (Dias, 2013; Fleseriu, 2015).

Diabetes Insipidus

Vasopressin deficiency evident in diabetes insipidus (DI) is most commonly due to neurohypophysis agenesis or destruction. True DI rarely complicates pregnancy. Instead, other types of DI encountered during pregnancy include primary polydipsia, gestational DI, and nephrogenic DI. These show suppressed secretion of, increased degradation of, and renal insensitivity to vasopressin, respectively (Robertson, 2016). In our experiences, transient secondary DI is more likely encountered with acute fatty liver of pregnancy (Nelson, 2013). This probably stems from altered vasopressinase clearance because of hepatic dysfunction (Chap. 58, p. 1035).

DI therapy is intranasal administration of a synthetic analogue of vasopressin, *desmopressin*, which is 1-deamino-8-D-arginine vasopressin (DDAVP). Available data on the safety of DDAVP during pregnancy is reassuring (Chanson, 2019). Most women require higher doses during pregnancy because of an increased metabolic clearance rate stimulated by placental vasopressinase (Lindheimer, 1994). The prevalence of placental vasopressinase-induced DI is estimated at 2 to 4 cases per 100,000 pregnancies (Wallia, 2013).

Sheehan Syndrome

Sheehan (1937) reported that pituitary ischemia and necrosis associated with obstetrical blood loss could result in hypopituitarism. With modern methods of hemorrhagic shock treatment, Sheehan syndrome rates have gradually declined (Matsuzaki, 2017; Pappachan, 2015). Affected women may have persistent hypotension, tachycardia, hypoglycemia, and lactation failure. Because deficiencies of some or all pituitary-responsive hormones may develop after the initial insult, Sheehan syndrome can be heterogenous and may not be identified for years (Chanson, 2019). In one cohort study of 60 women with Sheehan syndrome, the average time to diagnosis was 13 years (Gei-Guardia, 2011). Because adrenal insufficiency is the most life-threatening complication, adrenal function should be immediately assessed. After glucocorticoid replacement, subsequent analyses and replacement of thyroid, gonadal, and growth hormones is considered. Women with Sheehan syndrome who become pregnant likely have a livebirth (Vila, 2020).

Lymphocytic Hypophysitis

This rare autoimmune pituitary disorder is characterized by massive infiltration by lymphocytes and plasma cells with parenchymal destruction of the gland. Many cases are temporally linked to pregnancy, and more than half of reported cases in women are identified during pregnancy or puerperium (Gubbi, 2018). However, more recent reports describe fewer cases associated with pregnancy (Chanson, 2019). The degrees of hypopituitarism or mass effect symptoms, including headaches and visual field defects, vary. A sellar mass is seen with CT or MR imaging. A mass accompanied by a modestly elevated serum prolactin level—usually <100 pg/mL—suggests lymphocytic hypophysitis. In contrast, levels >200 pg/mL are encountered with prolactinoma. The etiology is unknown, but nearly 30 percent have a history of coexisting autoimmune diseases including Hashimoto thyroiditis, Addison disease, type 1 diabetes, or pernicious anemia (Chanson, 2019). Treatment is with glucocorticoids and pituitary hormone replacement. The disease may be self-limited, and a careful withdrawal of hormone replacement is attempted after inflammation subsides (Foyouzi, 2011; Melmed, 2020). More than two thirds of women who require treatment for lymphocytic hypophysitis, however, will require long-term hormone replacement (Gubbi, 2018).

CHAPTER 62

Connective Tissue Disorders

Connective tissue disorders, also termed collagen vascular disorders, have two basic underlying causes. First are the *immune-complex diseases*, in which deposition of immune complexes causes connective tissue damage. Because these manifest by sterile inflammation—predominantly of the skin, joints, blood vessels, and kidneys—they are referred to as rheumatic diseases. Many of these immune-complex diseases are more prevalent in women, and systemic lupus erythematosus (SLE) and rheumatoid arthritis are examples. Second are the *inherited disorders* that involve bone, skin, cartilage, blood vessels, and basement membranes. These include Marfan syndrome, osteogenesis imperfecta, and Ehlers-Danlos syndrome.

IMMUNE-MEDIATED CONNECTIVE TISSUE DISEASES

These disorders can be separated into those associated with and those without autoantibody formation. The *rheumatoid factor* is an autoantibody found in many autoimmune inflammatory conditions such as SLE, rheumatoid arthritis, systemic sclerosis (scleroderma), mixed connective tissue disease, dermatomyositis, polymyositis, and various vasculitis syndromes. Instead, the *RF-seronegative spondyloarthropathies* are strongly associated with expression of the antigen termed human leukocyte antigen B27 (HLA-B27). These include ankylosing spondylitis, psoriatic arthritis, Reiter disease, and other arthritis syndromes.

The normal immunosuppression of pregnancy that allows and is essential for successful engraftment of fetal and placental tissues may mitigate activity in some of these syndromes. First, estrogens upregulate and androgens downregulate T-cell response, and progesterone is immunosuppressive (Abdul Hussain, 2020; Robinson, 2012). Second, pregnancy induces a predominance of T2 helper cells compared with cytokine-producing T1 helper cells (Petri, 2019). These changes are discussed in detail in Chapter 4 (p. 61).

However, active immune-mediated disease may contribute to obstetrical complications (Kither, 2020). One longitudinal cohort study found that unrecognized autoimmune systemic rheumatic disorders are associated with significant risk for preeclampsia and fetal-growth restriction (Spinillo, 2016). In this study, the prevalence of unrecognized systemic rheumatic diseases approximated 0.3 percent, and preeclampsia or fetal-growth restriction complicated 25 percent of these pregnancies.

Last, some immune-mediated diseases may be either caused or activated as a result of prior pregnancies. To explain, fetal cells and cell-free DNA are detectable in maternal blood beginning early in pregnancy (Simpson, 2013; Waldorf, 2008). *Fetal cell microchimerism* is the persistence of fetal cells in the maternal circulation and in organs following pregnancy. These fetal cells may become engrafted in maternal tissues and stimulate production of autoantibodies. Evidence for this includes fetal stem cells engrafted in tissues in women with autoimmune thyroiditis and systemic sclerosis (Jimenez, 2005; Srivatsa, 2001). Such microchimerism has also been described in women with SLE

TABLE 62-1. Some Autoantibodies Produced in Patients with Systemic Lupus Erythematosus

Antibody	Prevalence (%)	Clinical Associations
Antinuclear (ANA)	84–98	Best screening test, multiple antibodies; a second negative test makes SLE unlikely
Anti-dsDNA	62–70	High titers SLE-specific; may correlate with disease activity, nephritis, and vasculitis
Anti-Sm (Smith)	25–38	Specific for SLE
Anti-SS-A (Ro)	30–49	Not SLE-specific; associated with sicca syndrome, predisposes to cutaneous lupus, neonatal lupus with heart block, reduced risk of nephritis
Anti-SS-B (La)	10–35	Associated with anti-Ro
Antiphospholipid	21–50	Lupus anticoagulant and anticardiolipin antibodies associated with thrombosis, fetal loss, thrombocytopenia, valvular heart disease; false-positive test for syphilis
Anti-RNP	33–40	Not SLE-specific, high titers associated with rheumatic syndromes
Antihistone	70	Common in drug-induced lupus
Antierythrocyte	60	Direct Coombs test, may develop hemolysis
Antiplatelet	30	Thrombocytopenia in 15%; poor clinical test

ANA = antinuclear antibody; dsDNA = double-stranded DNA; RNP = ribonucleoprotein; SLE = systemic lupus erythematosus.
Data from Arbuckle, 2003; Hahn, 2018; Petri, 2020a,b.

and those with rheumatoid arthritis–associated HLA alleles (da Silva, 2016; Lee, 2010). Conversely, engrafted maternal cells may provoke autoimmune conditions in a woman's offspring (Stevens, 2016; Ye, 2012).

SYSTEMIC LUPUS ERYTHEMATOSUS

This autoimmune disease has an intricate pathogenesis that results from interactions between susceptibility genes and environmental factors (Hahn, 2018). Tissue-binding autoantibodies and immune complexes that are directed at one or more nuclear components lead to cellular and organ damage (Tsokos, 2011). In addition to this B-cell antibody production, immunosuppression is impaired, including regulatory T-cell function (Tower, 2013). Some autoantibodies produced in patients with SLE are shown in Table 62-1. Most patients have autoantibodies for many years before clinical disease manifests.

Genetic influences are implicated, and the concordance is higher with monozygotic compared with dizygotic twins—25 versus 2 percent, respectively. Moreover, the frequency in patients with one affected family member is 10 percent. The relative risk of disease rises if the "autoimmunity gene" on chromosome 16 that predisposes to SLE, rheumatoid arthritis, Crohn disease, and psoriasis is inherited. However, susceptibility genes such as *HLA-DR3*, *STAT4*, *APOL1*, *FCGR3A*, and *DNAse1* explain only a portion of the genetic heritability (Hahn, 2018; Yang, 2013).

Interestingly, maternal exposure to fetal genes elevates susceptibility to SLE development. A case-control study found that a child's *HLA-DRB1* genotype raises the risk of SLE in the mother (Cruz, 2016). In contrast, neonatal lupus has been reported in an infant conceived via oocyte donor to a mother with autoimmune disease with circulating anti-Ro and anti-La antibodies (Chiou, 2016).

Clinical Manifestations and Diagnosis

Almost 90 percent of SLE cases develop in women, and it more commonly affects African-American women compared with other populations (Izmirly, 2017; Stojan, 2018). Its prevalence in those of childbearing age approximates 1 case in 500 (Pons-Estel, 2010). Accordingly, the disease is encountered relatively frequently during pregnancy.

SLE notoriously varies in its presentation, course, and outcome (Table 62-2) (Hahn, 2018). Findings may be confined initially to one organ system, and others become involved later. Instead, the disease may first be multisystem. Frequent findings are malaise, fever, arthritis, rash, pleuropericarditis, photosensitivity, anemia, and cognitive dysfunction. At least half of patients have renal involvement. SLE is also associated with declines in attention, memory, and reasoning (Hahn, 2018; Kozora, 2008).

Identification of antinuclear antibodies (ANA) is the best screening test, however, a positive result is not specific for SLE. Low titers can be found in normal individuals, other autoimmune diseases, acute viral infections, and chronic inflammatory processes. Several drugs also can cause a positive reaction. Antibodies to double-stranded DNA (dsDNA) and to Smith (Sm) antigens are relatively specific for SLE, whereas other antibodies are not (see Table 62-1). Although hundreds of autoantibodies have been described in SLE, only a few have been shown to participate in tissue injury (Tsokos, 2011). Microarray profiles are being developed for more accurate diagnosis (Putterman, 2016).

Chronic anemia develops frequently, and there may be leukopenia and thrombocytopenia. Proteinuria and casts are found in the half of patients with glomerular lesions. Lupus nephritis can also cause renal insufficiency, which is more common if there are antiphospholipid antibodies (Riancho-Zarrabeitia, 2020). Other laboratory findings include false-positive syphilis serology, prolonged partial thromboplastin time, and higher rheumatoid factor levels. Increased serum D-dimer concentrations often follow a flare or infection, but unexplained persistent elevations are associated with a high risk for thrombosis (Wu, 2008).

The diagnostic criteria for SLE are listed in Table 62-3. If any four or more of the 11 clinical criteria are present, serially or simultaneously, the diagnosis is made. Importantly, numerous

TABLE 62-2. Some Clinical Manifestations of Systemic Lupus Erythematosus

Organ System	Clinical Manifestations	Percentage
Systemic	Fatigue, malaise, fever, weight loss	~95
Musculoskeletal	Arthralgias, myalgias, polyarthritis, myopathy	~95
Hematological	Anemia, hemolysis, leukopenia, thrombocytopenia, lupus anticoagulant, splenomegaly	70–85
Cutaneous	Malar (butterfly) rash, discoid rash, photosensitivity, oral ulcers, alopecia, skin rashes	50–80
Neurological	Cognitive dysfunction, mood disorder, headache, seizures, stroke	40–60
Cardiopulmonary	Pleuritis, pericarditis, myocarditis, endocarditis, pneumonitis, pulmonary hypertension	30–60
Renal	Proteinuria, nephrotic syndrome, renal failure	30–50
Gastrointestinal	Nausea, pain, diarrhea, abnormal liver enzyme levels	30–40
Vascular	Thrombosis: venous (10%), arterial (5%)	10–15
Ocular	Conjunctivitis, sicca syndrome	10–15

drugs can induce a lupus-like syndrome. These include proton-pump inhibitors, thiazide diuretics, antifungals, antihypertensives, chemotherapeutics, statins, and antiepileptics. Drug-induced lupus is rarely associated with glomerulonephritis and usually regresses when the medication is discontinued (Laurinaviciene, 2017).

Lupus and Pregnancy

In a metaanalysis of nearly 9 million pregnancies, the incidence of lupus approximated 1 case in 900 births (He, 2020). During pregnancy, lupus improves in a third of women, remains unchanged in a third, and worsens in the remaining third. Thus, in any pregnancy, the clinical condition can worsen or *flare* without warning (Hahn, 2018).

In a cohort of 13,555 pregnant women with SLE, the maternal mortality rate was 325 per 100,000 (Clowse, 2008). Maternal deaths invariably occur in those with active disease (Ritchie, 2012). Women with SLE are at greater risk for thrombotic complications, infection, postpartum hemorrhage, and blood transfusion. He and Wei (2020) reported increased risks of adverse pregnancy outcomes in women with SLE compared with unaffected women (Table 62-4).

During the past several decades, pregnancy outcomes in women with SLE have improved remarkably. For most women with inactive or mild/moderate disease activity, pregnancy outcomes are relatively favorable (Buyon, 2015). Women who have confined cutaneous lupus do not usually have adverse outcomes (Hamed, 2013). However, newly diagnosed SLE during pregnancy tends to be severe (Zhao, 2013). In general, pregnancy outcome is best in women for whom: (1) lupus activity has been quiescent for at least 6 months before conception; (2) lupus nephritis manifest by proteinuria or renal dysfunction

TABLE 62-3. Clinical Criteria for Classification of Systemic Lupus Erythematosus

Clinical Manifestations
Skin
Oral ulcers
Alopecia
Synovitis
Serositis

TABLE 62-4. Risk of Adverse Pregnancy Outcomes in Women with Systemic Lupus Erythematosus

Outcome	Relative Risk (CI)
Preeclampsia/Eclampsia	3.4 (3.2–3.6)
Cesarean delivery	1.4 (1.1–1.7)
Stillbirth	16.5 (2.9–92.1)
Fetal loss	7.6 (4.8–11.9)
Preterm birth	2.3 (1.8–3.1)
SGA infants	2.5 (1.4–4.5)
LBW infants	4.8 (3.7–6.3)
NICU admission	2.8 (2.3–3.4)

CI = confidence interval; LBW = low birth weight; NICU = neonatal intensive care unit; SGA = small for gestational age.

is absent; (3) neither antiphospholipid syndrome nor lupus anticoagulant are detected; and (4) superimposed preeclampsia does not develop (Peart, 2014; Petri, 2020a; Stojan, 2012).

Lupus Nephritis

Active nephritis is associated with adverse pregnancy outcomes, although these have improved substantially and especially if disease remains in remission (Stojan, 2012; Wagner, 2009). Of complications, women with renal disease have a high incidence of gestational hypertension and preeclampsia. Of 137 women with SLE reported by Rodrigues and colleagues (2019), 27 percent of gravidas with preexisting renal disease developed preeclampsia compared with only 16 percent of those without underlying renal disease. In a review of 309 pregnancies complicated by lupus nephritis, 30 percent suffered a flare, and 40 percent of these had associated renal insufficiency (Moroni, 2005). The maternal mortality rate was 1.3 percent. These findings were corroborated in a subsequent prospective study (Moroni, 2016). In addition, a third of the 113 pregnancies were delivered preterm. Compared with women without nephritis or with inactive nephritis, those with active nephritis have a significantly increased incidence of maternal and fetal complications (Rodrigues, 2019; Wagner, 2009). The higher the histological class, the greater the risk.

Most recommend continuation of immunosuppressive therapy for nephritis during pregnancy. Hydroxychloroquine, cyclosporine, azathioprine, and tacrolimus are permissible in pregnancy (American College of Obstetricians and Gynecologists, 2019b; Parikh, 2020). New-onset nephritis or severe renal flare is treated aggressively with tacrolimus, and consideration is given to adding intravenous corticosteroids, immunosuppressive drugs, or intravenous immunoglobulin (IVIG) therapy (Maynard, 2019; Parikh, 2020).

Lupus Versus Preeclampsia-Eclampsia

Chronic hypertension complicates up to 30 percent of pregnancies in women with SLE (Egerman, 2005). Preeclampsia is common, and in those with nephritis or antiphospholipid antibodies, superimposed preeclampsia is encountered even more often and earlier (Bertsias, 2008; Dong, 2020). Preeclampsia and SLE flares share features of hypertension, proteinuria, edema, and renal function deterioration. However, the management is distinct. Lupus nephritis is treated with immunosuppression, and severe preeclampsia/eclampsia requires delivery. It may be difficult, if not impossible, to discriminate a lupus flare with nephropathy from severe preeclampsia if the kidney is the only involved organ (Petri, 2020b). Serum uric acid and complement levels and dsDNA titers may aid in differentiating the two. Last, central nervous system involvement with SLE may culminate in convulsions similar to those of eclampsia.

Management During Pregnancy

Care consists primarily of monitoring maternal clinical and laboratory status and fetal well-being. Establishment of baseline renal disease and hematological values is important because pregnancy-induced laboratory changes later in gestation can resemble SLE disease activity. A 24-hour urine collection to assess proteinuria and serum creatinine level measurement determine initial renal function. A complete blood count (CBC) identifies preexisting anemia, leukopenia, and thrombocytopenia. Continued assessment of renal function and hematological parameters is undertaken each trimester unless symptoms develop. In this event, measures are monthly (Baer, 2011).

For monitoring of SLE activity, various laboratory techniques have been recommended. As just discussed, establishing baseline values will assist comparisons later in pregnancy. Serum complement levels (C_3 and C_4) and dsDNA titers are drawn at the first prenatal care visit and when symptoms develop. Serum complement levels are normally increased in pregnancy (Appendix, p. 1231). Although falling or low C_3 and C_4 levels are more likely to be associated with active disease, higher levels provide no assurance against disease flare. If symptoms develop, the combination of declining complement levels and rising dsDNA titers does indicate a lupus flare (Baer, 2011). Women with SLE are also screened for antiphospholipid antibodies at the beginning of pregnancy. Last, screening for anti-SS-A (anti-Ro) and anti-SS-B (anti-La) antibodies is recommended because of associated fetal complications described later.

The combination of serial hematological, rheumatological, and renal studies may detect changes in disease activity. SLE-associated hemolysis is characterized by a positive Coombs test, anemia, reticulocytosis, and unconjugated hyperbilirubinemia. Thrombocytopenia, leukopenia, or both may develop. Chronic thrombocytopenia in early pregnancy may be due to antiphospholipid antibodies (Lockshin, 1995). Later, thrombocytopenia may indicate preeclampsia.

The fetus also is closely observed for adverse effects such as growth restriction and oligohydramnios. Sonographic evaluations are performed every 4 weeks beginning at 24 weeks' gestation to assess for both. Antepartum testing for fetal well-being is initiated in the third trimester and described in Chapter 20 (p. 392) (American College of Obstetricians and Gynecologists, 2021a,b). Unless evidence of maternal or fetal compromise develops, pregnancy is allowed to progress to term.

Pharmacological Treatment

There is no cure for SLE, and complete remissions are rare. Approximately a fourth of pregnant women have mild disease, which is not life threatening but may be disabling because of pain and fatigue. Arthralgia and serositis can be managed by nonsteroidal antiinflammatory drugs (NSAIDs). However, during pregnancy, chronic or large intermittent dosing is avoided due to related oligohydramnios or ductus arteriosus closure (Chap. 8, p. 151).

Antimalarials reduce dermatitis, arthritis, and fatigue (Hahn, 2018). Although these agents cross the placenta, hydroxychloroquine (Plaquenil) does not appear to cause congenital malformations (Briggs, 2022). Most recommend continuation during pregnancy because therapy interruption can precipitate a flare (Marder, 2019; Petri, 2019). For those not previously using hydroxychloroquine, others favor initiation in the first trimester because its use is associated with an 85-percent reduction in the risk of having a small-for-gestational-age neonate (Parikh,

2020). Also, it lowers the risk of fetal congenital heart block by 50 percent in women with anti-SS-A antibodies. Low-dose aspirin can be used throughout gestation.

Severe disease is managed with corticosteroids such as prednisone, 1 to 2 mg/kg/d orally or methylprednisolone, 1000 mg given intravenously over 90 minutes daily for 3 days (Petri, 2007). After the disease is controlled, this dose is tapered to a daily morning dose of 10 to 15 mg. Corticosteroid therapy can lead to gestational diabetes. During labor, delivery, and postpartum, corticosteroids in "stress doses" are given to women who take these drugs chronically or who have done so recently. This augmented dose reflects a normal adrenal response, and one option on admission for delivery is hydrocortisone, 100 mg, given IV every 8 hours for 48 hours.

Tacrolimus, rituximab, and IVIG therapy also have been used to treat lupus flares (Petri, 2019). These are usually reserved for lupus nephritis or disease that is corticosteroid resistant. Azathioprine has a good safety record during pregnancy (Hahn, 2018; Petri, 2019). Its recommended daily oral dose is 2 mg/kg. Teratogenic medications to be avoided include mycophenolate mofetil, methotrexate, and cyclophosphamide (Briggs, 2022; Hahn, 2018). However, cyclophosphamide can be considered in the second or third trimester for severe disease (Lazzaroni, 2016).

In nonpregnant subjects, antihypertensive therapy often includes an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin-receptor blocker. For pregnancy, these should be changed to safer fetal options such as calcium-channel blockers, alpha methyldopa, or labetalol (Cabiddu, 2016).

Perinatal Mortality and Morbidity

Adverse perinatal outcome rates are significantly elevated in pregnancies complicated by SLE. Among these are preterm delivery, fetal-growth restriction, stillbirth, and neonatal lupus syndrome (see Table 62-4) (He, 2020; Phansenee, 2018). Perinatal outcome rates worsen in women with active disease, significant proteinuria, or renal impairment and in those with chronic hypertension, preeclampsia, or both (Lazzaroni, 2016). Adverse outcomes are also more common in women with neuropsychiatric lupus (de Jesus, 2017). Reasons at least partially responsible for adverse fetal consequences include decidual vasculopathy with placental infarction and decreased perfusion (Hanly, 1988).

Neonatal Lupus Syndrome

This is characterized by newborn skin lesions—*lupus dermatitis*; various hematological and systemic derangements; and occasionally congenital heart block (Hahn, 2018). Cutaneous manifestations can be present in 30 to 40 percent of infants and appear at 4 to 6 weeks of age (Silverman, 2010). These are usually associated with anti-SS-A and SS-B antibodies, and up to 50 percent of women with SLE are positive for these (see Table 62-1). Thrombocytopenia and hepatic involvement are seen in 5 to 10 percent of affected infants.

In a review of outcomes in 128 infants born to women with lupus, 16 percent developed cutaneous lupus and 26 percent showed hematological abnormalities and elevated transaminase levels (Cimaz, 2003). Cutaneous lupus, thrombocytopenia, and autoimmune hemolysis are transient and clear within a few months (Zuppa, 2017). In subsequent offspring, the recurrence risk for neonatal lupus may approach 25 percent (Bramham, 2012). The only maternal treatment that lowers the risk of neonatal lupus is hydroxychloroquine (Izmirly, 2020; Petri, 2019).

Congenital Heart Block

Fetal and neonatal heart block results from diffuse myocarditis and fibrosis in the region between the atrioventricular (AV) node and bundle of His. Natural killer cells have been detected in fetal myocytes (Ivanchenko, 2021). Congenital heart block develops almost exclusively in fetuses of women with antibodies to the SS-A or SS-B antigens (Buyon, 1993). Even in the presence of such antibodies, the incidence of fetal myocarditis is only 2 to 3 percent (Bramham, 2012; Lateef, 2017). However, it rises to 20 percent with a prior affected child. The cardiac lesion is permanent, and a pacemaker is generally necessary. Long-term prognosis is poor. Of 325 infants with cardiac neonatal lupus, nearly 20 percent died, and of these, a third were stillborn (Izmirly, 2011). Another autoimmune disease, Sjögren syndrome, also is associated with fetal heart block (Brito-Zerón, 2020).

Maternal administration of corticosteroids, plasma exchange, or IVIG therapy does not reduce the risk of congenital heart block. For women with anti-SS-B and anti-SS-A antibodies, fetal cardiac monitoring is performed between 18 and 26 weeks' gestation. Maternal corticosteroid administration for treatment of fetal congenital heart block is controversial and discussed further in Chapter 19 (p. 369). This therapy to treat fetal heart block has not been studied in randomized trials. However, some evidence derives from fetuses exposed to their mother's corticosteroid treatment for SLE and shows that exposure may mitigate fetal myocarditis. Specifically, Shinohara and coworkers (1999) reported no cases of heart block in 26 neonates whose mothers received corticosteroids before 16 weeks' gestation as part of SLE maintenance therapy. By contrast, 15 of 61 neonates with heart block were born to women in whom corticosteroid therapy was begun after 16 weeks for an SLE exacerbation. Maternal hydroxychloroquine therapy is associated with a lower incidence of fetal heart block, especially in those with a prior affected child (Izmirly, 2010, 2020).

Long-term Prognosis and Contraception

The survival rate for women with SLE is 95 percent at 5 years, 90 percent at 10 years, and 78 percent at 20 years (Hahn, 2018). Infection, lupus flares, end-organ failure, hypertension, stroke, and cardiovascular disease account for most deaths. In general, women with SLE and chronic vascular or renal disease may limit family size because of morbidity associated with the disease and greater risks for adverse perinatal outcomes. For contraception, combination oral contraceptives did not increase the incidence of lupus flares in two large multicenter trials (Petri, 2005; Sánchez-Guerrero, 2005). Notably, comorbid antiphospholipid antibodies are a contraindication to estrogen-containing methods

(Chap. 38, p. 672). Progestin-only implants and injections provide effective contraception with no known effects on lupus flare rates (Sammaritano, 2020). Data do not support the concern that intrauterine device use and immunosuppressive therapy lead to higher infection rates in these patients. Tubal sterilization may be advantageous and is performed with greatest safety postpartum or whenever SLE is quiescent (Chap. 39, p. 681).

ANTIPHOSPHOLIPID SYNDROME

This is an autoantibody-mediated acquired thrombophilia that predisposes to recurrent thrombosis or pregnancy morbidity (Moutsopoulos, 2018). Specifically, antiphospholipid syndrome (APS) is diagnosed in women with persistently positive serum tests for antiphospholipid antibodies (APAs) *plus* arterial and/or venous thromboses or obstetrical morbidity. APAs include lupus anticoagulant, anticardiolipin antibody, and anti-β2 glycoprotein-I antibody.

Phospholipids are the main lipid constituents of cell and organelle membranes. Certain proteins in plasma associate noncovalently with these phospholipids. APAs are directed against these phospholipids or these phospholipid-binding proteins (Garcia, 2018; Giannakopoulos, 2013). This antibody group may be of immunoglobulin G (IgG), IgM, and IgA classes, alone or in combination. APAs are most common with SLE, other connective tissue disorders, and APS. That said, a small proportion of normal women and men have low levels of these antibodies.

The stimulus for autoantibody production is unclear, but it possibly is due to a preceding infection or another event that causes endothelial disruption. The resulting pathophysiology is mediated by one or more of the following: (1) activation of various procoagulants, (2) inactivation of natural anticoagulants, (3) complement activation, and (4) inhibition of syncytiotrophoblast differentiation (Garcia, 2018). Clinically, these actions lead to vascular thromboses or to pregnancy morbidity. Virtually every organ system may be affected.

Central nervous system involvement is one of the most prominent clinical manifestations. In addition to cerebrovascular arterial or venous thrombotic events, psychiatric features and even multiple sclerosis can be present (Binder, 2010). Renovascular involvement may lead to renal failure that can be difficult to differentiate from lupus nephritis (D'Cruz, 2009). Peripheral and visceral thromboses also are features. In one case, a puerpera developed a mesenteric vessel infarction and subsequent spontaneous cecal perforation (Ahmed, 2009). Obstetrical complications encompass recurrent pregnancy loss and placental dysfunction reflected by fetal-growth restriction, stillbirth, early-onset preeclampsia, and preterm birth. Treatment using aspirin, heparin, and close monitoring has increased live-birth rates to more than 70 percent in these women (Hamulyák, 2020; Schreiber, 2016).

A small proportion of these patients develop the *catastrophic antiphospholipid antibody syndrome (CAPS)* or *Asherson syndrome*. This is defined as a rapidly progressive thromboembolic disorder simultaneously affecting three or more organ systems or tissues (Garcia, 2018; Schreiber, 2016). It has a high mortality rate from activation of a cytokine storm. In half of cases, a triggering event is identified.

Specific Antiphospholipid Antibodies

As mentioned, several antibodies in APS are directed against a specific phospholipid or a phospholipid-binding protein:

1. *β2 glycoprotein-I*, also known as apolipoprotein H, is a phospholipid-binding plasma protein that inhibits prothrombinase activity within platelets and prevents platelet aggregation (Giannakopoulos, 2013). Thus, its normal action is to limit procoagulant binding and thereby prevent coagulation cascade activation. Logically, antibodies directed against this glycoprotein would reverse its anticoagulant activity and promote thrombosis. This is important from an obstetrical viewpoint because β2 glycoprotein-I is expressed in high concentrations on the syncytiotrophoblast surface. Complement activation may contribute to its pathogenesis (Avalos, 2009; Tsokos, 2011). Teleologically, this seems appropriate because the decidua intuitively should be a critical area to prevent coagulation that might lead to intervillous space thrombosis.
2. *Lupus anticoagulant (LAC)* is a heterogeneous group of antibodies directed against phospholipid-binding proteins. This antibody group induces prolongation in vitro of the prothrombin, partial thromboplastin, and Russell viper venom times. Thus, paradoxically, this so-called anticoagulant is actually powerfully thrombotic in vivo. This is the only APA that has been consistently associated with adverse pregnancy outcomes (Petri, 2020a).
3. *Anticardiolipin antibodies (ACAs)* are directed against one of the many phospholipid cardiolipins found in mitochondrial membranes and platelets.

Antibodies Against Natural Anticoagulants

Some APAs are also directed against the natural anticoagulant proteins C and S. Another is directed against the anticoagulant protein annexin V, which is expressed in high concentrations by syncytiotrophoblast (Giannakopoulos, 2013). Testing for these other antibodies is not recommended (American College of Obstetricians and Gynecologists, 2019a). However, some studies have evaluated these nonconventional antiphospholipid antibodies in women who clinically meet APS criteria but do not have the classic antibody profile. In one study, treatment of women who had these nonconventional antibodies offered some benefits, such as a lower pregnancy loss rate (Mekinian, 2016).

Clinical features shown in Table 62-5 provide indications for testing. By international consensus, APS is diagnosed based on laboratory and clinical criteria (Table 11-4, p. 205). First, one of two clinical criteria—which are vascular thrombosis or certain pregnancy morbidity—must be present. With laboratory criteria, high IgG or IgM titers of ACA or anti-β2 glycoprotein-I or LAC positivity should be confirmed on two occasions 12 weeks apart. The diagnosis can be further stratified based on the number of these tests that are positive.

Tests for LAC are nonspecific coagulation tests. The *partial thromboplastin time* is generally prolonged because the anticoagulant interferes with conversion of prothrombin to thrombin in vitro. The *dilute Russell viper venom test* is considered more specific.

TABLE 62-5. Some Clinical Features of Antiphospholipid Syndrome

Venous thrombosis: thromboembolism, thrombophlebitis, livedo reticularis
Arterial thrombosis: stroke, transient ischemic attack, Libman-Sacks cardiac vegetations, myocardial ischemia, distal extremity and visceral thrombosis and gangrene
Hematological: thrombocytopenia, autoimmune hemolytic anemia
Renal: thrombotic microangiopathy, glomerular thrombosis
Other: neurological manifestations, migraine headaches, epilepsy; renal artery or vein thrombosis; arthritis and arthralgia
Pregnancy: preeclampsia and HELLP syndrome, recurrent miscarriage, preterm delivery, fetal-growth restriction, fetal death

HELLP = hemolysis, elevated liver enzyme levels, low platelet count.
Data from Garcia, 2018; Giannakopoulos, 2013; Moutsopoulos, 2018.

Branch and Khamashta (2003) recommend conservative interpretation of results that are based on repeated tests from a reliable laboratory and that are consistent with each clinical case. Only approximately 20 percent of patients with APS have a positive LAC assay alone. Thus, ACA enzyme-linked immunosorbent assay (ELISA) testing also should be performed. Efforts have been made to standardize ACA assays, however, these remain without international standards (Garcia, 2018). For each APS test, interlaboratory variation can be large, and agreement between commercial kits is poor.

■ Pregnancy and Antiphospholipid Antibodies

As many as 30 percent of patients with SLE have APAs. In women without autoimmune diseases who have pregnancy complications, the prevalence of positive results with APA testing is 7 percent (Garcia, 2018).

In women with elevated APA levels, and especially when LAC is identified, risks for decidual vasculopathy, placental infarction, fetal-growth restriction, early-onset preeclampsia, and recurrent fetal death are increased (Saccone, 2017). Some of these women, like those with SLE, also have a high incidence of venous and arterial thromboses, cerebral thrombosis, hemolytic anemia, thrombocytopenia, and pulmonary hypertension (American College of Obstetricians and Gynecologists, 2019a; Clowse, 2008). In 191 LAC-negative women with APS, those with ACAs and β2-glycoprotein-I had significantly greater miscarriage rates than if either one alone was positive (Liu, 2013). Women with higher titers tend to have more adverse outcomes (Alijotas-Reig, 2020; Gabbay-Benziv, 2018).

■ Pregnancy Pathophysiology

It is not precisely known how APAs cause damage, but it is likely that their actions are multifactorial. Platelets may be damaged directly by APAs or indirectly by binding β2-glycoprotein-I, which causes platelets to be susceptible to aggregation (Giannakopoulos, 2013). One theory proposes that phospholipid-containing endothelial cell or syncytiotrophoblast membranes may be damaged directly by the APA or indirectly by antibody binding to either β2 glycoprotein-I or annexin V (Rand, 1997, 1998). This prevents the cell membranes from protecting the syncytiotrophoblast and endothelium. This exposes the basement membrane, to which damaged platelets can adhere and form a thrombus.

Pierro and colleagues (1999) reported that APAs decreased decidual production of the vasodilating prostaglandin E_2. Diminished protein C or S activity and greater prothrombin activation also may be contributory (Zangari, 1997). Evidence supports that thrombosis with APS stems from activation of the tissue factor pathway (Amengual, 2003). Last, uncontrolled placental complement activation by APAs is implicated in fetal loss and growth restriction (Holers, 2002).

Complications in APS cannot be completely explained by thrombosis alone. Animal models suggest that effects stem from inflammation rather than thrombosis (Cohen, 2011). Some investigators hypothesize that APS-associated clotting is triggered as a "second hit" from innate inflammatory immune responses. These investigators recommend treatment with anti-inflammatory agents (Meroni, 2011).

■ Adverse Pregnancy Outcomes

Overall, APAs are associated with higher rates of fetal wastage (Chap. 11, p. 204). In most early reports that describe these outcomes, however, women were included *because* they had repeated adverse outcomes. Both antibody prevalence and miscarriage are common—recall that the incidence of APAs in the general obstetrical population is about 5 percent and early miscarriage approximates 20 percent of call conceptions. Accordingly, current data are too limited to conclude the exact risks for adverse effects of these antibodies on pregnancy outcomes. Fetal deaths, however, are more characteristic with APS than are first-trimester miscarriages (Garcia, 2018; Roque, 2004).

When otherwise unexplained fetal deaths are examined, the data are mixed. One study measured ACA levels in 309 pregnancies with fetal death and found no differences in their frequency compared with levels in 618 normal pregnancies (Haddow, 1991). In another study of women with recurrent pregnancy loss, those with APAs had an increased rate of preterm delivery (Clark, 2007). In a case-control study of 582 stillbirths and 1547 live births, a three- to fivefold higher risk for stillbirth was found in women with elevated ACA and anti-β2 glycoprotein-I levels (Silver, 2013). In women with APAs, adverse outcomes are more common in the presence of: (1) all three classic APA types, (2) comorbid SLE or systemic autoimmune diseases, and (3) prior thrombosis and pregnancy morbidity. Logistic regression found the probability of pregnancy failure was 93 percent with two or more APA types but was 63 percent for those with only one (Ruffatti, 2011).

Thrombosis Prevention in Pregnancy

Because of study heterogeneity, current treatment recommendations for women with APAs can be confusing. Therapy is directed at thrombosis prevention. As discussed, APAs are immunoglobulins that may be of G, M, or A classes. Those directed against the phospholipids (PL) are termed GPL, MPL, and APL, respectively. During testing, these are reported as semiquantified phospholipid binding-unit levels and expressed as negative, low-positive, medium-positive, or high-positive (American College of Obstetricians and Gynecologists, 2019a).

As discussed in Chapter 55 (p. 979), women with prior thromboembolic events who have APAs are at risk for recurrence in subsequent pregnancies. For these women, prophylactic anticoagulation with heparin throughout pregnancy and for 6 weeks postpartum is recommended (American College of Obstetricians and Gynecologists, 2019a). For those without prior thromboembolic events, recommendations for management vary and are listed in Table 55-5 (p. 984). Some acceptable schemes include close antepartum maternal observation with or without prophylactic or intermediate-dose heparin, and then some form of postpartum anticoagulation for 6 weeks. Sciascia and coworkers (2016) have presented preliminary salutary results with hydroxychloroquine treatment. This currently is considered investigational (Garcia, 2018; Latino, 2020).

Several researchers have questioned the need for heparin for women with APAs but no history of thrombosis (Branch, 2010). Although this is less clear, some recommend that women be treated if they have medium- or high-positive ACA titers or LAC activity and a prior second- or third-trimester fetal death not attributable to other causes (Dizon-Townson, 1998; Lockshin, 1995). Others report that women with recurrent early pregnancy loss and medium- or high-positive titers of antibodies may benefit from therapy (Robertson, 2006).

Due to the risk of fetal-growth abnormalities and stillbirth, serial sonographic assessment of fetal growth and antepartum testing in the third trimester is recommended (American College of Obstetricians and Gynecologists, 2019a, 2021a,b).

Specific Therapy in Pregnancy

Other agents are used to treat gravidas that have APS but no prior thromboembolic event. *Aspirin*, in doses of 60 to 80 mg orally daily, blocks conversion of arachidonic acid to thromboxane A_2 while sparing prostacyclin production. Thromboxane A_2 usually causes platelet aggregation and vasoconstriction, and prostacyclin has the opposite effect. The only major side effect from low-dose aspirin is a slight risk of small-vessel bleeding during surgical procedures. Low-dose aspirin does not reduce adverse pregnancy outcomes in women who have APAs but who lack the complete APS syndrome (Amengual, 2015). Thus, its use is recommended for women with SLE or APS (American College of Obstetricians and Gynecologists, 2020b; Rahman, 2020).

Unfractionated heparin is given subcutaneously in dosages of 5000 to 10,000 units every 12 hours. Some prefer low-molecular-weight heparin, such as 40 mg enoxaparin (Lovenox) once daily (Kwak-Kim, 2013). With therapeutic dosing, measurement of heparin levels may be useful because clotting tests can be altered by LAC. The rationale for heparin therapy is to prevent venous and arterial thrombotic episodes. Heparin therapy also prevents thrombosis in the microcirculation, including the decidual-trophoblastic interface (Toglia, 1996). As discussed, heparin binds to β2-glycoprotein-I, which coats the syncytiotrophoblast. This prevents binding of ACAs and anti-β2 glycoprotein-I antibodies to their surfaces, which likely prevents cellular damage (Tsokos, 2011). Heparin also binds to APAs in vitro and likely in vivo.

Aspirin plus heparin therapy is the most effective regimen (de Jesus, 2014; Hamulyák, 2020). However, despite treatment, 30 percent of women with APS do not achieve a successful outcome (Arslan, 2020). Heparin therapy is associated with several complications that include bleeding, thrombocytopenia, osteopenia, and osteoporosis. A description of various heparins and their adverse effects is found in Chapter 55 (p. 983).

Corticosteroids generally should not be used with *primary APS*—that is, without an associated connective tissue disorder. For women with SLE or those being treated for APS who develop SLE, corticosteroid therapy is indicated. In such cases of *secondary APS* seen with SLE, the dose of prednisone should be maintained at the lowest effective level to prevent flares.

IVIG therapy is controversial and has usually been reserved for women with overt disease—including catastrophic antiphospholipid syndrome or heparin-induced thrombocytopenia or both (Rahman, 2020). It is used when other first-line therapies have failed, especially in the setting of preeclampsia and fetal-growth restriction. IVIG is administered by some in doses of 0.4 g/kg/d for 5 days—total dose of 2 g/kg. This is repeated monthly, or it is given as a single dose of 1 g/kg each month. Treatment is expensive, as one course costs more than $10,000. Tenti and colleagues (2016) found no benefits from adding IVIG to low-dose aspirin and low-molecular-weight heparin. One Cochrane review found no improvement in the live-birth rate for IVIG therapy given to women with recurrent pregnancy loss (Wong, 2014). Trials are needed before application of this expensive and cumbersome therapy is recommended.

Immunosuppression with hydroxychloroquine is commonly used with low-dose aspirin in the treatment of women with SLE. This regimen may be beneficial by reducing the risk of thrombosis and improving pregnancy outcomes in women who also have APS (Mekinian, 2015; Sciascia, 2016).

Statins have been examined due to their protective effects on endothelium. In a small trial in 21 women with APS who developed fetal-growth restriction or preeclampsia, the addition of pravastatin to low-dose aspirin and low-molecular-weight heparin improved placental blood flow, preeclampsia features, and pregnancy outcomes (Lefkou, 2016). Larger trials are needed before this therapy is recommended.

Described earlier (p. 1114), catastrophic antiphospholipid syndrome is treated aggressively with full anticoagulation, high-dose corticosteroids, plasma exchange, and/or IVIG therapy (Garcia, 2018; Rahman, 2020).

Treatment Efficacy

Fetal loss is common in women with untreated APS, and especially in those with LAC positivity. Even with treatment,

TABLE 62-6. Pregnancy Outcomes (%) in 750 Women Treated for Antiphospholipid Syndrome—the PREGNANTS Study

Outcome	Triple-Positive (n = 20)	Double-Positive LAC Negative (n = 90)	LAC Alone (n = 54)	ACA Alone (n = 458)	Anti-β2 Glycoprotein-I (n = 128)
Livebirth	30	43	80	56	48
Stillbirth	45	34	7	21	30
Preeclampsia[a]	55	54	11	34	48

[a]Nonsevere only.
ACA = anticardiolipin antibodies; LAC = lupus anticoagulant.

recurrent fetal loss rates remain at 20 to 30 percent (Arslan, 2020; Empson, 2005; Ernest, 2011). Shown in Table 62-6 are pregnancy outcomes from 750 treated women with primary APS (Saccone, 2017). Participants were treated with low-dose aspirin and prophylactic low-molecular-weight heparin starting in the first trimester. Importantly, some women with SLE and APAs have normal pregnancy outcomes without treatment. It is also emphasized that women with LAC and prior poor pregnancy outcomes have had liveborn neonates without treatment.

In a manner similar to neonatal lupus syndrome (p. 1113), up to 30 percent of newborns demonstrate passively acquired APAs (Nalli, 2017). One group found higher rates of learning disabilities in these children (Tincani, 2009). Another reported a fourfold greater risk for perinatal strokes (Simchen, 2009). Of 141 newborns followed in a European registry, the rate of preterm birth was 16 percent; low birthweight occurred in 17 percent; and later behavioral abnormalities developed in 4 percent of the children. There were no cases of neonatal thrombosis (Motta, 2012). A 7-year study of 36 pregnancies in 26 women who had APS reported three cases of autism spectrum disorder. All were associated with persistent neonatal anti-β2 glycoprotein-I IgG antibodies (Abisror, 2013).

RHEUMATOID ARTHRITIS

This chronic inflammatory disease stems from immunological dysfunction, and infiltrating T cells secrete cytokines to cause inflammation, polyarthritis, and systemic symptoms. The cardinal feature is inflammatory synovitis that usually involves the peripheral joints. The disease has a propensity for cartilage destruction, bony erosions, and joint deformities. Pain, aggravated by movement, is accompanied by swelling and tenderness. Extraarticular manifestations include rheumatoid nodules, vasculitis, and pleuropulmonary symptoms. Other complaints are fatigue, anorexia, and depression. The American College of Rheumatology has published diagnostic criteria (Shah, 2018).

The worldwide prevalence of rheumatoid arthritis is 0.5 to 1 percent, women are affected three times more often than men, and peak onset is from 25 to 55 years (Shah, 2018). There is a genetic predisposition, and heritability is estimated at 15 to 30 percent (McInnes, 2011). Genome-wide associated studies have identified more than 30 loci involved in rheumatoid arthritis pathogenesis (Kurkó, 2013). Class II major histocompatibility complex molecule HLA-DR4 and HLA-DRB1 alleles also show an association (McInnes, 2011; Shah, 2018). Pregnancy provides a protection against rheumatoid arthritis development, and this may be related to HLA-disparate fetal microchimerism (Förger, 2020; Guthrie, 2010).

Management

Treatment is directed at pain relief, inflammation reduction, protection of articular structures, and preservation of function. Physical and occupational therapy and self-care instructions are essential.

Aspirin and other NSAIDs nonspecifically inhibit both cyclooxygenase 1 (COX-1), which is an enzyme critical to normal platelet function, and COX-2, which mediates inflammatory response mechanisms. However, in one systematic review, a small increased rate of cardiac malformations was found in newborns exposed to NSAIDs in the first trimester (Briggs, 2022). In addition, NSAIDs are associated with early spontaneous abortions, ductus arteriosus constriction, and neonatal pulmonary hypertension (Briggs, 2022). Another potential side effect of chronic NSAID therapy is gastritis with acute bleeding. Thus, risks versus benefits of these medications must be considered. Glucocorticoid therapy in low to moderate doses is given to achieve more rapid symptom control. Of these, prednisone, 7.5 mg orally daily for the first 2 years of active disease, substantively reduces progressive joint erosions (Shah, 2018).

Until recently, NSAIDs were the cornerstone of therapy, but they do not retard disease progression. The American College of Rheumatology recommends several disease-modifying antirheumatic drugs (DMARDs) that may reduce or prevent joint damage (Singh, 2016). According to Shah and St. Clair (2018), methotrexate has become the preferred DMARD outside of pregnancy. NSAIDs thus are important in pregnancy because methotrexate and leflunomide are contraindicated (Chap. 8, pp. 151–152). In one review of drug exposure, a fourth of women with rheumatoid arthritis took a DMARD within 6 months of conception (Kuriya, 2011). Of unplanned exposures during pregnancy, 4 percent of 393 pregnant women were given a category D or X medication—methotrexate was the most common at 2.9 percent.

Sulfasalazine and hydroxychloroquine are safe for use in pregnancy (Briggs, 2022; Partlett, 2011). These, combined with relatively low-dose prednisone—7.5 to 20 mg daily—usually successfully treat flares.

Biological DMARDs have revolutionized rheumatoid arthritis treatment. These include the tumor necrosis factor

alpha (TNF-α) inhibitors infliximab, adalimumab, golimumab, certolizumab, and etanercept (Shah, 2018). Their use in pregnancy is limited, but they appear to be safe for the fetus (Briggs, 2022). In one review, 13 percent of 393 pregnant women were given a biological cytokine-inhibiting DMARD—primarily etanercept (Kuriya, 2011). In another review of 300 exposures, no fetal effects were noted (Berthelot, 2009). A prospective study of 38 pregnant women found similar results (Hoxha, 2017). In 74 women exposed to adalimumab during pregnancy, no risks were identified (Burmester, 2017). Little is known regarding the pregnancy effects of anakinra, an interleukin 1 receptor antagonist, or of rituximab, an antagonist to the B-cell CD20 antigen. Other biologics are abatacept, tocilizumab, and tofacitinib.

■ Pregnancy and Rheumatoid Arthritis

In up to 70 percent of women with rheumatoid arthritis, disease will improve during pregnancy (Raine, 2020; Shah, 2018). Some studies suggest this may be due to regulatory T-cell alterations (Förger, 2020). Even so, some women develop disease during pregnancy, and others become worse. A downside to this respite during pregnancy is that postpartum exacerbation occurs in 40 to 50 percent of women (Eudy, 2018; Jethwa, 2019). This may stem from postpartum alterations in innate immunity (Häupl, 2008b).

Some studies report a protective effect of pregnancy against developing new-onset rheumatoid arthritis. In a case-control study of 88 affected women, pregnancy provided a degree of protection long term, but the likelihood of new-onset rheumatoid arthritis was increased sixfold during the first 3 postpartum months (Silman, 1992). Pikwer and colleagues (2009) reported a significant reduction in the risk of subsequent arthritis in women who breastfed longer than 12 months.

These findings may reflect the interference of sex hormones with several putative processes involved in arthritis pathogenesis, including immunoregulation (Förger, 2020; Häupl, 2008a,b). First, Unger and associates (1983) reported that amelioration of rheumatoid arthritis correlated with serum levels of *pregnancy-associated alpha$_2$-glycoprotein*. This compound has immunosuppressive properties. Second, Nelson and coworkers (1993) noted that disease improvement was associated with a disparity in HLA class II antigens between mother and fetus. They suggested that the maternal immune response to paternal HLA antigens may play a role in pregnancy-induced remission of arthritis. In addition to monocyte activations, there also may be T-lymphocyte activation (Förger, 2020).

Fertility is diminished in patients with rheumatoid arthritis, and adverse pregnancy outcomes are increased. Kishore and colleagues (2019) reported pregnancy outcomes from nearly 32,000 women with rheumatoid arthritis. Compared with unaffected women, those with rheumatoid arthritis had significantly greater rates of hypertensive diseases, preterm birth, hemorrhage, and fetal-growth restriction.

■ Juvenile Rheumatoid Arthritis

This group of diseases is the most frequent cause of chronic arthritis in children and persists into adulthood. In 76 pregnancies of 51 affected Norwegian women, pregnancy had no effects on clinical presentation, but disease activity usually became quiescent or remained so during pregnancy (Østensen, 1991). Similar to rheumatoid arthritis, postpartum flares were common. Joint deformities often developed in these women, and 15 of 20 cesarean deliveries were done for contracted pelves or joint prostheses. Results from a summary of 39 Polish women with juvenile rheumatoid arthritis were similar (Musiej-Nowakowska, 1999).

This arthritis portends few adverse pregnancy outcomes. The risk for preterm birth is elevated, but fetal development is normal (Mohamed, 2016; Rom, 2014; Wallenius, 2014). In a study of 1807 births, Remaeus and associates (2017) reported increased incidences of preterm birth, fetal-growth restriction, and preeclampsia. Disease severity in early pregnancy was predictive of preterm delivery and fetal-growth restriction in one cohort study (Bharti, 2015). And, patients with low disease activity scores in the first trimester are likely to have low disease activity or remission in the third trimester (Ince-Askan, 2017).

If the cervical spine is involved, particular attention is warranted during pregnancy. Subluxation is common, and pregnancy, at least theoretically, predisposes to this because of joint laxity. Importantly, there are anesthesia concerns during endotracheal intubation.

SYSTEMIC SCLEROSIS—SCLERODERMA

This is a chronic multisystem connective tissue disorder of unknown etiology. It is characterized by microvascular damage; inflammation from immune system activation; and excessive deposition of collagen in the skin, lungs, heart, gastrointestinal tract, and kidneys. It is uncommon, displays a 5-to-1 female dominance, and typically affects those aged 30 to 50 years (Clark, 2020; Varga, 2018).

This strong prevalence of scleroderma in women and its greater incidence in the years following childbirth give credence to the hypothesis that *microchimerism* is involved as discussed earlier (p. 1109) (Munira, 2020). Artlett and associates (1998) demonstrated Y-chromosomal DNA in almost half of women with systemic sclerosis compared with only 4 percent of controls. Rak and coworkers (2009) identified male microchimerism in peripheral blood mononuclear cells more frequently in women with limited versus diffuse scleroderma.

■ Clinical Course

The hallmark is overproduction of normal collagen. *Limited cutaneous systemic sclerosis* is the more benign form and progresses slowly. With *diffuse cutaneous systemic sclerosis*, skin fibrosis advances rapidly and is followed by gastrointestinal tract fibrosis, especially the distal esophagus (Varga, 2018). Pulmonary interstitial fibrosis along with vascular changes may cause pulmonary hypertension, which develops in 15 percent of patients. Antinuclear antibodies such as those listed in Table 62-1 are found in 95 percent of patients, and immunoincompetence often develops.

Raynaud phenomenon, which is typified by cold-induced, episodic, rapidly reversible digital ischemia, is seen in 95 percent of patients. There also may be swelling of the distal extremities

and face. Symptoms from esophageal involvement, especially fullness and epigastric burning pain, occur in half of patients. Pulmonary involvement is frequent and causes dyspnea. The 10-year cumulative survival rate is 70 percent in those with pulmonary fibrosis, and pulmonary arterial hypertension is the main cause of death (Clark, 2020; Varga, 2018). Women with limited cutaneous disease such as the *CREST syndrome—calcinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasia*—have milder disease.

Overlap syndrome refers to systemic sclerosis with features of other connective tissue disorders. *Mixed connective tissue disease* is a term used for the syndrome involving features of SLE, systemic sclerosis, polymyositis, rheumatoid arthritis, and high titers of anti-ribonucleoprotein (RNP) antibodies (Rudder, 2021). The disorder is also termed *undifferentiated connective tissue disease* (Radin, 2020; Zucchi, 2020).

Although systemic sclerosis is incurable, treatment directed at end-organ involvement can sometimes relieve symptoms and improve function. Renal involvement and hypertension are often comorbid. At times, ACE inhibitors may be required for blood pressure control despite their known teratogenicity. Obliterative vasculopathy of the renal cortical arteries characterizes *scleroderma renal crisis*, which develops in up to a fourth of these patients. This leads to renal failure and malignant hypertension. Interstitial restrictive lung disease is common and frequently becomes life threatening. Associated pulmonary hypertension is treated with bosentan or sildenafil (Chap. 52, p. 931).

■ Pregnancy and Systemic Sclerosis

The prevalence of scleroderma in pregnancy approximates 1 case in 22,000 pregnancies (Chakravarty, 2008). If baseline function is good, these women usually have stable disease during gestation. As perhaps expected, pregnancy aggravates dysphagia and reflux esophagitis (Steen, 1999). Dysphagia results from loss of esophageal motility due to neuromuscular dysfunction. A lower amplitude or disappearance of peristaltic waves in the lower two thirds of the esophagus is seen using manometry. Symptomatic treatment for reflux is described in Chapter 57 (p. 1017).

Women with renal insufficiency and malignant hypertension have a higher incidence of superimposed preeclampsia. With rapidly worsening renal or cardiac disease, pregnancy termination should be considered. Renal crisis is uncommon, but it is life threatening, and it does not improve with delivery (Zucchi, 2020). Pulmonary hypertension usually contraindicates pregnancy (Table 52-3, p. 919).

Vaginal delivery may be anticipated, unless the soft tissue thickening wrought by scleroderma produces dystocia requiring cesarean delivery. Tracheal intubation for general anesthesia has special concerns because of limited ability of these women to open their mouths widely (Sobanski, 2016). Because of esophageal dysfunction, aspiration is also more likely, and neuraxial analgesia is preferable. Warming the delivery room and intravenous fluids, extra blankets, and socks and gloves are considered to improve impaired circulation from Raynaud phenomenon. If corticosteroids were used frequently, stress doses of hydrocortisone, described earlier for SLE (p. 1113), are recommended (Sobanski, 2016).

Maternal and fetal outcomes correlate with underlying disease severity. In a review of 214 gravidas with systemic sclerosis, 45 percent had diffuse disease (Steen, 1999). Major complications included renal crisis in three and greater rates of preterm birth. A multicenter study of 109 pregnancies from 25 centers reported increased rates of preterm delivery, fetal-growth restriction, and very-low-birthweight newborns (Taraborelli, 2012). In a review of 307 affected pregnancies, risks for miscarriage, preterm births, and gestational hypertension were increased (Blagojevic, 2020). These are likely related to placental abnormalities that include decidual vasculopathy, acute atherosis, and infarcts (Sobanski, 2016). Somewhat related, perinatal outcomes are similar with undifferentiated connective tissue diseases (Radin, 2020; Zucchi, 2020).

Scleroderma may be associated with subfertility (Bernatsky, 2008; Lambe, 2004). For women who do not choose pregnancy, several reversible contraceptive methods are acceptable. However, hormonal agents, especially combination oral contraceptives, probably should not be used, especially in women with pulmonary, cardiac, or renal involvement. Due to the often unrelenting progression of systemic sclerosis, permanent sterilization also is considered.

VASCULITIS SYNDROMES

Inflammation and damage to blood vessels may be primary or caused by another disease. Immune-complex deposition is presumed to underlie most cases (Ross, 2020). Primary types are listed in Table 62-7 (Langford, 2018). Small vessel vasculitides such as *granulomatosis with polyangiitis* and *eosinophilic granulomatosis with polyangiitis* have antibodies directed against proteins in the cytoplasmic granules of leukocytes—*antineutrophil cytoplasmic antibodies (ANCA)* (Pagnoux, 2016). In general, women with a vasculitis syndrome have elevated rates of preterm birth and preeclampsia (Nguyen, 2021).

■ Polyarteritis Nodosa

This necrotizing vasculitis of small and medium-sized arteries is characterized clinically by myalgia, neuropathy, gastrointestinal disorders, hypertension, and renal disease (Goodman, 2014). A third of cases are associated with hepatitis B antigenemia (Langford, 2018). Symptoms are nonspecific, and fever, weight loss, and malaise are present in more than half of cases. Diagnosis is made by biopsy, and treatment is high-dose prednisone plus cyclophosphamide. Vasculitis due to hepatitis B antigenemia responds to antivirals, glucocorticosteroids, and plasma exchange (Chap. 58, p. 1037).

TABLE 62-7. Primary Vasculitis Syndromes

Polyarteritis nodosa
Wegener granulomatosis
Takayasu arteritis
Behçet disease
Churg-Strauss
Henoch-Schönlein
Giant cell arteritis

Only a few reports describe polyarteritis nodosa associated with pregnancy. Of 12 affected gravidas, polyarteritis first manifested during pregnancy in seven, and it was rapidly fatal by 6 weeks postpartum (Owen, 1989). The diagnosis was not made until autopsy in six of the seven women. Four women continued pregnancy, which resulted in one stillborn and three successful outcomes.

Granulomatosis with Polyangiitis—Wegener Granulomatosis

This is a small-vessel necrotizing granulomatous vasculitis affecting the upper and lower respiratory tract and kidney (Pagnoux, 2016). Disease frequently includes sinusitis and nasal disease (90 percent); pulmonary infiltrates, cavities, or nodules (85 percent); glomerulonephritis (75 percent); and musculoskeletal lesions (65 percent) (Sneller, 1995). At least 90 percent have polyangiitis (Langford, 2018). It is uncommon and usually encountered after age 50. Koukoura and associates (2008) reviewed 36 cases in association with pregnancy and found a higher preterm birth rate. In another report, a second woman had disease-related pneumonitis, but pregnancy did not appear to affect disease activity (Pagnoux, 2011). Because subglottic stenosis is found in up to a fourth of patients, the anesthesiology service is ideally consulted antepartum (Engel, 2011).

Therapeutic options are limited by teratogenicity and fetotoxicity (Daher, 2020). Corticosteroids are standard treatment, but azathioprine, cyclosporine, and IVIG therapy may also be used. For severe disease in the late second or third trimester, cyclophosphamide in combination with prednisolone is highly effective. Rituximab is also approved for this disorder and appears to be safe for the fetus (Briggs, 2022).

Takayasu Arteritis

Also called *pulseless disease*, this is a chronic inflammatory arteritis affecting large vessels (Abisror, 2020). Unlike *temporal arteritis*, which develops almost exclusively after age 55, the onset of Takayasu arteritis is almost always before age 40. It is associated with abnormal angiography of the upper aorta and its main branches and with upper extremity vascular impairment. Death usually results from congestive heart failure or cerebrovascular events. Computed tomography or magnetic resonance angiography can detect this disorder before the development of severe vascular compromise. Takayasu arteritis may respond symptomatically to corticosteroid therapy, however, it is not curative. Surgical bypass or angioplasty improves survival rates.

Comorbid severe renovascular hypertension, cardiac involvement, or pulmonary hypertension worsen pregnancy prognosis (Comarmond, 2020; Singh, 2015). Hypertension is relatively common and should be carefully controlled. Blood pressure is most accurately measured in the lower extremity. Overall, the prognosis for pregnancy is good (Kirshenbaum, 2018). A study of 43 pregnancies in 33 women with Takayasu arteritis reported that half had complications (Abisror, 2020). Authors described an increased risk of pregnancy-related hypertension and preeclampsia but overall favorable maternal and fetal outcomes. A review from Comarmond and colleagues (2020) cites a 5-percent life-threatening cardiovascular complication rate. Involvement of the abdominal aorta portends worse perinatal outcome (Sharma, 2000). Vaginal delivery is preferred, and epidural analgesia has been advocated for labor and delivery.

Other Vasculitides

Behçet disease is rare, and its prevalence approximates 1 case per 100,000 births (Lee, 2019). In one series of 298 pregnancies in 94 affected women, rates of miscarriage and smaller babies were higher than those in healthy controls (Gungor, 2014). Although greater risks for preeclampsia, preterm delivery, and venous thromboembolism are reported, pregnancy is not contraindicated (Elliot, 2019; Merlino, 2020).

Formerly *Churg-Strauss vasculitis*, eosinophilic granulomatosis with polyangiitis is rare in pregnancy (Jennette, 2013). One case report described a pregnant woman who responded to IVIG therapy (Hot, 2007). Another presented an affected 35-year-old woman at term whose necrotizing vasculitis involved the heart, and she subsequently underwent cardiac transplantation (Corradi, 2009). Edwards (2015) described one woman who developed postpartum relapses of this vasculitis in each of two pregnancies.

Henoch-Schönlein purpura is uncommon after childhood. Characteristic signs of the disorder include purpuric rash, arthralgia, abdominal pain, and gastrointestinal bleeding. In one review of 20 pregnancies complicated by this vasculitis, cutaneous lesions and arthralgias were present in three fourths and in approximately one half, respectively (Tayabali, 2012). Henoch-Schönlein purpura responds well to corticosteroid therapy, and pregnancy outcomes are generally good (Kalmantis, 2008).

INFLAMMATORY MYOPATHIES

These are acquired and potentially treatable causes of skeletal muscle weakness with a prevalence of 14 to 32 cases in 100,000 persons (Greenberg, 2018). Three major groups are polymyositis, dermatomyositis, and inclusion-body myositis, which all present with progressive asymmetrical muscle weakness. They have a variable association with connective tissue diseases, malignancy, drugs, systemic autoimmune disease such as Crohn disease, and viral, bacterial, and parasitic infections.

Polymyositis is a subacute inflammatory myopathy that is frequently associated with one of the autoimmune connective tissue disorders (Bitencourt, 2020; Munira, 2020). *Dermatomyositis* manifests as a characteristic rash accompanying or preceding weakness. Laboratory findings include elevated muscle enzyme levels in serum and an abnormal electromyogram. Confirmation is by biopsy, which shows perivascular and perimysial inflammatory infiltrates, vasculitis, and muscle fiber degeneration. It usually develops alone but can overlap with systemic sclerosis or mixed connective tissue disease.

Prevailing theories suggest that the syndromes are caused by viral infections, autoimmune disorders, or both. *Importantly, approximately 15 percent of adults who develop dermatomyositis have an associated malignant tumor*. The timing of myositis and tumor appearance may be separated by several years. The most common sites of associated cancer are breast, lung, stomach, and ovary. The disease usually responds to high-dose corticosteroid therapy, immunosuppressive drugs such as azathioprine or methotrexate, or IVIG (Dalakas, 2012; Linardaki, 2011).

Experiences in pregnancy are garnered mostly from case series and reviews. One cohort of 17 gravidas with polymyositis/dermatomyositis had higher rates of hypertension (23 percent), antepartum hemorrhage (11 percent), cesarean delivery (88 percent), and preterm birth (35 percent) compared with unaffected pregnant women (Chen, 2015). In another series of 60 women with dermatomyositis and 38 with polymyositis, 80 percent had no adverse effect on their disease. Similar results have been reported by others (Missumi, 2015; Pinal-Fernandez, 2014). Pregnancy outcome is related to dermatomyositis activity, and new-onset disease is particularly aggressive (Munira, 2020).

HEREDITARY CONNECTIVE TISSUE DISORDERS

Numerous inherited mutations involve genes that encode for structural proteins of bone, skin, cartilage, blood vessels, and basement membranes. Although connective tissues contain many complex macromolecules such as elastin and more than 30 proteoglycans, the most common constituents are fibrillar collagen types I, II, and III. Various mutations, some recessively and some dominantly inherited, result in clinical syndromes that include Marfan and Ehlers-Danlos syndromes, osteogenesis imperfecta, chondrodysplasias, and epidermolysis bulla. Of concern during pregnancy is the predilection for these disorders to result in aortic aneurysms (Schoenhoff, 2013).

Marfan Syndrome

This is an autosomal dominant connective tissue disorder that has a population prevalence of 1 case in 3000 to 5000 (Prockop, 2018). Marfan syndrome affects both sexes equally. The syndrome is due to abnormal fibrillin—a constituent of elastin—caused by any of several different mutations in the *FBN1* gene (Biggin, 2004). Located on chromosome 15q21, the *FBN1* gene has a high mutation rate. The lack of distinct genotype-phenotype correlation and large clinical variability limits the ability to predict disease severity in progeny. Currently, preimplantation genetic testing and prenatal diagnosis are limited to the 80 percent of cases in which the mutation in the *FBN1* gene is known (Smok, 2014).

In severe disease, the elastic lamina in the media of the aorta shows degeneration. This predisposes to aortic dilation or dissecting aneurysm, which appears more commonly during pregnancy (Curry, 2014; Roman, 2016). Marfan syndrome was found to underlie 65 percent of cases of aortic dissection in 27 pregnant women (Braverman, 2021). Marfan syndrome complicating pregnancy is discussed in more detail in Chapter 52 (p. 936).

Ehlers-Danlos Syndrome

This disease is characterized by various connective tissue changes, including skin hyperelasticity. Its prevalence is 7 cases per 100,000 births (Spiegel, 2020). Several disease types vary based on skin, joint, or other tissue involvement. In the more severe types, rupture of any of several arteries can cause either stroke or bleeding. Some types are autosomal dominant, some recessive, and some X-linked (Solomons, 2013). Types I, II, and III are autosomally dominant, and each accounts for approximately 30 percent of cases. Type IV is uncommon but is known to predispose to preterm delivery, great-vessel rupture, postpartum bleeding, and uterine rupture (Pepin, 2000). In most, the underlying molecular defect affects collagen or procollagen.

In general, women with Ehlers-Danlos syndrome have a higher frequency of preterm rupture of membranes, preterm delivery, antepartum and postpartum hemorrhage, placenta previa, and cervical insufficiency (Hurst, 2014; Spiegel, 2020). Several cases of spontaneous uterine rupture have been described (Rudd, 1983). Tissue fragility makes episiotomy repair and cesarean delivery difficult. A maternal and fetal death from spontaneous rupture of the right iliac artery has been reported (Esaka, 2009). In another case, a newborn was found to have multiple congenital skull fractures and intracranial hemorrhage caused by Ehlers-Danlos type VIIC (Bar-Yosef, 2008).

Osteogenesis Imperfecta

This disorder has a prevalence of 1 case in 20,000 births for type I and 1 case in 60,000 for type II (Prockop, 2018). It is characterized by brittle bones, and affected patients often have blue sclerae, hearing loss, multiple prior bone fractures, and dental abnormalities. There are up to 15 subtypes based on the causative gene and clinical picture, which ranges from mild to severe (Van Dijk, 2010). Genetic inheritance includes autosomal dominant, autosomal recessive, and sporadic patterns. Type I is the mildest form, and the typical mutation affects the *COL1A1* gene (Sykes, 1990). Type II is typically lethal in utero.

Women with osteogenesis imperfecta, most commonly type I, may have successful pregnancies. However, risks include fractures, complications related to scoliosis with restrictive lung disease, micrognathia, brittle teeth, an unstable cervical spine, uterine rupture, and cephalopelvic disproportion. A retrospective cohort of 295 women with osteogenesis imperfecta found greater risks of antepartum hemorrhage, placental abruption, fetal-growth restriction, congenital malformations, and preterm birth (Ruiter-Ligeti, 2016). It is not unusual for affected women to enter pregnancy with 20 to 30 prior fractures. Most require minimal treatment other than management of the fractures and consideration of bisphosphonates to decrease bone loss.

Depending on the type of osteogenesis imperfecta, the fetus may be affected and may also suffer fractures in utero or during delivery. Preimplantation genetic testing and prenatal diagnosis is available in many situations, if desired. In utero stem cell therapy is being evaluated (Couzin-Frankel, 2016).

CHAPTER 63

Neurological Disorders

Many neurological disorders precede pregnancy. Most affected women will have successful perinatal outcomes, although some disorders carry specific risks. Other women will have new-onset neurological symptoms during pregnancy, and these must be distinguished from pregnancy complications. Neurovascular disorders are an important cause of maternal mortality and accounted for more than 7 percent of maternal deaths in the United States from 2007 through 2016 (Petersen, 2019). Psychiatric disorders can manifest with cognitive and neuromuscular abnormalities and should be considered in the evaluation of neurological symptoms.

CENTRAL NERVOUS SYSTEM IMAGING

Computed tomography (CT) and magnetic resonance (MR) imaging assist in the diagnosis, classification, and management of many neurological disorders. As discussed in Chapter 49, (p. 873), these can be used safely during pregnancy (Chansakul, 2017; Lum, 2020). CT scanning is often used when rapid diagnosis is necessary and is excellent for detecting recent hemorrhage. That said, MR imaging is often preferred and is particularly helpful to diagnose demyelinating diseases, arteriovenous malformations (AVMs), congenital and developmental nervous system abnormalities, posterior fossa lesions, and spinal cord diseases (Jamieson, 2020). Whenever either modality is employed, a woman with advanced pregnancy should be positioned in a lateral tilt with a wedge under one hip to prevent hypotension and to diminish aortic pulsations, which may degrade the image.

Cerebral angiography with contrast injection, usually via the femoral artery, is a valuable adjunct to the diagnosis and treatment of some cerebrovascular diseases. Fluoroscopy delivers more radiation but can be performed with abdominal shielding. Positron emission tomography (PET) and functional MR imaging (fMRI) have not been evaluated in detail for use in gravidas (van den Heuvel, 2016).

HEADACHE

In one national survey in the United States in 2012, 17 percent of persons aged 18 to 44 years reported a severe headache or migraine within the past 3 months (Blackwell, 2014). Burch and coworkers (2015) reported that 24 percent of nonpregnant women in this age group were similarly affected. Of pregnant women presenting with headache who received a neurological consultation, two thirds were due to primary disorders. The diagnosis was migraine in more than 90 percent. Of the other third due to secondary conditions, more than half stemmed from hypertensive disorders (Robbins, 2015). In one recent observational study at University of Texas Southwestern's Clements University Hospital, 20 percent of emergency department postpartum visits were for headache (Rodriguez, 2021).

TABLE 63-1. Headache Classification

Primary
Migraine
Tension-type
Trigeminal cephalalgia
Other

Secondary
Trauma
Vascular disorders
Substance abuse
Infection
Disorders of homeostasis
Craniofacial disorders
Psychiatric disorders

The classification by the International Headache Society (2018) is shown in Table 63-1. As discussed, in pregnant women, primary headaches are more common than those derived from secondary causes (Sperling, 2015). Migraine headaches are those most likely to be affected by the hormonal changes of pregnancy (Pavlovic, 2017). The incidences of different etiologies of severe headaches in pregnancy are shown in Figure 63-1 (Robbins, 2015).

Tension Headache

These are the most frequent cause of all headaches. They may be episodic or chronic. Their characteristic muscle tightness and mild to moderate pain in the back of the neck and head can persist for hours. Importantly, neurological disturbances or nausea are typically absent, which distinguishes them from migraines. The pain usually responds to rest, massage, local heat or ice, nonsteroidal antiinflammatory drugs (NSAIDs), or mild tranquilizers. Hospital admission is seldom necessary. For chronic headaches, amitriptyline can be effective (Goadsby, 2018).

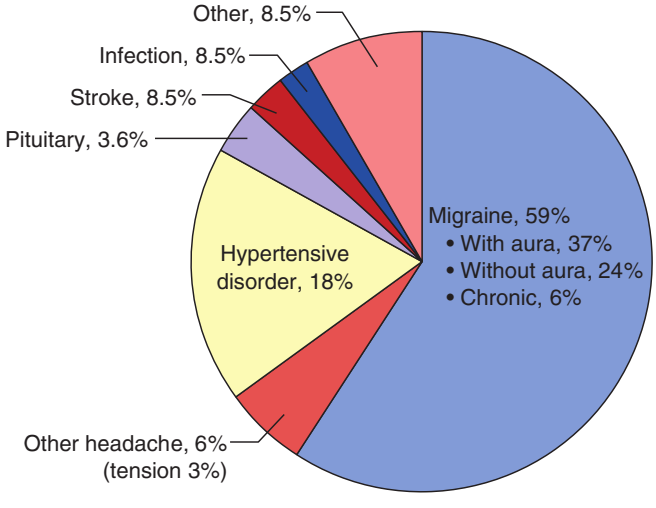

FIGURE 63-1 Incidences of headache causes in 140 consecutive pregnant women for whom in-hospital neurology consultation was requested.

Migraine Headache

This is a periodic, sometimes incapacitating neurological disorder with episodic attacks of severe headache and autonomic nervous system dysfunction (Ashina, 2020; Charles, 2017). The International Headache Society (2018) classifies three migraine types based on chronicity and on the presence or absence of an aura.

1. *Migraine without aura*-formerly termed common migraine-is characterized by a unilateral throbbing headache, nausea and vomiting, or photophobia.
2. *Migraine with aura*-formerly termed classic migraine-has similar symptoms preceded by premonitory neurological phenomena such as visual scotoma or hallucinations. A third of patients have this type, which sometimes can be averted if medication is taken at the *first premonitory sign.*
3. *Chronic* migraine is defined by a migraine headache occurring at least 15 days each month for more than 3 months.

Migraine headaches may begin in childhood, peak in adolescence, and tend to diminish in both frequency and severity with advancing years. According to Ashina (2020), their annual prevalence is 15 percent in women and 6 percent in men. Another 5 percent of women have *probable migraine*, that is, they have all criteria but one.

These headaches are especially common in young women and have been linked to hormone levels (Burch, 2020; Charles, 2017). Sensory sensitivity with migraines is likely caused by monoaminergic sensory control systems in the brainstem, hypothalamus, and cortex (Goadsby, 2018). The exact pathophysiology is uncertain, but symptoms develop when neuronal dysfunction leads to decreased cortical blood flow, activation of vascular and meningeal nociceptors, and stimulation of trigeminal sensory neurons. Importantly, migraines are not primarily a vascular disorder (Charles, 2017). Migraine headaches—especially those with aura in young women—are associated with increased risk for ischemic strokes (Tietjen, 2020). Other associated conditions are asthma, anxiety and depression, and other pain disorders.

Migraine in Pregnancy

Migraine headaches are frequently encountered during pregnancy. Most migraineurs have improvement during pregnancy (Lucas, 2019). Still, migraines—usually those with an aura—occasionally appear for the first time during pregnancy. Pregnant women with preexisting migraine symptoms may have other symptoms that suggest a more serious disorder, and new neurological symptoms should prompt a complete evaluation (Charles, 2017).

Migraines during pregnancy are associated with increased rates of preeclampsia, gestational hypertension, preterm birth, and other cardiovascular morbidities that include ischemic stroke (Grossman, 2017; Wabnitz, 2015). Bushnell and associates (2009) identified a migraine incidence during pregnancy of 185 cases per 100,000 deliveries. Of diagnoses associated in these gravid migraineurs, risks were significantly higher for stroke, 16-fo1d; myocardial infarction, fivefold; and heart disease, venous thromboembolism, and preeclampsia/gestational hypertension, each twofold. In a systematic review of 14

TABLE 63-2. Medications for Treatment of Acute Migraine in Pregnancy

Simple Analgesics
- Acetaminophen
- NSAIDs: naproxen, ibuprofen

5-HT Receptor Agonists
- Triptans: oral, nasal, parenteral

Dopamine-receptor Antagonists
- Metoclopramide

5-HT = 5-hydroxytryptamine (serotonin); NSAIDs = nonsteroidal antiinflammatory drugs.
From Ashina, 2020; Charles, 2017; Goadsby, 2018.

studies, risks for preeclampsia and low-birthweight neonates were significantly increased (Aukes, 2019).

Management

Several effective medications are shown in Table 63-2. Mild headaches respond to oral therapy in 50 to 70 percent of cases. Initial therapy with acetaminophen or an NSAID, along with an antiemetic, usually suffices for many early headaches. For severe headaches, parenteral therapy is indicated (Goadsby, 2018). Multitargeted drug therapy is necessary in most cases for migraine relief (Gonzalez-Hernandez, 2014). Headaches are treated aggressively with intravenous hydration, parenteral antiemetics, and triptans, and opioids are reserved for the most recalcitrant headaches. Although a 2-g infusion of magnesium sulfate has gained favor in the past few years, a metaanalysis reported no benefits (Choi, 2014). *Ergotamine derivatives are potent vasoconstrictors and are avoided in pregnancy because of their uterotonic effects* (Briggs, 2022).

Triptans are serotonin 5-$HT_{1B/2D}$-receptor agonists that effectively relieve headaches, nausea, and vomiting and greatly reduce analgesic needs. Triptans can be given as an oral tablet, injection, rectal suppository, or intranasal spray. They are best used in combination with NSAIDs (Goadsby, 2018). However, chronic NSAID use is avoided in pregnancy, especially later pregnancy because of fetal ductus arteriosus constriction and fetal urine production decline (Chap. 18, p. 151). The greatest triptan experience is with sumatriptan (Imitrex), and although not studied extensively in pregnancy, it is not a major teratogen (Saldanha, 2021; Spielmann, 2018). However, in one study at 36 months of children exposed to triptans in pregnancy, Wood and colleagues (2016) found neurodevelopment differences, including emotionality and activity problems.

Some women will benefit from peripheral nerve blocks, and Govindappagari and coworkers (2014) described their experiences with 13 pregnant women. For women with frequent migraine headaches, oral prophylactic therapy is warranted. Amitriptyline (Elavil), 10 to 175 mg daily; propranolol (Inderal), 40 to 120 mg daily; or metoprolol (Lopressor, Toprol), 25 to 100 mg daily, are successful options (Contag, 2010; Lucas, 2009).

Calcitonin gene-related peptide (CGRP) receptor antagonists to prevent migraines have garnered enthusiasm. Several of these monoclonal antibodies have been approved since 2018 for clinical use but not evaluated in pregnancy (Ashina, 2020; Tepper, 2018). Similarly, in a Cochrane review, botulinum toxin type A for chronic migraine may reduce migraine days per month by 2 days compared with placebo (Herd, 2018).

Cluster Headache

This rare primary headache disorder is characterized by severe unilateral lancinating pain radiating to the face and orbit, lasting 15 to 180 minutes, and occurring with autonomic symptoms and agitation. Pregnancy does not affect symptom severity. Affected women should avoid tobacco and alcohol. Acute management includes 100-percent oxygen therapy and sumatriptan given as a 6-mg dose subcutaneously (Vander Pluym, 2016). If recurrent, prophylaxis employs verapamil.

SEIZURE DISORDERS

After headaches, seizures are the next most prevalent neurological condition encountered in pregnancy. The Centers for Disease Control and Prevention reported that 3 million adults in 2015 had active epilepsy (Tian, 2018). Less than half were seizure free in the past year. Importantly, epilepsy accounted for 5 percent of maternal deaths in the United Kingdom from 2011 to 2013 (Knight, 2015).

Pathophysiology

A seizure is a transient combination of signs and symptoms stemming from abnormal excessive or synchronous neuronal activity in the brain (Lowenstein, 2018). Some identifiable causes of convulsive disorders in young adults include head trauma, alcohol- and other drug-induced withdrawals, cerebral infections, brain tumors, biochemical abnormalities, and arteriovenous malformations. A search for these is prudent with a new-onset seizure disorder in a pregnant woman. The diagnosis of idiopathic epilepsy is one of exclusion.

Classification

Epilepsy encompasses different syndromes whose cardinal feature is a predisposition to recurrent unprovoked seizures. The International League Against Epilepsy recently updated the following definitions (Fisher, 2017). Main categories describe seizure onset and include focal, generalized, and unknown groups.

Focal seizure onset describes those that originate in one localized brain area and affect correspondingly localized

neurological function. They are believed to result from trauma, abscess, tumor, or perinatal factors, although a specific lesion is rarely demonstrated. Seizures may occur with either intact or impaired awareness.

Focal seizures without dyscognitive features start in one region of the body and progress toward other ipsilateral areas of the body and produce tonic and then clonic movements. Seizures can affect sensory function or produce autonomic dysfunction or psychological changes. Cognitive function is not impaired, and recovery is rapid.

Focal seizures with dyscognitive features are often preceded by an aura and followed by impaired awareness manifested by sudden behavioral arrest or motionless stare. Involuntary movements such as picking motions or lip smacking are common.

Generalized seizure onset describes those that involve both brain hemispheres and may be preceded by an aura before an abrupt loss of consciousness. They may be motor or nonmotor. There is a strong hereditary component. In *generalized tonic-clonic seizures*, loss of consciousness is followed by tonic contraction of the muscles and rigid posturing, and then by clonic contractions of all extremities while the muscles gradually relax. Return to consciousness is gradual, and the patient may remain confused and disoriented for several hours. *Absence seizures*—also called petit mal seizures—are a form of generalized epilepsy that involve a brief loss of consciousness without muscle activity and are characterized by immediate recovery of consciousness and orientation.

Unknown seizure onset describes seizures with an unwitnessed onset. Thus, they remain unclassified as to focal or generalized onset until further information allows categorization. However, these can be further subgrouped as motor or nonmotor, or unclassified.

■ Preconceptional Counseling

Women with epilepsy ideally are counseled before pregnancy, and relevant points are presented also in Chapter 9 (p. 166). Oral folic acid supplementation with 0.4 mg per day is begun at least 1 month before conception. The dose is increased to 4 mg when the woman taking antiepileptic medication becomes pregnant. These medications are assessed and adjusted with a goal of monotherapy using the least teratogenic medication. If this is not feasible, attempts are made to reduce the number of medications and to use the lowest effective dose (Stephen, 2019; Tomson, 2019b). Medication withdrawal should be considered if a woman is seizure free for 2 years or more.

■ Pregnancy Complications

The major pregnancy-related risks to women with epilepsy are fetal malformations and convulsions. Seizure control is a priority to avoid its attendant morbidity and mortality. Early studies described worsening seizure activity during pregnancy, however, this is less common now because of more effective drugs (Pennell, 2020). Contemporary studies cite higher rates of seizure activity in only 20 to 30 percent of gravidas (Tomson, 2019b). Women who are seizure free for at least 9 months before conception will likely remain so during pregnancy (Harden, 2009b).

Greater seizure frequency is often associated with subtherapeutic anticonvulsant serum levels, a lower seizure threshold, or both. Numerous pregnancy-associated alterations can result in subtherapeutic serum levels. These include nausea and vomiting, slower gastrointestinal motility, antacid use that diminishes drug absorption, pregnancy hypervolemia offset by protein binding, induction of hepatic enzymes such as cytochrome oxidases, placental enzymes that metabolize drugs, and increased glomerular filtration that hastens drug clearance. Importantly, some women discontinue medication because of teratogenicity concerns. Last, the seizure threshold can be affected by pregnancy-related sleep deprivation and by hyperventilation and pain during labor (Tomson, 2019b).

Status epilepticus is a medical emergency. It is more likely to occur in women with refractory epilepsy (Kusznir Vitturi, 2019). In a randomized trial of 384 nonpregnant patients with benzodiazepine-refractory status, intravenous levetiracetam, fosphenytoin, or valproate yielded similar results (Kapur, 2019). Only one half of patients in each cohort had cessation of seizures and improved alertness by 60 minutes.

In addition to seizure-control challenges, women with epilepsy have a small increased risk of pregnancy complications that include miscarriage, hemorrhage, hypertensive disorders, placental abruption, preterm birth, fetal-growth restriction, and cesarean delivery (Salman, 2018; Viale, 2015). Importantly, MacDonald (2015) also reports a tenfold higher maternal death rate, and, as mentioned earlier, epilepsy accounted for 5 percent of maternal deaths in the United Kingdom. Postpartum depression rates also are increased in epileptic women (Turner, 2009). Last, children of epileptic mothers have a 10-percent risk of developing a seizure disorder.

With embryofetal malformations, it was difficult for years to separate the influence of epilepsy from that of its therapy as the primary cause. Now, untreated epilepsy is thought not to be associated with an elevated fetal malformation rate (Tomson, 2019b). That said, the fetus of an epileptic mother who takes certain anticonvulsant medications has an indisputably greater risk for congenital malformations. Moreover, monotherapy is associated with a lower rate of birth defects compared with multiagent therapy. Adherence to these principles has resulted in declining malformation rates from antiepileptic drugs (Tomson, 2019a).

Specific drugs, when given alone, raise the malformation rate (Chap. 8, p. 150). Some are listed in Table 63-3. Phenytoin and phenobarbital increase the major malformation rate two- to threefold above baseline (Perucca, 2005; Thomas, 2008). Valproate is a particularly potent teratogen, which has a dose-dependent effect and raises the malformation risk four- to eightfold (Klein, 2014; Tomson, 2019b). Valproate is also associated with lower cognitive performance (Kasradze, 2017). In general, with polytherapy, the risk rises with each drug added. A metaanalysis of 31 studies found lamotrigine and levetiracetam to carry the lowest malformation risk (Weston, 2016).

■ Management in Pregnancy

The American Academy of Neurology and the American Epilepsy Society have guidelines regarding treatment in pregnancy

TABLE 63-3. Teratogenic Effects of Common Anticonvulsant Medications

Drug (Brand Name)	Abnormalities Described	Affected	Embryofetal Risks[a]
Valproate (Depakote)	Neural-tube defects, clefts, cardiac anomalies; associated developmental delay; ADHD	7–10% with monotherapy; higher with polytherapy	
Phenytoin (Dilantin)	Fetal hydantoin syndrome: craniofacial anomalies, fingernail hypoplasia, growth deficiency, developmental delay, cardiac anomalies, clefts	5–11%	Yes
Carbamazepine; oxcarbazepine (Tegretol; Trileptal)	Fetal hydantoin syndrome, as above, spina bifida	2–5%	Yes
Phenobarbital	Clefts, cardiac anomalies, urinary tract malformations	6–20%	Suggested
Lamotrigine (Lamictal)	Increased risk for clefts (registry data)	Up to 2% (4- to 10-fold higher than expected)	Suggested
Topiramate (Topamax)	Clefts	2–3% (15- to 20-fold higher than expected)	Suggested
Levetiracetam (Keppra)	Theoretical: skeletal abnormalities; impaired growth in animals	1–3%	Suggested

ADHD = attention deficit hyperactivity disorder.
[a]Risk categories from Briggs, 2022; Bromley, 2017; Christensen, 2019; Food and Drug Administration, 2011; Harden, 2009b; Tomson, 2018, 2019b.

(Harden, 2009a,b,c). The major goal is seizure prevention. To accomplish this, treatment for nausea and vomiting is provided, seizure-provoking stimuli are avoided, and medication compliance is emphasized. The fewest necessary anticonvulsants are given at the lowest dosage needed for seizure control. Although some providers routinely monitor serum drug levels, these concentrations may be unreliable because of altered protein binding. Free or unbound drug levels, although perhaps more accurate, are not widely available. Importantly, no evidence suggests that such monitoring improves seizure control (Adab, 2006). For these reasons, drug levels may be most informative if measured following seizures or if noncompliance is suspected.

For women taking anticonvulsant drugs, a targeted sonographic examination in midpregnancy is recommended to evaluate for anomalies. Testing to assess fetal well-being is generally not indicated for women with uncomplicated epilepsy.

For women desiring to breastfeed, data regarding the safety of the various anticonvulsant medications are limited. However, no obvious deleterious effects, such as long-term cognitive issues, have been reported (Birnbaum, 2020; Briggs, 2022). Of birth control methods, combination oral contraceptive (COC) pill failure rates are higher with some of the anticonvulsant agents. For example, lamotrigine efficacy is substantially lowered by COCs. Thus, other more reliable methods should be considered (Chap. 38, p. 664).

CEREBROVASCULAR DISEASES

Abnormalities of the cerebrovascular circulation include both ischemic and hemorrhagic strokes and anatomical anomalies, such as AVMs and aneurysms. Cerebral ischemia is caused by reduction in blood flow that lasts longer than several seconds. Early, neurological symptoms may manifest. After a few minutes, however, infarction often follows. Hemorrhagic stroke is caused by bleeding directly into or around the brain. It produces symptoms by its mass effect, by blood's toxic effects, or by elevated intracranial pressure. Strokes in nonpregnant women are predominately ischemic. In gravidas, roughly half are ischemic, and the other half are hemorrhagic (Zofkie, 2018).

The obesity endemic in this country, along with a concomitant rise in rates of heart disease, hypertension, and diabetes, has increased the prevalence of strokes. Compared with men, women have a higher lifetime risk of stroke and associated mortality rate (Martinez-Sánchez, 2011; Virani, 2021). Moreover, pregnancy raises the immediate and lifetime risk of both ischemic stroke and hemorrhagic stroke (Jamieson, 2010; Jung, 2010).

With an incidence of 10 to 40 cases per 100,000 births, stroke is relatively uncommon in gravidas. However, it contributes disparately to maternal mortality rates (Leffert, 2016; Pacheco, 2019; Elgendy, 2021). The incidence is rising as measured by pregnancy-related hospitalizations for stroke (Callaghan, 2008; Kuklina, 2011). Most events are associated with hypertensive disorders or heart disease. Of the pregnancy-related mortality rate in the United States from 2007 to 2016, 7.2 percent was due to cerebrovascular accidents, and 7.8 percent was associated with hypertension (Petersen, 2019). Of maternal deaths after 42 days postpartum, 9.8 percent were attributable to stroke (Creanga, 2017).

Risk Factors

Most strokes in pregnancy manifest either during labor and delivery or in the puerperium. In a study of 2850 pregnancy-

related strokes, approximately 10 percent developed antepartum, 40 percent intrapartum, and 50 percent postpartum (James, 2005). Of 145 ischemic strokes, Leffert (2016) reported a timing of 45 percent antepartum, 3 percent intrapartum, and 53 percent postpartum.

Several risk factors both unrelated and related to pregnancy have been recognized. Unrelated causes are age; migraines, hypertension, obesity, and diabetes; cardiac disorders such as endocarditis, valvular prostheses, and patent foramen ovale; and smoking. Stroke etiologies related to pregnancy include hypertensive disorders, gestational diabetes, obstetrical hemorrhage, and cesarean delivery. *By far, the most common is pregnancy-associated hypertensive disorders*. A third of strokes are associated with gestational hypertension, and hypertensive women compared with normotensive counterparts have a three- to eightfold greater risk of stroke (Scott, 2012; Wang, 2011). Stroke is the major cause of maternal mortality associated with preeclampsia (Judy, 2019). Moreover, women with preeclampsia undergoing general anesthesia may be at higher risk of stroke compared with those given neuraxial anesthesia (Huang, 2010). Cesarean delivery raises the peripartum stroke risk 1.5-fold compared with vaginal delivery (Lin, 2008). Sepsis from any source increases the risk for postpartum stroke (Miller, 2019).

Pregnancy-induced effects on cerebrovascular hemodynamics include enhanced autoregulation that maintains blood flow despite changes in systemic blood pressure (van Teen, 2016). Although cerebral blood flow *decreases* by 20 percent from midpregnancy until term, it *increases* significantly with gestational hypertension (Zeeman, 2003, 2004b). Such hyperperfusion at least intuitively would be dangerous for women with certain vascular anomalies.

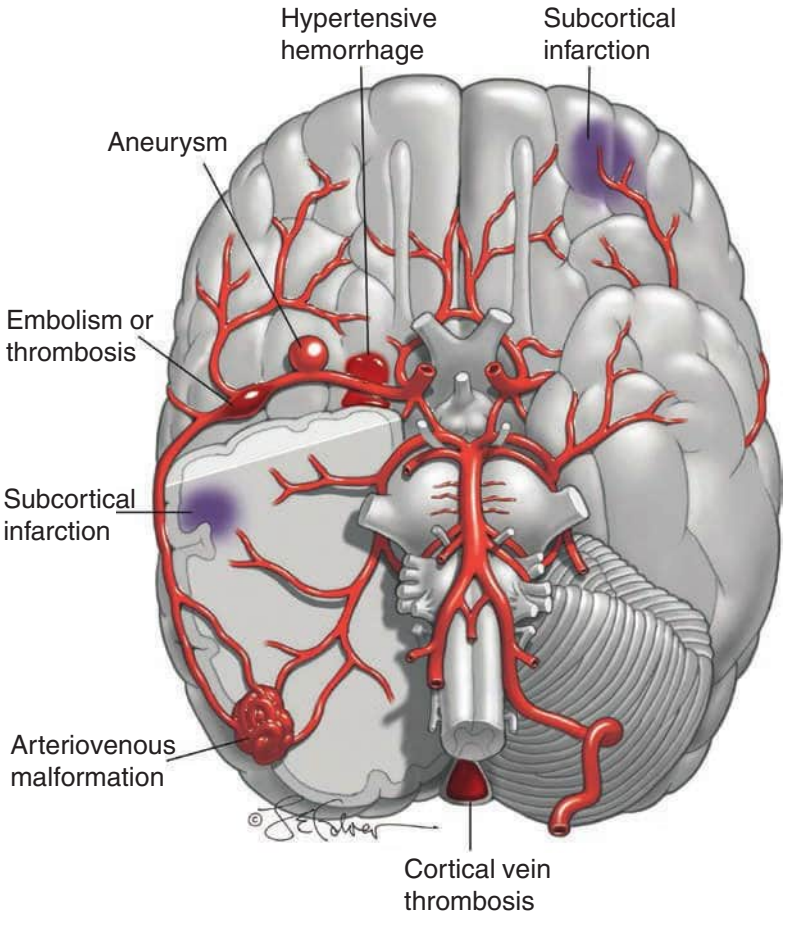

FIGURE 63-2 Illustrations of a brain showing various types of strokes seen in pregnancy: (1) subcortical infarction (preeclampsia), (2) hypertensive hemorrhage, (3) aneurysm, (4) embolism or thrombosis in middle cerebral artery, (5) arteriovenous malformation, and (6) cortical vein thrombosis.

■ Ischemic Stroke

Acute occlusion or embolization of an intracranial blood vessel causes cerebral ischemia, which may result in death of brain tissue (Fig. 63-2). The more commonly associated etiologies of ischemic stroke are shown in Table 63-4. A *transient ischemic attack (TIA)* is caused by reversible ischemia, and symptoms usually last less than 24 hours. Approximately 10 percent of these patients have a stroke by 1 year (Amarenco, 2016).

Stroke usually incites sudden severe headache, hemiplegia, or other neurological deficits. Seizures occasionally develop. Immediate assessment and CT scanning is indicated (Pacheco, 2019). Further evaluation includes echocardiography and additional cranial imaging with CT, MR imaging, or angiography. Serum lipids are measured with the caveat that their values are distorted by normal pregnancy (Appendix, p. 1231). Tests to detect antiphospholipid antibodies, lupus anticoagulant, other thrombophilias, and, if indicated, sickle-cell syndromes are performed (Buonanno, 2016).

TABLE 63-4. Some Associated Disorders or Causes of Ischemic and Hemorrhagic Strokes During Pregnancy or the Puerperium

Ischemic Stroke	Hemorrhagic Stroke
Preeclampsia syndrome	Chronic hypertension
Arterial thrombosis	Preeclampsia syndrome
Venous thrombosis	Arteriovenous malformation
Lupus anticoagulant	Saccular aneurysm
Antiphospholipid antibodies	Angioma
Thrombophilias	Cocaine, methamphetamines
Migraine	Vasculopathy
Paradoxical embolus	
Cardioembolic	
Sickle hemoglobinopathy	
Arterial dissection	
Vasculitis	
Moyamoya disease	
Cocaine, amphetamines	

From Smith, 2018; Yager, 2012; Zofkie, 2018.

These underlie up to a third of ischemic strokes in otherwise healthy young women.

With a thorough evaluation, most causes of embolism can be identified. Some of these include cardiac-associated embolism, vasculitis, or vasculopathy such as Moyamoya disease (Miyakoshi, 2009; Pacheco, 2019). Outcomes of embolic strokes are reported to be favorable and similar to those of nonpregnant women (Leffert, 2016). For some, thrombolysis for ischemic stroke during pregnancy should be considered (Pacheco, 2019). However, published experiences are sparse (Ryman, 2019). For some, mechanical thrombectomy can be used.

Preeclampsia Syndrome

In reproductive-age women, a significant proportion of pregnancy-related ischemic strokes are caused by gestational hypertension and preeclampsia (Miller, 2020; Zofkie, 2018). As shown in Figure 63-2, areas of subcortical edema and petechial hemorrhage may progress to cerebral infarction (Aukes, 2007, 2009; Zeeman, 2004a). Although these usually clinically manifest by an eclamptic convulsion, a few women will suffer a symptomatic stroke from a larger cortical infarction (Chap. 40, p. 700).

Other conditions with findings similar to preeclampsia are *thrombotic microangiopathies* (Chap. 59, p. 1060) and the *reversible cerebral vasoconstriction syndrome* (Chap. 40, p. 700). The latter, also termed *postpartum angiopathy*, can cause extensive cerebral edema, necrosis and widespread infarction, and areas of hemorrhage (Edlow, 2013; Miller, 2016).

Cerebral Embolism

These strokes usually involve the middle cerebral artery (see Fig. 63-2). The diagnosis can be made with confidence only after thrombosis and hemorrhage are excluded and is more certain if an embolic source is identified. Hemorrhage may be more difficult to exclude because both embolization and thrombosis can be followed by hemorrhagic infarction. Paradoxical embolism is an uncommon cause, even considering that more than a fourth of adults have a patent foramen ovale. Through the defect, right-sided venous thromboemboli are deported (Scott, 2012). Foraminal closure may not improve outcomes in these patients, however, this procedure has been performed during pregnancy (Dark, 2011). Assorted cardioembolic causes of stroke include arrhythmias—especially atrial fibrillation, valvular lesions, mitral valve prolapse, mural thrombus, infective endocarditis, and peripartum cardiomyopathy.

Management of embolic stroke in pregnancy consists of supportive measures and antiplatelet therapy. Thrombolytic therapy and anticoagulation in pregnancy are controversial (Li, 2012).

Cerebral Artery Thrombosis

Most thrombotic strokes affect older individuals and are caused by atherosclerosis, especially of the internal carotid artery. Many are preceded by one or more TIAs. Thrombolytic therapy with a recombinant tissue plasminogen activator (rtPA) is recommended. Alteplase is one of these. It is given intravenously within the first 3-hour window if neurological deficits are noted and if neuroimaging has excluded hemorrhage (Pacheco, 2019). A principal risk is hemorrhagic transformation of an ischemic stroke. This agent can be used in pregnancy, but published experiences of rtPA in this group are few (Ryman, 2019).

Cerebral Venous Thrombosis

In one study in the United States, 6 percent of cerebral venous thromboses were associated with pregnancy (Leavell, 2018). However, in more than 8 million deliveries from the Nationwide Inpatient Sample, cerebral venous thrombosis caused only 2 percent of pregnancy-related strokes (James, 2005). Predisposing causes are numerous, and for gravidas, late pregnancy and the puerperium are times of greatest risk (Silvis, 2019).

Thrombosis of the lateral or superior sagittal venous sinus usually occurs in the puerperium and often in association with preeclampsia, sepsis, or thrombophilia (see Fig. 63-2). It is more common in patients with inherited thrombophilias or antiphospholipid antibodies. Headache is the most frequent presenting symptom, neurological deficits are common, and up to a third of women have seizures (Pacheco, 2019). Oh and colleagues (2020) described a postpartum case in which cerebral vein thrombosis was misdiagnosed as postdural puncture headache. The diagnosis is made using MR venography.

Management includes anticonvulsants for seizures, and anticoagulation with heparin (Pacheco, 2019; Smith, 2018). Antimicrobials are given for septic thrombophlebitis, and fibrinolytic therapy is reserved for those women failing systemic anticoagulation. The acute prognosis for venous thrombosis in gravidas is better than in nonpregnant subjects, and mortality rates are <10 percent (McCau11ey, 2011).

In women with a prior cerebral venous thrombosis, one systematic review found only one recurrence in 217 pregnancies and five noncerebral venous thrombotic events in 186 pregnancies (Aguiar de Sousa, 2016). In a study of 52 women on prophylactic anticoagulation with prior cerebral venous thrombosis, recurrent thrombosis or bleeding did not develop. However, 24 percent had late obstetrical complications (Martinelli, 2016).

Ischemic Stroke Recurrence

Women with prior ischemic stroke have a low risk for recurrence during a subsequent pregnancy unless a specific, persistent cause is identified. During a 5-year follow-up of 441 reproductive-aged women with prior ischemic stroke or cerebral venous thrombosis, 13 had a recurrent ischemic stroke, and only two were associated with pregnancy. The authors concluded that the risk of stroke recurrence is low and a previous ischemic stroke is not a contraindication to pregnancy (Lamy, 2000). In one study of nonpregnant women, the ischemic stroke recurrence rate was similar between those with and without antiphospholipid antibodies as long as the former received warfarin or aspirin (Levine, 2004). The recurrence rate of reversible cerebral vasoconstriction syndrome in a subsequent pregnancy was noted to be 9 percent (Boitet, 2019).

Currently, no firm guidelines define prophylaxis in pregnant women with a stroke history (Smith, 2018). The American Heart Association stresses the importance of controlling risk factors such as hypertension and diabetes (Furie, 2011). As discussed in Chapters 52 and 55, those with antiphospholipid syndrome or certain cardiac conditions should be considered for prophylactic anticoagulation. For most of these

women, low-dose aspirin given throughout pregnancy seems reasonable.

Hemorrhagic Stroke

Intracerebral Hemorrhage

The symptoms of a hemorrhagic stroke are similar to those of an ischemic stroke, and their differentiation is possible only with CT or MR imaging (Hemphill, 2015; Smith, 2018). The two distinct categories of spontaneous intracranial bleeding are subarachnoid hemorrhage and intracerebral hemorrhage.

Intracerebral hemorrhage is bleeding into the brain parenchyma. It most often stems from the spontaneous rupture of Charcot-Bouchard aneurysms of small vessels damaged by chronic hypertension (see Fig. 63-2). Thus, pregnancy-associated hemorrhagic strokes such as the one shown in Figure 63-3 are often associated with chronic hypertension and superimposed preeclampsia (Cunningham, 2005; Martin, 2005). Because of its location, this type of hemorrhage has much higher morbidity and mortality rates than subarachnoid hemorrhage (Smith, 2018). Pressure-induced rupture causes bleeding into the putamen, thalamus, adjacent white matter, pons, and cerebellum. In the 28 women described by Martin and associates (2005), half died and most survivors had permanent disabilities. This underscores proper management of gestational hypertension, especially systolic hypertension.

Subarachnoid Hemorrhage

In a study of 639 cases of pregnancy-related subarachnoid hemorrhage from the Nationwide Inpatient Sample, the incidence was 8.5 per 100,000 pregnancies (Limaye, 2019). A remarkably similar incidence was reported in Japanese women (Yoshida, 2017). These bleeding events are more likely caused by an underlying cerebrovascular malformation in an otherwise normal patient (see Fig. 63-2). Ruptured saccular or "berry" aneurysms cause 80 percent of all subarachnoid hemorrhages (Lawton, 2017). The remaining cases stem from a ruptured AVM, coagulopathy, angiopathy, venous thrombosis, infection, drug abuse, tumors, or trauma. The mortality rate of subarachnoid hemorrhage during pregnancy is lower than that reported for nonpregnant women—8 versus 17 percent (Limaye, 2019).

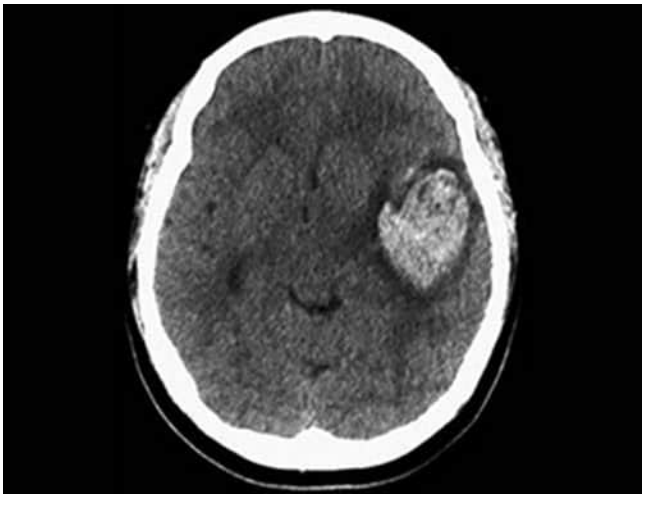

FIGURE 63-3 A noncontrast computed tomography axial head image demonstrates a large intraparenchymal hemorrhage in this woman with preeclampsia.

Intracranial Aneurysm. Approximately 1 to 2 percent of adults have this lesion (Lawton, 2017). Only a small percentage rupture. The rate approximates 0.1 percent for aneurysms <10 mm and 1 percent for those >10 mm (Smith, 2018). Most aneurysms identified during pregnancy arise from the circle of Willis, and in 20 percent of cases, lesions are multiple. Pregnancy does not raise the risk for aneurysmal rupture. However, because of their high population prevalence, they are more likely to cause subarachnoid bleeding than other etiologies (Hirsch, 2009; Tiel Groenestege, 2009). A systematic review of 44 women with 50 aneurysms in pregnancy reported that 72 percent ruptured during pregnancy, and 78 percent of these did so during the third trimester (Barbarite, 2016). This proclivity for rupture late in pregnancy is reported by others (Yoshida, 2017).

The cardinal symptom of aneurysmal rupture leading to subarachnoid hemorrhage is sudden severe headache that is accompanied by visual changes, cranial nerve abnormalities, focal neurological deficits, and altered consciousness. Signs of meningeal irritation, nausea and vomiting, tachycardia, transient hypertension, low-grade fever, leukocytosis, and proteinuria are typical. Prompt diagnosis and treatment may prevent potentially lethal complications. The American Heart Association recommends noncontrast cranial CT imaging as the first diagnostic test, although MR imaging may be superior (Smith, 2018).

Treatment of subarachnoid hemorrhage includes bed rest, analgesia, neurological monitoring, and strict blood pressure control. Repair of a potentially accessible aneurysm during pregnancy weighs surgical risks against the risk of recurrent hemorrhage. At least in nonpregnant patients, the risk of subsequent bleeding with conservative treatment is 20 to 30 percent for the first month and then 3 percent per year. The risk of rebleeding is highest within the first 24 hours, and recurrent hemorrhage leads to death in 70 percent (Smith, 2018).

Early repair after the sentinel hemorrhage is accomplished by open craniotomy or endovascular coil placement. In one systematic review of management in pregnancy, coil embolization yielded lower complication rates than aneurysmal clipping (Barbarite, 2016). For unruptured aneurysms, surgical management resulted in a third fewer complications than no treatment. For gravidas remote from term, repair without hypotensive anesthesia seems optimal. For women near term, cesarean delivery followed by aneurysm repair is a consideration. We have successfully done this in several cases.

For aneurysms repaired before or during pregnancy, most allow vaginal delivery if labor ensues remote from aneurysmal repair. Problems arise in defining "remote," and although some recommend 2 months, the time for complete healing is unknown. For women who survive subarachnoid hemorrhage, but in whom surgical repair is not done, we agree with Cartlidge (2000) and recommend against bearing down and favor cesarean delivery.

Arteriovenous Malformations. These are congenital focal abnormal conglomerations of dilated arteries and veins with subarteriolar disorganization (see Fig. 63-2). They

lack capillaries and have resultant arteriovenous shunting. Although unclear, the risk of bleeding during pregnancy may rise with gestational age. When AVMs bleed, half do so into the subarachnoid space, whereas half are intraparenchymal with subarachnoid extension (Smith, 2018). Uncommon, they affect an estimated 0.01 percent of the general population. Of identified AVM cases in pregnancy, 83 percent ruptured during pregnancy or postpartum, and more than 80 percent of these ruptured in the second or third trimester. Hemorrhage is associated with poor maternal outcome but does not appear to be more likely during pregnancy. (Lu, 2016). Although correspondingly rare during pregnancy, AVM bleeding accounted for 17 percent of hemorrhagic strokes in one study (Yoshida, 2017). At Parkland Hospital in a 35-year period and nearly 500,000 births, 62 women had a stroke, and five of these were due to a bleeding AVM (Simolke, 1991; Zofkie, 2018).

Treatment of AVMs in nonpregnant patients is individualized. No consensus guides whether all accessible lesions should be resected. Factors include AVM symptoms; its anatomy and size; an associated aneurysm, which is found in up to 60 percent of cases; and especially, prior AVM bleeding. After hemorrhage, the risk of recurrent bleeding in unrepaired lesions is 6 to 20 percent within the first year, and 2 to 4 percent per year thereafter (Friedlander, 2007; Smith, 2018). The mortality rate from a bleeding AVM is 10 to 20 percent. In pregnancy, the decision to operate is usually based on neurosurgical considerations. Because of the high risk of recurrent hemorrhage from an unresected or inoperable lesion, we favor cesarean delivery.

DEMYELINATING OR DEGENERATIVE DISEASES

The demyelinating diseases are neurological disorders characterized by immune-mediated focal or patchy destruction of myelin sheaths accompanied by an inflammatory response. The degenerative diseases are multifactorial and characterized by progressive neuronal death.

Multiple Sclerosis

This autoimmune demyelinating disease is second only to trauma as a cause of neurological disability in middle adulthood. The demyelinating effects stem predominantly from T cell–mediated autoimmune destruction of oligodendrocytes that synthesize myelin. It has a familial occurrence with an environmental trigger, it affects women twice as often as men, and it usually begins in the 20s and 30s (Cree, 2018; Fang, 2020). In one study, 0.03 percent of California deliveries were complicated by multiple sclerosis (MS) between 2001 and 2009 (Fong, 2018).

There are three clinical types of multiple sclerosis:

1. *Relapsing MS (RMS)* is the initial presentation in 90 percent of affected individuals. With it, unpredictable recurrent episodes of focal or multifocal neurological dysfunction usually are followed by full recovery. Over time, however, relapses lead to persistent deficits.
2. *Secondary progressive MS (SPMS)* is relapsing disease that begins to pursue a progressive downhill course after each relapse. All patients likely develop this type eventually.
3. *Primary progressive MS (PPMS)* accounts for 10 percent of cases. With it, disability gradually progresses from the time of initial diagnosis.

Classic findings of MS include sensory loss, visual symptoms from optic neuritis, weakness, and paresthesias. Clinical diagnosis is aided by MR imaging and cerebrospinal fluid analysis. In greater than 95 percent of cases, MR imaging shows characteristic multifocal white-matter plaques that represent discrete areas of demyelination (Fig. 63-4). Their appearance and extent are less helpful for predicting treatment response.

Formerly considered an MS variant, neuromyelitis optica spectrum disorder (NMOSD) is viewed as a distinct autoimmune disease. Antibodies target astrocytes and lead to autoimmune inflammation of the spinal cord and optic nerve. Some evidence suggests that pregnancy worsens this disorder (Mao-Draayer, 2020).

Multiple Sclerosis in Pregnancy

Women with MS experience fewer attacks during pregnancy, but with a significantly greater relapse rate postpartum (Cree, 2018). This may be related to higher pregnancy-induced numbers of T-helper lymphocytes and an increased T2/Tl ratio. In a metaanalysis of women with more than 1200 pregnancies complicated by MS, their relapse rate was 0.4 per year before pregnancy; 0.26 per year during pregnancy; and 0.7 per year after delivery (Finkelsztejn, 2011). A systematic review reported similar findings (Bove, 2014). Factors associated with postpartum relapse include a high relapse rate before pregnancy, relapses during pregnancy, and a high MS disability score (Portaccio, 2014). Breastfeeding has no effect on postpartum relapses (Hellwig, 2015; Portaccio, 2011).

With uncomplicated disease, pregnancy outcomes are usually not adversely affected (Bove, 2014; Fong, 2018). Some women

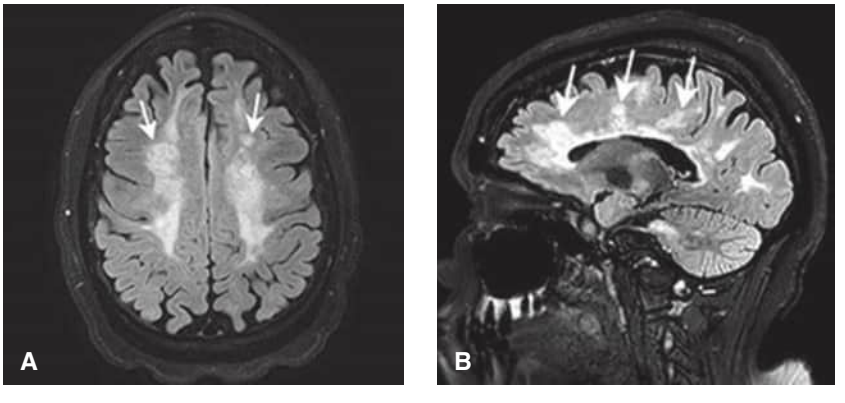

FIGURE 63-4 Magnetic resonance cranial images from a woman with multiple sclerosis. **A.** T2-weighted axial image shows bright signal abnormalities in white matter (*arrows*), typical for multiple sclerosis. **B.** Sagittal T2-FLAIR image shows periventricular hyperintense lesions (Dawson fingers; *arrows*) representative of demyelination in multiple sclerosis.

may fatigue more easily, those with bladder dysfunction are predisposed to urinary infection, and women with spinal lesions at or above T_6 are at risk for autonomic dysreflexia. In one study of 449 pregnancies in affected women, the labor induction rate was higher, and second-stage labor was longer (Dahl, 2006). The greater induction rate and elective operations contributed to the overall higher cesarean delivery rate. In an analysis of 649 affected women, the mean birthweight was lower, but the perinatal mortality rate was similar to controls (Dahl, 2005). In a study of 3875 pregnancies in women with MS, risks for infections and preterm delivery were increased (MacDonald, 2019).

Management

Goals in pregnancy are to arrest acute or initial attacks, employ disease-modifying agents, and provide symptomatic relief. Some treatments may require modification during pregnancy. Acute or initial attacks are treated with high-dose intravenous methylprednisolone—500 to 1000 mg daily for 3 to 5 days. This is followed by oral prednisone for 2 weeks. Plasma exchange may help those with fulminant attacks resistant to corticosteroid therapy. Symptomatic relief can be provided by analgesics. Carbamazepine, phenytoin, or amitriptyline are suitable after the first trimester for neurogenic pain; baclofen, for spasticity; α_1-adrenergic blocking agents, for bladder neck relaxation; and cholinergic and anticholinergic drugs, for bladder-contraction stimulation or inhibition, respectively.

Several disease-modifying therapies are now available to treat relapsing MS or for exacerbations. Examples include interferons, glatiramer, fingolimod, dimethyl fumarate, natalizumab, and ocrelizumab (Cree, 2018; Tintore, 2019). Data regarding their safety in pregnancy are limited (Briggs, 2022). In 246 women with MS, glatiramer was not teratogenic to their offspring (Herbstritt, 2016). In a review of 92 pregnancies, first-trimester natalizumab exposure was associated with an increased miscarriage risk (Portaccio, 2018). Fetal exposure in 89 pregnancies to fingolimod was associated with six fetal malformations and nine spontaneous losses. Because of this and associated animal teratogenicity, its use in pregnancy is not recommended. Due to its prolonged persistence, contraception is recommended for 2 months after fingolimod cessation (Alroughani, 2016). Last, prevention of relapses postpartum has been reported with intravenous immunoglobulin (IVIG). A dose of 0.4 g/kg is given daily for 5 days during weeks 1, 6, and 12 (Argyriou, 2008).

Myasthenia Gravis

This autoimmune-mediated neuromuscular disorder is more common in women, and its incidence peaks in their 20s and 30s (Waters, 2019). The etiology is unknown, but genetic factors likely play a role. Of affected patients, 80 to 90 percent demonstrate antibodies to the acetylcholine receptor (Lee, 2019). Those that are seronegative often have antibodies to muscle-specific tyrosine kinase (MuSK), which regulates assembly of the acetylcholine receptor subunits at the neuromuscular junction.

Cardinal features of myasthenia are weakness and easy fatigability of facial, oropharyngeal, extraocular, and limb muscles. Deep-tendon reflexes are preserved. Cranial muscles are involved early and disparately, and diplopia and ptosis are common. Facial muscle weakness causes difficulty in smiling, chewing, and speaking. In 85 percent of patients, the weakness becomes generalized. Other autoimmune diseases may coexist, and hypothyroidism should be excluded. The clinical course is marked by exacerbations. These can be life threatening and include *myasthenic crises*, which are characterized by severe muscle weakness, inability to swallow, and respiratory muscle paralysis (Lee, 2019). Another is a *cholinergic crisis*, which is caused by excessive cholinergic medication and leads to nausea, vomiting, muscle weakness, abdominal pain, and diarrhea.

Management

Myasthenia gravis is manageable but not curable. The oral anticholinesterase pyridostigmine (Mestinon) is first-line treatment. Thymectomy is recommended but postponed until after pregnancy (Amato, 2018a; Wolfe, 2019). Anticholinesterase medications improve symptoms by impeding acetylcholine degradation but seldom produce normal muscle function. Ironically, overdose is manifest by the cholinergic crisis mentioned earlier and may be difficult to differentiate from myasthenic symptoms. Most gravidas refractory to anticholinesterase therapy respond to immunosuppressive therapy with glucocorticoids, azathioprine, or cyclosporine. When short-term, rapid improvement is needed—such as for a surgical procedure or a myasthenic crisis—high-dose IVIG or plasma exchange is usually effective (Amato, 2018a; Sanders, 2016).

Myasthenia Gravis and Pregnancy

The greatest period of risk is within the first year following diagnosis. Thus, postponing pregnancy until improvement is sustained is reasonable. Antepartum management of myasthenia gravis includes close observation, liberal rest, and prompt treatment of infection (Waters, 2019). Women in remission who become pregnant while taking corticosteroids or azathioprine should continue these. Acute onset or exacerbation of myasthenia gravis demands prompt hospitalization and supportive care. Plasmapheresis and high-dose IVIG are options for emergencies (Waters, 2019). In refractory cases, thymectomy has been successfully performed during pregnancy.

Although pregnancy does not appear to affect the overall course of myasthenia gravis, fatigue common to most pregnancies may be exacerbated, and the expanding uterus may compromise respiration. Maternal hypotension or hypovolemia are ideally avoided because they can trigger crises. The clinical course of myasthenia gravis during pregnancy is unpredictable, and frequent hospitalizations are the norm. Up to a third of women have worsening symptoms during pregnancy, and exacerbations develop equally in all three trimesters (Djelmis, 2002; Podciechowski, 2005). In women with stable disease, most will remain stable throughout pregnancy but likely worsen in the first few months postpartum (Sanders, 2016).

Myasthenia gravis has no significant adverse effects on pregnancy outcomes (Wen, 2009). Preeclampsia is a concern because magnesium sulfate may precipitate a severe myasthenia crisis (Hamaoui, 2009; Heaney, 2010). Although phenytoin use also is problematic in this regard, its adverse effects are less troublesome.

Because smooth muscle is unaffected, most women have normal labor. Oxytocin is given for the usual indications, and cesarean delivery is reserved for obstetrical indications. Narcotics may cause respiratory depression, and close observation and respiratory support are essential during labor and delivery. Curariform drugs are avoided. Examples include magnesium sulfate, muscle relaxants used with general anesthesia, and aminoglycosides. Neuraxial analgesia is accomplished with amide-type local agents. Regional analgesia is preferred unless bulbar involvement or respiratory compromise is significant (Almeida, 2010; Blichfeldt-Lauridsen, 2012). During second-stage labor, some women may have impaired voluntary expulsive efforts that may warrant operative vaginal delivery.

Neonatal Effects

As discussed, 80 percent of mothers with myasthenia gravis have immunoglobulin G (IgG) antibodies against the acetylcholine receptor. These and anti-MuSK antibodies cross transplacentally, and the fetus can be affected. Poor fetal swallowing may yield hydramnios (Heaney, 2010). Similarly, 10 to 20 percent of neonates manifest myasthenia symptoms (Jovandaric, 2016). Transient symptoms usually include a feeble cry, poor suckling, and respiratory distress. Symptoms usually respond to anticholinesterase agents and resolve within a few weeks as maternal IgG antibodies clear.

NEUROPATHIES

Peripheral neuropathy is a general term for peripheral nerve(s) disorders, in which one or more nerves are affected. *Mononeuropathies* are relatively common in pregnancy and signify focal involvement of a single nerve trunk. These imply local causation such as trauma, compression, or entrapment. For example, traumatic pudendal, obturator, femoral, and common fibular mononeuropathies can stem from childbirth (Chap. 36, p. 644). *Polyneuropathies* can be axonal or demyelinating and can be acute, subacute, or chronic (Amato, 2018b). These are often associated with systemic diseases such as diabetes, with drug or environmental toxin exposure, or with genetic disease. Late-stage syphilis is a rare cause (Ghanem, 2020).

■ Guillain–Barré Syndrome

In 75 percent of cases, this acute demyelinating polyradiculoneuropathy has clinical or serological evidence of an acute infection. Common associated infections are *Campylobacter jejuni*, cytomegalovirus, Zika virus, and Epstein-Barr virus; surgical procedures; and immunizations (Leonhard, 2019). Guillain–Barré syndrome is thought to be immune-mediated from antibodies formed against nonself antigens. Demyelination causes sensory and motor conduction blockade, and remyelination yields recovery in most cases.

Clinical features include an areflexic, ascending paralysis, with or without sensory disturbances. Autonomic dysfunction is common. The full syndrome develops over 1 to 3 weeks. Some manifest as chronic inflammatory demyelinating polyneuropathy, and our experiences indicate that this may be relatively common in these young women.

Guillain-Barré syndrome is not more common in pregnancy, and its clinical course mirrors that for nonpregnant individuals. After an insidious onset, paresis and paralysis most often continue to ascend to cause ventilatory weakness.

Management is supportive and incorporates venous thromboembolism prophylaxis, pressure ulcer prevention, and enteral nutrition. In the worsening phase, patients are hospitalized, and a fourth require ventilatory assistance. IVIG or plasmapheresis are beneficial if begun within 1 to 2 weeks of motor symptoms, but neither decreases mortality rates (Leonhard, 2019). Up to 10 percent of patients deteriorate after initial improvement on therapy, and re-treatment with 2 g/kg IVIG over 5 days is recommended. Although most patients recover fully within several months to a year, the mortality rate is 5 percent, mainly due to pulmonary complications and arrhythmias (Pacheco, 2016).

■ Bell Palsy

This disfiguring palsy is usually a mononeuropathic acute facial paralysis that is relatively common in reproductive-aged women (Fig. 63-5). It has a female predominance, and rates in pregnancy may be increased (Beal, 2018; Choi, 2020). The disease is characterized by facial nerve inflammation and often is associated with reactivation of herpes simplex virus or herpes zoster virus. Other causes are Lyme disease and borreliosis.

Bell palsy usually has an abrupt and painful onset with maximum weakness by 48 hours. In some cases, hyperacusis and loss of taste accompany paralysis (Beal, 2018). Management includes supportive care with facial muscle massage and eye protection against corneal injury from drying. Consensus supports that prednisone, 1 mg/kg given orally daily for 5 days, will improve outcomes and shorten the recovery period (Beal, 2018; Madhok, 2016). It is controversial whether added valacyclovir or acyclovir will hasten recovery (Beal, 2018; Gagyor, 2019).

It is unclear if pregnancy alters the prognosis for spontaneous facial palsy recovery. In one study, compared with 90 percent of nonpregnant women and men, only half of pregnant women recovered to a satisfactory level after 1 year (Gillman,

FIGURE 63-5 Bell facial nerve palsy developing on the day of cesarean delivery for dichorionic twins. This woman was treated with prednisone and antiviral medication, and 3 weeks postpartum, the palsy had almost resolved.

2002). In another report, pregnancy-associated Bell palsy had worse long-term outcomes compared with those of nonpregnant cohort (Phillips, 2017). Some prognostic markers for incomplete recovery are bilateral palsy, recurrence in a subsequent pregnancy, greater percentage of nerve function loss, and a faster rate of loss (Cohen, 2000; Gilden, 2004). Other than a fivefold greater rate for gestational hypertension or preeclampsia, women with Bell palsy do not have increased adverse pregnancy outcomes rates (Katz, 2011).

Carpal Tunnel Syndrome

This syndrome results from compression of the median nerve and is the most frequent mononeuropathy in pregnancy (Oliveira, 2019). Symptoms include burning, numbness, or tingling along the inner half of one or both hands. Others are wrist pain and numbness extending into the forearm and sometimes into the shoulder. Symptoms are bilateral in 80 percent of gravidas, and 10 percent have evidence for severe denervation. Differential diagnosis includes cervical radiculopathy of C_6–C_7 and de Quervain tendonitis. The latter is caused by swelling of the conjoined tendons and their sheaths near the distal radius. Nerve conduction studies may help to clarify.

In pregnancy, the reported incidence of carpal tunnel syndrome is 7 to 43 percent and varies greatly because the range of symptoms is marked (Meems, 2015; Oliveira, 2019). Symptomatic treatment with a splint applied to a slightly flexed wrist during sleep lightens pressure and usually provides relief. Although symptoms typically are self-limited, occasionally surgical decompression and corticosteroid injections are necessary (Keith, 2009; Shi, 2011). Symptoms may persist in more than half of patients at 1 year and in a third at 3 years (Padua, 2010).

Meralgia paresthetica is another common pregnancy-induced compression neuropathy (Gooding, 2020). Compression of the lateral femoral cutaneous nerve creates pain, burning, and numbness on the outside of the thigh. For treatment, the site at which the nerve crosses the crease in the groin can be injected with corticosteroids. Oral gabapentin is another treatment.

SPINAL CORD INJURY

According to the National Spinal Cord Injury Statistical Center (2021), approximately 18,000 new spinal cord injuries are sustained each year. The average age is 42 years, and males account for 80 percent of new cases. Cord injury severity determines the short- and long-term prognosis and pregnancy prognosis. For women, many have altered sexual function and transient hypothalamic pituitary hypogonadism. Despite this, pregnancy is not uncommon, and in a review of nearly 2000 women, 2 percent reported pregnancy in the prior 12 months (Lezzoni, 2015).

Two serious and life-threatening events can complicate spinal cord injuries. First, if the cord is transected above T_{10}, the cough reflex is impaired, respiratory function may be compromised, and pneumonitis from covert aspiration can be serious. Pulmonary function tests are considered to assess this risk, and some women may need ventilatory support in late pregnancy or labor.

Second, women with lesions above T_5–T_6 are at risk for autonomic dysreflexia. With this, stimuli from structures innervated below the level of the spinal lesion lead to massive, disordered sympathetic stimulation. Abrupt catecholamine release can prompt vasoconstriction with severe hypertension and symptoms that include throbbing headaches, facial flushing, sweating, bradycardia, tachycardia, arrhythmias, and respiratory distress. Dysreflexia can be precipitated by various stimuli. These include distention or manipulation of reproductive tract or lower urinary tract organs or bowel (American College of Obstetricians and Gynecologists, 2020; Krassioukov, 2009). In one report, 12 of 15 women at risk for autonomic dysreflexia suffered at least one episode during pregnancy (Westgren, 1993).

Gravidas with spinal cord injury have an increased frequency of other complications. In a review of 37 affected pregnant women, 30 percent had pyelonephritis, 32 percent had lower urinary tract infections, and 9 percent had pressure sores (Le Liepvre, 2017). Two women developed autonomic dysreflexia, which caused cerebral hemorrhage in one. Urinary infections may be related to altered vaginal microbiota (Pires, 2016). Bowel dysfunction causes constipation in more than half, and anemia and pressure-necrosis skin lesions are common.

Vaginal delivery is generally successful (Robertson, 2020). Operative vaginal delivery is frequently necessary. Because uterine contractions are not affected by spinal cord lesions, labor is usually easy, comparatively painless, and at times precipitous. If the lesion is below T_{12}, uterine contractions are felt normally. For lesions above T_{12}, the risk of out-of-hospital delivery is substantial and can be minimized by teaching women to palpate for uterine contractions. This is especially important because up to 20 percent of women deliver preterm (Westgren, 1993). Some recommend tocodynamometry and weekly cervical examinations beginning at 28 to 30 weeks' gestation. Another reasonable option that we frequently employ at Parkland Hospital is elective hospitalization after 36 to 37 weeks. Spinal or epidural analgesia extending to T_{10} prevents autonomic dysreflexia and should be instituted at the start of labor (Kuczkowski, 2006). If severe symptoms are identified before epidural placement, steps are taken to abolish the provoking stimulus. A parenteral antihypertensive agent such as hydralazine or labetalol is given.

IDIOPATHIC INTRACRANIAL HYPERTENSION

Also known as *pseudotumor cerebri*, this disorder is typified by increased intracranial pressure without hydrocephalus. The cause is unknown, but it may result from overproduction or underabsorption of cerebrospinal fluid (CSF), or both. Symptoms include headache in at least 90 percent of cases, visual disturbances such as loss of a visual field or central visual acuity in 70 percent, and commonly occurring papilledema that may be sight-threatening (Heaney, 2010; Kesler, 2013). Other complaints are stiff neck, back pain, pulsatile tinnitus, and cranial nerve palsies (Dinkin, 2019).

The syndrome is often found in young women and is prevalent in those who are obese, who recently gained weight, or both (Fraser, 2011). Along with symptoms, other criteria for diagnosis include elevated intracranial pressure >25 cm H_2O,

normal CSF composition, normal cranial CT or MR imaging findings, papilledema, and no evidence for systemic disease. If papilledema is not present, other criteria are required (Friedman, 2013).

Idiopathic intracranial hypertension is usually self-limited, but long-term vision loss is common (Hatem, 2018). Visual defects can be prevented by lowering the CSF pressure, and agents include acetazolamide to reduce fluid production, furosemide, or topiramate.

Corticosteroids are now rarely used. Surgical intervention is occasionally necessary and is accomplished by either lumboperitoneal shunting of spinal fluid or optic nerve sheath fenestration. Another treatment is stenting of dural venous sinus stenosis (Dinkin, 2019). It is controversial if pregnancy is a risk factor for idiopathic intracranial hypertension. Certainly, symptoms may first appear in pregnancy, and women previously diagnosed may become symptomatic. Symptoms usually develop by midpregnancy, tend to be self-limited, and usually resolve postpartum.

Pregnancy does not alter management. Some recommend serial visual-field testing to forestall permanent vision loss. In a report of 16 pregnant women, visual-field loss developed in four, and it became permanent in one (Huna-Baron, 2002). Visual-field loss is often coincident with the development of papilledema, for which acetazolamide is given. Lee and associates (2005) reported successful treatment of 12 pregnant women. Although outmoded for treatment of nonpregnant individuals, repeated lumbar punctures are generally successful in providing temporary relief throughout pregnancy. In some pregnant women, surgical therapy becomes necessary, including optic nerve sheath fenestration (Thambisetty, 2007).

Pregnancy complications are likely due to associated obesity and not to intracranial hypertension. Rates of adverse maternal and perinatal outcomes are not increased (Kesler, 2013). The route of delivery depends on obstetrical indications, and conduction analgesia is safe (Aly, 2007; Karmaniolou, 2011).

MATERNAL VENTRICULAR SHUNTS

Pregnancies in women with previously placed ventricular shunts for obstructive hydrocephalus usually have satisfactory outcomes. Shunts may be ventriculoperitoneal, ventriculoatrial, or ventriculopleural. Partial obstruction of a shunt is common, especially late in pregnancy (Schiza, 2012). In one report of 17 such pregnancies, neurological complications were reported in 13 (Wisoff, 1991). Findings included headaches in 60 percent, nausea and vomiting in 35 percent, lethargy in 30 percent, and ataxia or gaze paresis, each in 20 percent. Most symptoms respond to conservative management. However, if CT scanning during symptom evaluation discloses acute hydrocephaly, the shunt is tapped or pumped several times daily. In some cases, surgical revision is necessary and may be emergently indicated (Murakami, 2010). Another shunting procedure is placement of an endoscopic third ventriculostomy for hydrocephalus. With this, a small hole is created in the floor of the third ventricle to allow CSF to flow directly into lower cisterns. One report described successful results in five gravidas who underwent endoscopic ventriculostomy (Riffaud, 2006).

Vaginal delivery is preferred in women with shunts, and unless there is a meningomyelocele, conduction analgesia is permitted. Antimicrobial prophylaxis is indicated if the peritoneal cavity is entered for cesarean delivery or puerperal sterilization.

MATERNAL BRAIN DEATH

Brain death is rare in obstetrics, and only a few institutional brain-death policies address pregnancy (Lewis, 2016). Life-support systems and parenteral alimentation for up to 20 weeks while awaiting delivery have been described (Hussein, 2006; Powner, 2003; Reinhold, 2019). Some women were treated with aggressive tocolysis and antimicrobial therapy. In one review of 17 women with persistent vegetative state who were given various levels of support, five women died after delivery, and most of the others remained in their vegetative state (Chiossi, 2006). The ethical, financial, and legal implications, both civil and criminal, that arise from providing or withdrawing such care are profound (Feldman, 2000). In some women, perimortem cesarean delivery is performed.

CHAPTER 64

Psychiatric Disorders

Pregnancy and the puerperium are at times sufficiently stressful to provoke mental illness. Such illness may represent recurrence or exacerbation of a preexisting psychiatric disorder, or it may signal the onset of a new condition. Especially prevalent in pregnancy and the puerperium are depressive and anxiety disorders (Kendig, 2017). Many of these disorders are associated with less prenatal care, substance use, preterm delivery, and other poor obstetrical and neonatal outcomes. In affected gravidas, the postpartum psychiatric illness rate also is higher (Baer, 2016). Last, perinatal mood disorders can adversely hinder the mother-child relationship.

Despite these known risks, obstetrical providers often are reluctant to confront or fail to identify mental health issues during pregnancy. Lyell and colleagues (2012) found that the diagnosis of depression was not documented in nearly half of the records of affected women.

PSYCHOLOGICAL ADJUSTMENTS TO PREGNANCY

Biochemical factors and life stressors can markedly influence mental health and mental illness during the perinatal period (Meltzer-Brody, 2018b). Intuitively, pregnancy exacerbates some coexisting psychological disorders. Namely, a higher risk for mood disorders is linked with pregnancy-related shifts in sex steroid and monoamine neurotransmitter levels, dysfunction of the hypothalamic-pituitary-adrenal axis, thyroid dysfunction, and immune response alterations (Yonkers, 2011). These changes, coupled with familial clustering of depression cases, suggest that a subgroup of women may be at greater risk for developing a unipolar major depressive disorder during pregnancy.

Women respond variably to the stresses of pregnancy. Some express persistent concerns regarding fetal health, child care, lifestyle changes, or fear of childbirth pain. Anxiety, sleep disorders, and functional impairment are common (Romero, 2014; Vythilingum, 2008). The level of perceived stress is significantly higher for women whose fetus is at high risk for a malformation, for those with preterm labor or delivery, and for those with other medical complications (Alder, 2007; Ross, 2006). For example, Hippman and associates (2009) screened for depression in 81 women who had an increased risk for a fetus with aneuploidy. Half of these women had a positive depression screening score, whereas only 2.4 percent of those with a normal pregnancy did so.

Several steps can diminish psychological stress in the event of a poor obstetrical outcome. For example, following a stillbirth, parental contact with the newborn and provision of photographs and other infant memorabilia is encouraged (Gold, 2007). Addressing associated sleep disorders also seems reasonable (Juulia Paavonen, 2017).

The Puerperium

This is a particularly stressful time for women, and risks for mental illness are increased. Up to 15 percent of women develop a nonpsychotic postpartum depressive disorder within 6 months of delivery (Tam, 2007; Yonkers, 2011). Depressive disorders are more likely in women with obstetrical complications such as severe preeclampsia or fetal-growth restriction, especially if associated with early delivery. Prior psychiatric disorders or childhood trauma also raises the risk for postpartum depression (Tebeka, 2021). Instead, some have a psychotic illness following delivery, and half of these manifest as a bipolar disorder.

Importantly, stressors beyond those directly related to the pregnancy also can raise perinatal depression rates. Tarney and colleagues (2015) identified spouse military deployment as a factor for postpartum depression. But, among women with a history of bipolar disorder, these elements play a lesser role in the development of mania or depression (Yonkers, 2011).

Maternity Blues

Also called *postpartum blues*, this is a time-limited period of heightened emotional reactivity experienced by half of women within the first week after parturition. Prevalence estimates for the blues range from 26 to 84 percent depending on diagnostic criteria (O'Hara, 2014). This emotional state generally peaks on the fourth or fifth postpartum day and normalizes by day 10 (O'Keane, 2011).

The predominant mood during the puerperium is happiness, but affected mothers are more emotionally labile. They also may have insomnia, weepiness, depression, anxiety, poor concentration, and irritability. Mothers may be transiently tearful for several hours and then recover completely, only to be tearful again the next day. Supportive treatment is indicated, and affected women are reassured that the dysphoria is transient and most likely due to biochemical changes. They are monitored for development of depression and other severe psychiatric disturbances.

Perinatal Evaluation and Screening

Both the American College of Obstetricians and Gynecologists (2018b) and the United States Preventive Services Task Force now recommend screening at least once during the perinatal period for depression and anxiety (Siu, 2016). Indeed, it has recently been recommended that all obstetrical care providers complete a full assessment of mood and emotional well-being during the comprehensive postpartum visit (American College of Obstetricians and Gynecologists, 2018a). Identification of psychiatric disorders in pregnancy can be challenging because changes in behavior and mood are often attributed to pregnancy. To differentiate these, Yonkers and associates (2011) recommend assessment of cognitive symptoms—for example, loss of concentration. Excessive anxiety and insomnia—even during periods of infant sleep—also can suggest postpartum depression. Specific factors for depression are reviewed and include a prior personal or family history of depression.

Universal screening programs for depression continue to evolve (Venkatesh, 2016). One major step forward is state-level support for screening. Beginning July 1, 2018, mothers who take newborns for Texas Health Steps routine examination are able to receive testing and counseling (Texas Health and Human Services, 2019). At Parkland Hospital, mental illness screening is completed at the first prenatal visit using a brief risk-based query and again postpartum using a recognized screening tool for postpartum depression. Questions search for psychiatric disorders, related therapy, prior or current use of psychoactive medications, and current symptoms. Women with a history of sexual, physical, or verbal abuse; illicit substance use; and personality disorders are also at greater risk for depression (Meltzer-Brody, 2014). Smoking and nicotine dependence and obesity also raise rates of *all* mental disorders in pregnancy (Molyneaux, 2014). Last, because eating disorders may be exacerbated by pregnancy, affected women are followed closely (p. 1149).

Several screening instruments shown in Table 64-1 are available and have been validated for use during pregnancy and the puerperium (Bhat, 2017). Use of one of these is encouraged because symptom- or risk-based screening alone may be insufficient. Cerimele and colleagues (2013) found that obstetrician-gynecologists failed to identify 60 percent of depressed women in clinical practice. In one study at Parkland Hospital, 17,000 women were screened during their first postpartum visit using the Edinburgh Postnatal Depression Scale (EPDS). Of these, 6 percent had scores that indicated either minor or major depressive symptoms, and 12 women had thoughts of self-harm (Nelson, 2013). In another study, Kim and coworkers (2015) assessed suicidal ideation in more than 22,000 women screened

These screening tools are also available in Spanish.

using the EPDS both during pregnancy and postpartum. They found rates of depression as high as 3.4 percent during the puerperium. A small fraction of those with thoughts of self-harm had a credible plan, intent, and means for attempted suicide.

Screening for perinatal depression alone was previously considered insufficient, however, evidence now suggests that screening itself has clinical benefit (American College of Obstetricians and Gynecologists, 2018b). One systematic review of six randomized trials that screened pregnant or postpartum women found that follow-up of these women weeks to months later demonstrated an absolute risk reduction in the depression rate by a range of 2.1 to 9.1 percent (O'Connor, 2016). However, this review included studies with and without treatment components compared with usual care. Another limitation is that four of the six studies did not exclude women previously known to be depressed. Findings from this analysis prompted an interim update by the American College of Obstetricians and Gynecologists (2018b) to state that screening alone can have clinical benefit, although treatment initiation or referral to a mental health care provider offers maximum benefit.

Mechanisms to ensure adequate ensuing care can be problematic. Nelson and associates (2013) found that more than three fourths of the 1106 women with abnormally elevated EPDS scores did not keep their later appointment for more formal psychiatric evaluation. Barriers include access to care, personal perception of depression, and societal stigmata. Women referred to a behavioral health provider located at the same site as their obstetrical care are four times more likely to access treatment than those referred elsewhere (Smith, 2009). To take advantage of this, at Parkland Hospital, mental health counselors also practice at postpartum clinic sites.

Other promising interventions for puerperal depression include home visits, telephone-based peer support, and interpersonal psychotherapy (Dennis, 2013; Lavender, 2013; Yonemoto, 2017). A report from Kaiser Permanente, which describes the benefits and hurdles of system-based perinatal mental health care, provides a glimpse into the possible future of universal perinatal screening and treatment (Avalos, 2016; Flanagan, 2016).

Treatment Considerations

Once a positive mental health screen result is identified, a stage-based response protocol is triggered (Kendig, 2017). In brief, the initial response focuses on maternal and infant safety, and if possible, onsite patient assessment by either a mental health provider or mental health counselor. Integrating on-site assessment and access to counselors quadruples later attendance rates to mental health appointments (Byatt, 2015).

For women with suicidal or homicidal ideation, perinatal care providers first determine a working diagnosis. Second, emergency psychiatric consultation is sought and ambulance transport is implemented if needed. Concurrently, perinatal care and psychiatric teams ideally communicate closely. Last, the patient, her family, and clinical staff are emotionally supported. Appreciation for this issue's significance has grown with the recent national emphasis on maternal mortality. For example, Palladino and associates (2011) found that pregnancy-associated homicide and suicide were significant contributors to maternal mortality in a multistate sample from the National Violent Death Reporting system.

Many psychiatric disorders can be improved with counseling and psychotherapy. In some instances, medications are needed. Shared decision making is employed by patients and their health-care providers. In particular, women taking psychotropic medication are informed of likely side effects. Many of these drugs are discussed in Chapter 8, and some are discussed subsequently.

Pregnancy Outcomes

As noted, maternal psychiatric illness can be linked to untoward outcomes such as preterm birth, low birthweight, and perinatal mortality (Grigoriadis, 2013; Jarde, 2016; Steinberg, 2014). In a study of 16,334 deliveries, a significant association between posttraumatic stress disorder (PTSD) and spontaneous preterm delivery was identified (Shaw, 2014). Domestic abuse—another aforementioned risk factor for perinatal mood disorder—also is linked with adverse perinatal outcomes (Yost, 2005).

CLASSIFICATION OF PSYCHIATRIC DISORDERS

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)* is the most recent version from the American Psychiatric Association (2013). The manual assists in classifying mental disorders and specifies criteria for each diagnosis. It is presumed that correct diagnosis leads to specific treatment.

MOOD DISORDERS

Historically, depressive disorders include major depression—a unipolar disorder—and manic-depression—a bipolar disorder with both manic and depressive episodes. It also includes dysthymia, which is chronic, mild depression.

Major Depression

This is the most common depressive disorder, and the 12-month prevalence of major depressive episodes among adult women is 8.2 percent (Center for Behavioral Health Statistics and Quality, 2015). From 2011 to 2014, 16 percent of women had used an antidepressant in the prior month (Pratt, 2017). The diagnosis is made by identifying symptoms listed in Table 64-2, but very few patients manifest all of these.

Major depression is multifactorial and prompted by genetic and environmental factors. Families of affected individuals often also have members suffering with alcohol abuse and anxiety disorders. Provocative conditions leading to depression include substance abuse, certain medications, other medical disorders, and life events that prompt grief reactions. Although life events can trigger depression, genes influence the response to these events and render the distinction between genetic and environmental factors difficult.

TABLE 64-2. Symptoms of Depressive Illness[a]

Hopelessness and/or pessimism
Persistent sad, anxious, or "empty" feelings
Guilt, worthlessness, and/or helplessness
Irritability, restlessness
Loss of interest in activities once pleasurable, including sex
Fatigue and decreased energy
Difficulty concentrating, remembering details, and making decisions
Insomnia, early-morning wakefulness, or excessive sleeping
Overeating or appetite loss
Thoughts of suicide, suicide attempts
Persistent aches, or pains, headaches, cramps, or digestive problems that do not ease with treatment

[a]Not all patients experience the same symptoms.
From National Institute of Mental Health, 2019.

Pregnancy and Depression

Pregnancy is a major life stressor that can precipitate or exacerbate depressive tendencies. In addition, various pregnancy-induced effects are implicated. Hormones certainly affect mood, as evidenced by premenstrual syndrome and menopausal depression. Estrogen has been linked to enhanced serotonin synthesis, decreased serotonin breakdown, and serotonin-receptor modulation (Deecher, 2008). Concordantly, women who experience postpartum depression often have higher pre-delivery serum estrogen and progesterone levels and experience a greater decline postpartum (Ahokas, 1999).

The prevalence of antenatal depression averaged 11 percent in one Cochrane Database review (Dennis, 2007). In more than 1800 women enrolled for prenatal care at a single clinic, Melville and coworkers (2010) found rates of nearly 10 percent. A higher rate has been seen in those after antepartum complications (Toscano, 2021).

Postpartum Depression

Major or minor depression develops postpartum in 10 to 20 percent of women (Mental Health America, 2019). Postpartum depressive symptoms are associated with young maternal age, antenatal depression, unmarried status, smoking, newborns requiring intensive care, and stressors during pregnancy (Ko, 2017; Silverman, 2017). Specifically, physical or verbal abuse is a potent risk for postpartum depression (McFarlane, 2014). Last, serious adverse obstetrical events, especially those involving the neonate, are strongly linked (Nelson, 2013, 2015).

Depression is frequently recurrent. Up to 70 percent of women with previous postpartum depression have a subsequent episode. Women with both prior puerperal depression and a current episode of "maternity blues" carry an inordinately high risk for major depression. Indeed, 2 to 9 months postpartum, assistance with postpartum depression was the fourth most common challenge identified in women in the Pregnancy Risk Assessment Monitoring System—PRAMS (Kanotra, 2007).

Postpartum depression is generally underrecognized and undertreated. Major depression during pregnancy or after delivery can have devastating consequences for affected women, their children, and families. One of the most significant contributions to the mortality rate among new mothers is suicide, which is most frequent among women with mental illness (Koren, 2012; Palladino, 2011). If left untreated, up to 25 percent of women with postpartum depression will be depressed 1 year later. As the duration of depression increases, so too does the number of sequelae and their severity. Maternal depression during the first weeks and months after delivery can lead to insecure attachment and later behavioral problems in the child (Mezzacappa, 2017; Viktorin, 2017).

Depression Treatment

Therapy for mood disorders during pregnancy and postpartum has evolved. Babbitt (2014) and Pozzi (2014) and their associates have reviewed principles of perinatal care of women with major mental disorders. In general, for mild and mild-moderate depression, psychological treatment options, such as cognitive behavioral therapy, are considered first (Yonkers, 2011). Light- to moderate-intensity exercise may be beneficial (McCurdy, 2017).

Antidepressant medications together with some form of psychotherapy are indicated for moderate to severe depression during pregnancy or the puerperium (American College of Obstetricians and Gynecologists, 2018b). Shown in Figure 64-1 is one algorithm regarding mood disorder treatment. Some of these medications are listed in Table 64-3. For women with severe depression, a selective serotonin-reuptake inhibitor (SSRI) is selected initially. If depressive symptoms improve during a 6-week trial, the medication is continued for a minimum of 6 months to prevent relapse (Wisner, 2002).

If the response is suboptimal or a relapse occurs, another SSRI is substituted, or psychiatric referral is considered. At least 60 percent of women taking antidepressant medication before pregnancy have symptoms during pregnancy. In one study, approximately three fourths of women taking antidepressants before pregnancy stopped taking them before or during early pregnancy (Hayes, 2012). For those who discontinue treatment, almost 70 percent have a relapse compared with approximately 25 percent who continue therapy.

In one metaanalysis, women using antidepressants during pregnancy had higher rates of preterm birth and low-birthweight neonates (Huang, 2014). Some of the included studies failed

TABLE 64-3. Drugs Used for Treatment of Major Mood Disorders in Pregnant Women

Indication	Examples	Comments
Antidepressants		
SSRIs[a]	Citalopram, sertraline, fluoxetine, paroxetine	Some have possible link with heart defects, neonatal withdrawal syndrome, and pulmonary hypertension
Others	Bupropion, duloxetine, nefazodone, venlafaxine	
Tricyclics	Amitriptyline, desipramine, doxepin, imipramine, nortriptyline	No evidence of teratogenicity, not commonly used
Antipsychotics		
Typical	Chlorpromazine, fluphenazine, haloperidol, thiothixene	
Atypical	Aripiprazole, clozapine, olanzapine, risperidone, ziprasidone	
Bipolar Disorders		
Lithium[a]	Lithium carbonate	Manic episodes; teratogenic for cardiac defects (Ebstein anomaly)
Valproic acid[b]		Teratogenic for neural-tube defects
Carbamazepine[b]		Antiepileptic; hydantoin syndrome

to control for the underlying depressive illness (Susser, 2016). Nevertheless, in their review, Ray and Stowe (2014) concluded that the relative reproductive safety data are reassuring and that antidepressants remain a reasonable treatment option. Furthermore, recurrence sometime after medication is discontinued develops in 50 to 85 percent of women with an initial postpartum depressive episode. Surveillance includes monitoring for thoughts of suicide or infanticide, emergence of psychosis, and response to therapy. For some women, the course of illness is severe enough to warrant hospitalization.

Fetal and Neonatal Effects of Therapy. Some known and possible fetal and neonatal effects of treatment are listed in Table 64-3. Some studies suggest that SSRIs pose an elevated teratogenic risk for fetal cardiac defects, and these have mainly focused on paroxetine (Paxil). Associations were most consistent for ventricular septal defects. The estimated risk is no greater than 1 case in 200 exposed newborns (Koren, 2012). Nevertheless, the American College of Obstetricians and Gynecologists (2018b) recommends that paroxetine be avoided in women who are either pregnant or planning pregnancy. In women exposed to paroxetine in the first trimester, fetal echocardiography is considered. In one analysis of SSRIs, exposure to SSRIs during pregnancy and perinatal mortality were not linked (Jimenez-Solem, 2013). Andersen and associates (2014) found that women discontinuing SSRI treatment in early pregnancy had a small increased risk of miscarriage. However, the risk was similar to that in women discontinuing SSRI treatment months before pregnancy. These investigators concluded that treatment with SSRIs during pregnancy should not be discontinued for fear of miscarriage.

Of other potential effects, the risk of persistent pulmonary hypertension of the newborn is sixfold higher in neonates exposed to SSRIs after 20 weeks' gestation (Chambers, 2006). This translates to an overall pulmonary hypertension risk of less than 1 case in 100 exposed newborns (Koren, 2012). A population-based cohort study of 1.6 million pregnancies identified a twofold greater rate in exposed neonates. This yields an estimated attributable risk of 2 cases per 1000 births (Kieler, 2012). In a study of more than 120,000 women prescribed antidepressants, an attributed risk of 1 case per 1000 births was found (Huybrechts, 2015).

The maternal risk associated with discontinuing or tapering SSRI use during pregnancy must be weighed against marginally elevated neonatal risks (Ornoy, 2017). Women who abruptly discontinue either serotonin- or norepinephrine-reuptake inhibitor therapy typically experience some form of withdrawal.

Not surprisingly, up to 30 percent of exposed neonates also may exhibit withdrawal symptoms. Symptoms are similar to opioid withdrawal but typically are less severe. Neonatal SSRI withdrawal is usually self-limited, and the newborn rarely remains in the nursery more than 5 days (Koren, 2009). Recent magnetic resonance imaging studies show brain volume differences in SSRI-exposed fetuses compared with unexposed ones (Lugo-Candelas, 2018). Still, at this time, convincing evidence of long-term neurobehavioral effects of fetal exposure to these medications is lacking (Grzeskowiak, 2016; Man, 2017; Mezzacappa, 2017; Viktorin, 2017).

Some psychotropic medications pass into breast milk. In most cases, however, levels are very low or undetectable. Effects may be transient irritability, sleep disturbances, and colic.

Allopregnanolone. A recent Food and Drug Administration (FDA)-approved therapeutic agent for treatment of postpartum depression is brexanolone, which is an allopregnanolone analogue. Plasma allopregnanolone levels rise in connection with progesterone throughout pregnancy, and after childbirth these concentrations drop abruptly. Failure of gamma-aminobutyric acid type A (GABA-A) receptors to adapt to these changes following delivery is a suggested antecedent to postpartum depression. In small randomized trials, intravenous infusions of brexanolone significantly reduced Hamilton Rating Scale for Depression scores compared with placebo (Kanes, 2017; Meltzer-Brody, 2018a). Treatment is prohibitively expensive, and further studies are needed before its use is widely accepted.

Ketamine. This anesthetic drug is given intravenously for refractory depression, but studies in pregnant or postpartum women are lacking. Similarly, the recent FDA-approved esketamine nasal spray has not been studied in these women.

Electroconvulsive Therapy. This form of depression treatment is occasionally necessary during pregnancy for women with major mood disorders unresponsive to pharmacotherapy. Women undergoing electroconvulsive therapy (ECT) should be fasting for at least 6 hours. They are given a rapid-acting antacid before the procedure, and their airway is protected to decrease the likelihood of aspiration. After midpregnancy, a wedge is placed under the right hip to prevent sudden maternal hypotension from aortocaval compression. Other important preparatory steps include assessment of the cervix, discontinuation of nonessential anticholinergic medication, uterine and fetal heart rate monitoring, and intravenous hydration. During the procedure, excessive hyperventilation is avoided. In most cases, maternal and fetal heart rate and maternal blood pressure and oxygen saturation remain normal throughout the procedure.

With proper preparation, the risks to both mother and fetus appear to be reasonable (Ray-Griffith, 2016). Such therapy is relatively safe in the first trimester (Calaway, 2016). That said, adverse maternal and perinatal outcomes have followed ECT. Balki and associates (2006) reported a pregnancy in which fetal brain damage likely was caused by sustained maternal hypotension associated with treatment of status epilepticus stimulated by ECT.

At least two extensive reviews have evaluated ECT outcomes in pregnancy. In one, Miller (1994) found 300 cases and reported complications in 10 percent. These included fetal arrhythmias, vaginal bleeding, abdominal pain, and self-limited contractions. Women not adequately prepared had higher risks for aspiration, aortocaval compression, and respiratory alkalosis. In another review, Anderson and Reti (2009) described 339 cases, undoubtedly with some homology with the earlier study. In most cases, ECT therapy was done to treat depression, and it was 78-percent effective. They reported a 5-percent maternal ECT-related complication rate. The associated perinatal complication rate was 3 percent and included two fetal deaths.

In sum, we agree with Richards (2007) that ECT in pregnancy is not "low risk" and that it should be reserved for women whose severe depression is resistant to intensive pharmacotherapy.

Suicide

Self-harm is a primary cause of death among women during the perinatal period, and major depression is among the strongest predictors (Melville, 2010). Between 2004 and 2012, self-harm, suicide, or drug overdose was the leading cause of maternal death in Colorado (Metz, 2016). During a similar time period in Ontario, perinatal suicide accounted for 5.3 percent of all maternal deaths (Grigoriadis, 2017). Fetal loss is associated with a three- to fivefold greater risk for suicide (Weng, 2018). And, 54 percent of pregnancy-associated suicides reportedly involved intimate-partner conflict (Palladino, 2011).

Bipolar and Related Disorders

According to the National Institute of Mental Health (2017a), the lifetime prevalence for manic-depression illness is 4.4 percent. The prevalence of bipolar disorder does not vary between gravidas and nonpregnant reproductive-aged women (Yonkers, 2011). It has a strong genetic component and has been linked to possible mutations on chromosomes 16 and 8 (Jones, 2007). The risk that monozygotic twins are both affected is 40 to 70 percent, and the risk for first-degree relatives is 5 to 10 percent (Muller-Oerlinghausen, 2002).

Periods of depression last at least 2 weeks. At other times, patients are manic, in which mood is abnormally raised, expansive, or irritable. Potential organic causes of mania include substance abuse, hyperthyroidism, and central nervous system tumors. These are all excluded during an acute event. Importantly, pregnancy frequently prompts medication discontinuation, which poses a substantially increased risk for relapse. Approximately one third of patients with manic-depression illness will attempt suicide during their lifetime (Novick, 2010).

Bipolar Disorder in Pregnancy

This disorder has also been associated with adverse perinatal outcomes such as preterm birth (Mei-Dan, 2015). Women who experience pregnancy complications are more likely to exhibit periods of mania or depression (Di Florio, 2013). Moreover, symptomatic women during pregnancy more likely have postpartum relapses that can be severe (Taylor, 2018). Women who tend to be manic present with exacerbations earlier in the postpartum period.

Typical therapy for bipolar disorder includes mood stabilizers such as lithium, valproic acid, and carbamazepine and antipsychotic medications (see Table 64-3). Treatment of bipolar disorder in pregnancy is complex and is ideally managed concurrently with a psychiatrist. Decisions include risks versus benefits of mood stabilizers, some of which are teratogenic (Clark, 2018). For example, lithium has been linked to Ebstein anomaly in exposed fetuses. More recent data, however, suggest a lower risk of cardiac malformations than previously indicated (Munk-Olsen, 2018; Patorno, 2017). Nevertheless, many recommend fetal echocardiography for lithium-exposed fetuses. Some limited evidence suggests that lithium in breast milk, when its elimination is impaired as in dehydration or immaturity, can adversely affect the infant (Davanzo, 2011). However, lithium use in mothers with a healthy, term fetus is considered moderately safe. Children born to bipolar women do not appear to suffer long-term adverse effects (Santucci, 2017). A more detailed discussion of other mood stabilizers and antipsychotic medications side effects is found in Chapter 8 (p. 153).

Postpartum Psychosis

This severe mental disorder is usually a bipolar disorder, but it may be due to major depression (American Psychiatric Association, 2013). Its estimated incidence is 1 case in every 1000 deliveries, and it is more common in nulliparas, especially those with obstetrical complications (Bergink, 2016; Tinkelman, 2017). In most cases, illness manifests within 2 weeks of delivery and lasts 2 to 3 months. Because those with underlying psychiatric disease have a 10- to 15-fold risk for recurrence postpartum, close monitoring is recommended.

Women with a history of bipolar disease typically exhibit symptoms within 1 to 2 days after delivery (Heron, 2007, 2008). Manic symptoms include feeling excited or elated, being active or energetic, feeling "chatty," and suffering insomnia. Affected women may display confusion and disorientation but may also have lucid episodes.

Postpartum psychosis has a 50-percent recurrence risk in the next pregnancy. As a result, Bergink and associates (2016) recommend initiating lithium therapy immediately after delivery in women with a history of postpartum psychosis.

The clinical course of bipolar illness with postpartum psychosis is comparable with that for nonpregnant women. Patients usually require hospitalization, pharmacological treatment, and long-term psychiatric care. Psychotic women may have delusions leading to thoughts of self-harm or harm to their infants. Unlike women with nonpsychotic depression, these women commit infanticide, albeit uncommonly (Kim, 2008). In most instances, women with postpartum psychosis ultimately develop relapsing, chronic, psychotic manic-depression.

Anxiety Disorders

The prevalence of anxiety disorder in the prior year among women in the United States is 23 percent (National Institute of Mental Health, 2017b). These relatively common disorders include panic attack, panic disorder, social anxiety disorder, specific phobia, separation anxiety disorder, and generalized anxiety disorder. All are characterized by irrational fear, tension, and worry, which are accompanied by physiological changes such as trembling, nausea, hot or cold flashes, dizziness, dyspnea, insomnia, and frequent urination (Schneier, 2006). They are treated with psychotherapy and medication, which may be an SSRI, tricyclic antidepressant, monoamine oxide inhibitor, or other.

Anxiety Disorders in Pregnancy

Despite the relatively high prevalence in childbearing-aged women, data regarding anxiety disorders in pregnancy are few. Most reports conclude that rates between pregnant

and nonpregnant women do not differ. One analysis of 268 gravidas with generalized anxiety disorder demonstrated that both symptoms and anxiety severity decline across pregnancy (Buist, 2011).

From their review, Thorsness and colleagues (2018) concluded that some of the anxiety disorders may have important maternal-fetal implications. Some researchers, but not all, have linked these disorders to preterm birth, fetal-growth restriction, and poor neurobehavioral development (Yonkers, 2017). Children with a history of in utero exposure to maternal anxiety are felt to be at greater risk for various neuropsychiatric conditions such as attention-deficit/hyperactivity disorder (ADHD).

Anxiety Disorder Treatment

Anxiety disorders can be effectively treated during pregnancy with psychotherapy, cognitive behavioral therapy, or medication (Williams, 2018). Mood and anxiety disorders coexist in more than half of women identified with either diagnosis. Thus, antidepressants—specifically, SSRIs—listed in Table 64-3 are often the first line of pharmacotherapy. As with other medication exposures in pregnancy, choosing a single SSRI agent at the lowest effective dose is preferred.

Benzodiazepines also are commonly used to treat anxiety or panic disorders (Thorsness, 2018). Earlier case-control studies linked their use to a possible increased risk for cleft lip and palate. A metaanalysis of more than 1 million exposed pregnancies, however, did not identify a teratogenic risk (Enato, 2011). Benzodiazepines, especially when taken during the third trimester, can cause neonatal withdrawal syndrome, which persists for days to weeks after delivery. Importantly, benzodiazepines should be avoided in women with current or past history of substance misuse (Thorsness, 2018).

SCHIZOPHRENIA SPECTRUM DISORDERS

This major form of mental illness affects 1.1 percent of adults (National Institute of Mental Health, 2016). Schizophrenia spectrum disorders are defined by abnormalities in one or more of the following domains: delusions, hallucinations, disorganized thinking, grossly disorganized or abnormal motor behavior, and negative symptoms. Brain-scanning techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) show that schizophrenia is a degenerative brain disorder. Subtle anatomical abnormalities are present early in life and worsen with time.

Schizophrenia has a major genetic component, and concordance was 33 percent in monozygotic twins in large database (Hilker, 2018). If one parent has schizophrenia, the risk to offspring is 5 to 10 percent (Rasic, 2014). Some data, including a strong association between schizophrenia and the velocardiofacial syndrome, suggest associated genes. Some cases are related to chromosome 22q11, but sophisticated gene mapping studies clearly show that schizophrenia is not related to a single gene or mutation (Kukshal, 2012). Other putative risks for subsequent schizophrenia in an exposed fetus remain unproven, for example, the association with maternal influenza A infection (Chap. 67, p. 1187).

Signs of illness begin approximately at age 20 years, and work and psychosocial functioning typically deteriorate over time. Women have a slightly later onset than men. Thus, many investigators theorize that estrogen is protective. With appropriate treatment, patients can experience a decline or cessation of symptoms. Within 5 years from the first signs of illness, 60 percent have social recovery, 50 percent are employed, 30 percent are mentally handicapped, and 10 percent require continued hospitalization (American Psychiatric Association, 2013).

■ Schizophrenia in Pregnancy

Most studies have reported no adverse maternal outcomes, although some earlier ones found higher rates of low birthweight, fetal-growth restriction, and preterm delivery. In a study of more than 3000 pregnancies in schizophrenic women, the rate of placental abruption was elevated threefold and that of "fetal distress"—vaguely defined—was increased 1.4-fold (Jablensky, 2005).

Because schizophrenia has a high recurrence rate if medications are discontinued, continued therapy during pregnancy is advised. That said, "typical" antipsychotic drugs listed in Table 64-3 are associated with adverse fetal or maternal sequelae in some, but not all studies (Coughlin, 2015; Robinson, 2012). Because less is known about "atypical" antipsychotics, the American College of Obstetricians and Gynecologists (2018c) recommends against their routine use in pregnant and breastfeeding women. The FDA (2011) issued a safety communication concerning the potential risk for abnormal muscle movements and withdrawal symptoms in newborns of mothers treated with antipsychotic drugs during the third trimester.

EATING DISORDERS

These include *anorexia nervosa*, in which the patient refuses to maintain normal body weight, and *bulimia nervosa*, in which binge eating is usually followed by purging or excessive fasting to maintain normal body weight (American Psychiatric Association, 2013). Eating behavior disturbances largely affect adolescent females and young adults. With anorexia and bulimia, the lifetime prevalence for each is 2 to 3 percent (National Institute of Mental Health, 2016a).

Bulik and coworkers (2009) studied pregnancy outcomes in almost 36,000 Norwegian women screened for eating disorders. Approximately 0.1 percent had anorexia nervosa, 0.85 percent had bulimia nervosa, and 5.1 percent reported a binge-eating disorder. This 6-percent pregnancy prevalence is similar to the 6-month prevalence for nonpregnant individuals (National Institute of Mental Health, 2016a). The last subtype had a higher risk for large-for-gestational age neonates with a concomitantly increased cesarean delivery rate. All eating disorders begin with the desire to be slim, and women with chronic eating disorders may migrate between subtypes (Andersen, 2009).

■ Eating Disorders in Pregnancy

Early pregnancy complication rates are increased with both eating disorders, but especially in women with bulimia nervosa

(Hoffman, 2011). Generally, eating disorder symptoms improve during pregnancy, and remission rates may reach 75 percent. In contrast, a typical case of hyperemesis gravidarum may actually be a new or relapsing case of bulimia nervosa or of binge-purge type anorexia nervosa. As perhaps expected, anorexia is associated with low-birthweight, smaller head circumference, and small-for-gestational-age newborns (Micali, 2016). Children born to these mothers are more likely to have psychopathology at 7 years (Barona, 2016). Additional maternal risks associated with eating disorders include poor wound healing and difficulties with breastfeeding. At a minimum, closely monitoring gestational weight gain in women with a suspected history of an eating disorder seems prudent.

Care for these women involves a multidisciplinary team that includes an obstetrician, mental health provider, and either dietician or nutritionist. Psychological treatment is the cornerstone for treatment in women with eating disorders and frequently includes cognitive behavioral therapy. Anorexia nervosa often responds to motivational interactions with meal planning (Cardwell, 2013). After delivery, women with eating disorders are more prone to postpartum depression. Women with bulimia are at particular risk for disease rebound after delivery because of body image concerns.

SUBSTANCE USE DISORDERS

According to the American Psychiatric Association (2013), substance-related disorders encompass 10 classes of drugs that include caffeine, tobacco, cannabis, hallucinogens, opioids, anxiolytics, and stimulants. Their essential feature is a cluster of cognitive, behavioral, and physiological symptoms indicating that the individual continues to use the substance despite significant related problems. Central to these disorders is an underlying change in brain circuits that may persist beyond detoxification and characterized by repeated relapses.

It is estimated that 10 percent of fetuses are exposed to one or more illicit drugs. Agents may include heroin and other opiates, cocaine, amphetamines, barbiturates, and marijuana (American College of Obstetricians and Gynecologists, 2019). Well-documented sequelae include fetal-growth restriction, low birthweight, and drug withdrawal soon after birth. Adverse effects of marijuana are being delineated with expanding legalization. As noted by Metz and Borgelt (2018), adverse perinatal outcomes associated with marijuana use are especially seen with heavy use. Moreover, later childhood neurobehavioral consequences may follow prenatal exposure. Thus, women are currently advised to refrain from using marijuana during pregnancy and lactation. Women who use such drugs frequently do not seek prenatal care, which in itself is associated with risks for preterm and low-birthweight newborns.

Opioid Use Disorder

These disorders have reached epidemic proportions in the United States. The rates of maternal opioid-related diagnoses at delivery (0.8 percent) and of neonatal abstinence syndrome (0.7 percent) in 2017 in the United States were significantly higher than those in 2010 (Hirai, 2021). Because of this, the American College of Obstetricians and Gynecologists and the American Society of Addiction Medicine (2017) recommend universal screening by questionnaire at the first prenatal visit. Urine drug testing to detect or confirm substance use is performed only with patient consent and in compliance with state laws.

Medication-Assisted Treatment

For women who abuse opioids, *methadone maintenance* can be initiated within a registered treatment program to reduce opioid use complications and narcotic withdrawal, to encourage prenatal care, and to avoid drug culture risks (American College of Obstetricians and Gynecologists, 2017). Buprenorphine also may be offered and managed by physicians with specific credentialing (Boyars, 2018; Jones, 2018). Available programs can be found through the treatment locator of the Substance Abuse and Mental Health Services Administration at www.samhsa.gov. Methadone dosages usually are initiated at 10 to 30 mg daily and titrated as needed. Concomitant chronic use of naloxone with buprenorphine is discouraged given risks of precipitating neonatal withdrawal.

Medically Supervised Withdrawal

In some women, careful *medication-assisted withdrawal* may be an appropriate option. This is controversial because of the relatively high relapse rate, and it is discouraged by the American College of Obstetricians and Gynecologists and the American Society of Addiction Medicine (2017). From their review of more than 600 treated women, Boyars and Guille (2018) caution against this approach but concluded that assisted withdrawal is a reasonable approach. At Parkland Hospital, pregnant opioid users who decline maintenance therapy are offered inpatient hospitalization for controlled methadone taper. The goal is reduction of neonatal opioid withdrawal syndrome rates (Dashe, 2002; Stewart, 2013). In 2017, 69 women who were enrolled in our opioid perinatal intervention program delivered at Parkland Hospital. Of these women, 37 (54 percent) delivered without use of opioids at delivery. Their neonates' median length of stay was 4.5 days, which was significantly shorter than the 23.5 days required for newborns whose mothers were using opioids at delivery.

Neonatal Opioid Withdrawal Syndrome

This is a drug withdrawal syndrome that most commonly follows maternal opioid use. It is discussed in Chapter 33 (p. 605).

POSTTRAUMATIC STRESS DISORDER

This is included in trauma– and stressor–related disorders (American Psychiatric Association, 2013). The essential feature of PTSD is development of characteristic symptoms following exposure to one or more traumatic events. One example in obstetrics is PTSD following hyperemesis gravidarum (Chap. 57, p. 1014). Symptoms may be anxiety or fear but can be anhedonia, dysphoria, or dissociative behavior. According to Yonkers and coworkers (2014), 8 percent of pregnant women have facets of this syndrome. Psychotherapy is one first-line therapy (National Institute of Mental Health, 2019). These

women are also treated with benzodiazepines or antidepressants. Those with concordant major depression are at high risk for preterm birth.

PERSONALITY DISORDERS

These disorders are characterized by the chronic use of certain coping mechanisms in an inappropriate, stereotyped, and maladaptive manner. They are rigid and unyielding personality traits. The American Psychiatric Association (2013) recognizes three clusters of personality disorders:

1. Paranoid, schizoid, and schizotypal personality disorders, which are characterized by oddness or eccentricity.
2. Histrionic, narcissistic, antisocial, and borderline disorders, which are all characterized by dramatic presentations along with self-centeredness and erratic behavior.
3. Avoidant, dependent, compulsive, and passive-aggressive personalities, which are characterized by underlying fear and anxiety.

In the United States, the prevalence of any personality disorder in the past year approximates 9 percent (National Institute of Mental Health, 2017c). Genetic and environmental factors are thought important in their genesis. Psychotherapy is appropriate treatment, but most affected individuals do not recognize their problem, and thus only 20 percent seek help. In an observational study of 202 women with borderline personality disorder, De Genna and associates (2012) noted that affected women become pregnant during the most severe trajectory of their illness. They are at higher risk for adolescent and unintended pregnancies. Notably, Conroy and coworkers (2010) found that a mother's ability to care for her newborn was impaired only when a personality disorder was coupled with depression.

CHAPTER 65

Dermatological Disorders

PREGNANCY-SPECIFIC DERMATOSES

Four dermatoses considered unique to pregnancy are pemphigoid gestationis (PG), pruritic urticarial papules and plaques of pregnancy (PUPPP), atopic eruption of pregnancy (AEP), and intrahepatic cholestasis of pregnancy. Descriptions of these are given in Table 65-1. Their gross appearance can be similar to each other or to other skin disorders, and pruritus is a common feature. Of these four, adverse fetal outcomes are linked only with PG and intrahepatic cholestasis. The latter is discussed in detail in Chapter 58 (p. 1032). It generally lacks primary skin lesions, but pruritus is usually associated with abnormally elevated serum bile acid levels and mildly increased hepatic transaminase levels.

Pemphigoid Gestationis

In this rare autoimmune bullous disease, pruritic papules and urticarial plaques initially form. Vesicles or bullae usually follow after 1 to 2 weeks. Lesions frequently involve umbilicus and other skin surfaces but typically spare mucous membranes, scalp, and face (Fig. 65-1).

Previously termed *herpes gestationis*, PG is not related to the herpesvirus. Instead, maternal immunoglobulin G (IgG) antibodies target collagen XVII found in the basement membrane of skin and amnionic epithelium (Kelly, 1988; Sadik, 2016). Collagen XVII is also termed *bullous pemphigoid 180 (BP180)*. Autoantibody binding to BP180 activates complement to promote eosinophil chemotaxis to the antigen-antibody complexes. Eosinophilic degranulation damages the dermal–epidermal junction and leads to blistering.

Pregnancy

In most cases, PG develops during a first pregnancy. Most subsequent pregnancies also are affected, usually earlier and more severely (Tani, 2015). Additionally, other autoimmune diseases, especially Graves disease, are frequent in affected women (Jenkins, 1999; Shornick, 1992).

PG usually begins during the second or third trimester, but postpartum onset or exacerbation is common (Lawley, 1978). The disease course is often marked by antepartum flares and remissions. In cases with early-onset and blistering, PG can be associated with preterm birth, oligohydramnios, and fetal-growth restriction (Al-Saif, 2016; Chi, 2009; Dabas, 2018). One theory suggests mild placental insufficiency stems from IgG and complement deposition along the amnionic basement membrane (Huilaja, 2013). Thus, surveillance for and management of these complications in affected pregnancies is reasonable.

In 5 to 10 percent of cases, IgG antibodies passively transfer from the mother to cause similar skin lesions in the newborn (Erickson, 2002). These eruptions in the neonate require only wound care and clear spontaneously within a few weeks as the passively acquired IgG levels drop. After delivery, maternal lesions resolve without scarring, and most women are disease-free after 6 months (Jenkins, 1999). In some, however, resolution is protracted. Disease may be exacerbated during menses or by oral contraceptives (Fania, 2017; Semkova, 2009).

Diagnosis and Treatment

Before bullae form, these lesions may resemble PUPPP. Other diagnoses include bullous pemphigoid, pustular psoriasis,

TABLE 65-1. Pregnancy-specific Dermatoses

Disorder	Frequency	Characteristic Lesion	Adverse Pregnancy Effects	Treatment
PUPPP	Common	Erythematous pruritic papules or plaques; patchy or generalized on abdomen, thighs, buttocks, especially within striae, but with umbilical sparing	None	Oral antipruritics, emollients, topical corticosteroids, and if severe, oral steroids
AEP			None	
Eczema in pregnancy	Common	Dry, red scaly patches on extremity flexures, neck, face		
Prurigo of pregnancy	Common	1–5 mm pruritic red papules on extensor surfaces, trunk		
Pruritic folliculitis of pregnancy	Rare	Small red papules, sterile pustules on trunk		
Pemphigoid gestationis	Rare	Erythematous pruritic papules, plaques, vesicles, and bullae; abdomen often with umbilical involvement, extremities	Preterm birth, fetal-growth restriction, transient neonatal lesions	
Cholestasis of pregnancy	Common	No primary lesions, secondary excoriations from scratching	Increased perinatal morbidity	Oral antipruritics, cholestyramine, ursodeoxycholic acid

AEP = atopic eruptions of pregnancy; PUPPP = pruritic urticarial papules and plaques of pregnancy.

erythema multiforme, linear IgA bullous dermatosis, urticaria, dermatitis herpetiformis, allergic contact dermatitis, and AEP (Lipozenčić, 2012). Potentially life-threatening drug-induced blistering syndromes, such as Stevens-Johnson syndrome and toxic epidermal necrolysis, also must be excluded (Stern, 2012).

Diagnostically, immunofluorescent staining of a skin punch biopsy sample is the most accurate. With this, C3 complement and sometimes IgG are seen deposited along the basement membrane between the epidermis and the dermis (Katz, 1976; Tani, 2015). Circulating IgG antibodies against BP180 also can be detected in maternal serum using enzyme-linked immunosorbent assay (ELISA) (Al Saif, 2017; Sitaru, 2004).

Pruritus with PG can be severe. Early in its course, topical high-potency corticosteroids and oral antihistamines may be effective (p. 1158). For refractory lesions, an oral corticosteroid is provided, and prednisone or prednisolone is preferable. Either is inactivated by placental 11-β-hydroxylase enzyme, which significantly lowers fetal exposure (Benediktsson, 1997). Oral prednisone, 0.5 to 1 mg/kg daily and gradually tapered to a maintenance dose, is one option. In rare intractable cases,

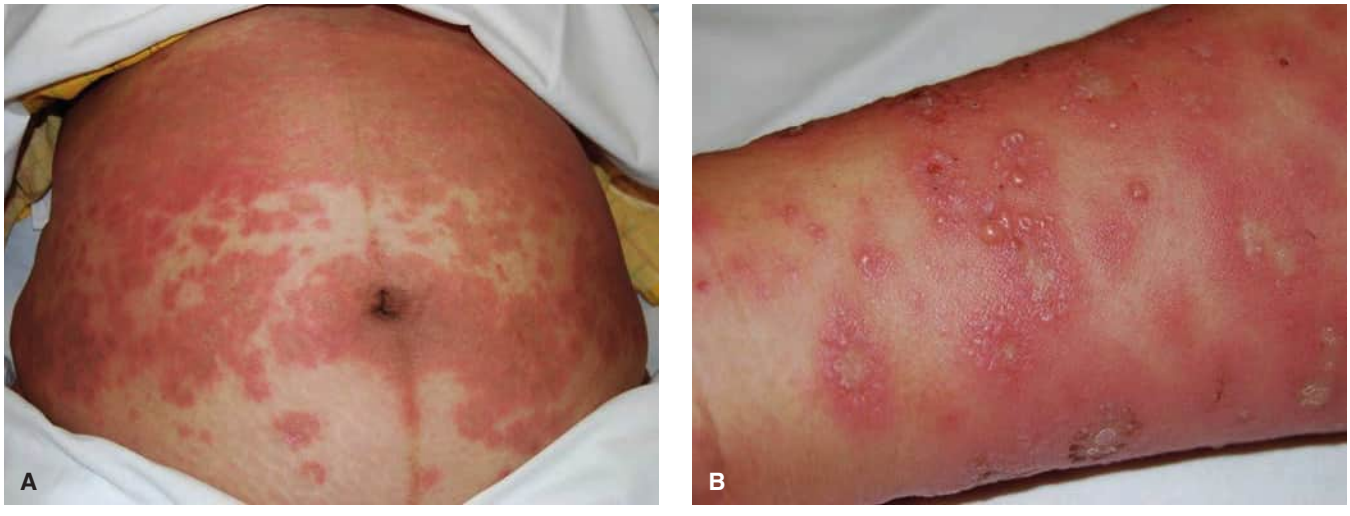

FIGURE 65-1 Pemphigoid gestationis. **A.** Abdominal plaques classically involve the umbilicus. **B.** Blistered lesions on the wrist and forearm. (Reproduced with permission from Dr. Kara Ehlers.)

intravenous immunoglobulin (IVIG) therapy, cyclosporine, or plasmapheresis has been used (Huilaja, 2015; Marker, 2011; Yang, 2018). Rituximab early in pregnancy also is described, but its later use carries the risk of transient newborn immunosuppression risks (Chakravarty, 2011; Tourte, 2017).

Pruritic Urticarial Papules and Plaques of Pregnancy

This common pregnancy-specific dermatosis is characterized by intensely pruritic, 1- to 2-mm erythematous papules that coalesce to form urticarial plaques. Also known as *polymorphic eruption of pregnancy*, PUPPP usually appears late in pregnancy (Rudolph, 2005). Rarely, onset is postpartum (Park, 2013). The rash affects the abdomen and proximal thighs in 97 percent of women (Fig. 65-2). Lesions often initially form within striae but spare periumbilical skin. The face, palms, and soles are rarely involved (High, 2005). It is more frequent in whites and nulliparas, those with multifetal gestation, and those carrying a male fetus (Regnier, 2008). PUPPP seldom recurs in subsequent pregnancies. Its cause is unknown, but an autoimmune basis is not implicated (Ambros-Rudolph, 2011; Lawley, 1979).

PUPPP mimics several other skin eruptions. Some include contact dermatitis, drug eruption, viral exanthem, insect bites, scabies infestation, pityriasis rosea, and the other pregnancy-specific dermatoses (Brandão, 2017). Specifically, it may appear similar to early PG that has not yet blistered. In unclear cases, skin biopsy and negative serum BP180 antibody levels help to differentiate the two.

Pruritus will usually respond to treatment with oral antihistamines, skin emollients, and topical corticosteroids (Lehrhoff, 2013). A few women will need short-course systemic corticosteroids to relieve severe itching (Scheinfeld, 2008).

PUPPP carries no adverse pregnancy effects. It usually resolves within several days following delivery and does not scar. In 15 to 20 percent of women, however, symptoms persist for 2 to 4 weeks postpartum (Vaughan Jones, 1999).

FIGURE 65-2 Pruritic urticarial papules and plaques of pregnancy (PUPPP) shows small papules on the buttock and proximal thigh and within abdominal striae.

Atopic Eruption of Pregnancy

This umbrella term encompasses three conditions previously considered separately: eczema in pregnancy, prurigo of pregnancy, and pruritic folliculitis of pregnancy (Ambros-Rudolph, 2006). Two thirds of women with AEP have widespread eczematous changes, whereas the other third have papular lesions (American Academy of Dermatology, 2019). Diagnosis is greatly aided by a history of prior atopy and by rash characteristics. As a group, these three pose no risk to the fetus (Roth, 2016).

Eczema in pregnancy appears as traditional eczema but with a pregnancy onset. It is the most common pregnancy-specific dermatosis, and affected skin shows dry, thickened, scaly, red patches involving extremity flexures, nipples, neck, and face (Ambros-Rudolph, 2011). In contrast, *prurigo of pregnancy*, also known as *prurigo gestationis,* is characterized by 5- to 10-mm, itchy, erythematous papules or nodules commonly found on the extensor surfaces and trunk. Last, *pruritic folliculitis of pregnancy* is rare and notable for small, erythematous follicular papules and sterile pustules predominantly on the trunk. Of AEP cases, 75 percent develop in the first or second trimesters (Ambros-Rudolph, 2006). All lesions usually resolve with delivery but may persist for up to 3 months postpartum. Recurrence with subsequent pregnancies is variable but common.

Diagnosis is one of exclusion. Biopsy findings and serology results specific for PG are negative (p. 1155). Serum bile acid levels help exclude cholestasis of pregnancy. Many women with eczema of pregnancy have elevated serum immunoglobulin E (IgE) levels (Ambros-Rudolph, 2006).

For all three AEP manifestations, skin lesions and pruritus are usually controlled with chronic emollient use, as-needed oral antihistamines, and low- or moderate-potency topical corticosteroid preparations (Roth, 2016). With the latter, twice-daily application is continued for several weeks to achieve improvement. For maintenance, moisturizer alone or once- or twice-weekly topical corticosteroid use is reasonable. For severe eczema, second-line agents include short-course ultrapotent topical corticosteroids. In some cases, topical tacrolimus, narrow-band ultraviolet B therapy, an oral corticosteroid, or cyclosporine is required (Eichenfield, 2014; Vestergaard, 2019).

OTHER DERMATOLOGICAL CONDITIONS

Acne Vulgaris

This is a common chronic dermatosis that may worsen, improve, or remain stable during pregnancy. In symptomatic gravidas, either 2.5- to 5-percent benzoyl peroxide or 15- to 20-percent azelaic acid is a suitable topical, antiinflammatory, comedolytic agent (Chien, 2016). If needed, 5-percent benzoyl peroxide can instead be coupled with either topical erythromycin or clindamycin, and combined solutions are available. In these combinations, benzoyl peroxide minimizes development of *Propionibacterium acnes* drug resistance (Zaenglein, 2016). Topical retinoids include tretinoin and adapalene. Large studies have not found higher rates of major birth defects with their topical use (Jick, 1993; Shapiro, 1997). However, these are probably best avoided during pregnancy, especially the first trimester (Kaplan, 2015; Panchaud, 2012). The topical retinoid tazarotene is

contraindicated. For more severe cases, oral antibiotics that include erythromycin, azithromycin, cephalexin, or amoxicillin may be coupled with benzoyl peroxide. Systemic antibiotics are ideally delayed until the second trimester, and therapy duration limited to 4 to 6 weeks (Chien, 2016). Refractory cases often merit dermatological consultation. Also, for severe cases, a short course of oral corticosteroid or intralesional injection is an option. Of these, oral agents are delayed until after the first trimester due to the small risk for facial clefts (Chap. 8, p. 153).

Psoriasis and Pustular Psoriasis of Pregnancy

Psoriasis is a common dermatosis with a variable course during pregnancy, however, postpartum flares are common (Murase, 2005). The National Psoriasis Foundation offers pregnancy guidelines (Bae, 2012). Emollients alone are given initially, and low- or moderate-potency topical corticosteroids can be added. In resistant cases, restrained use of high-potency or ultrapotent topical corticosteroids appears safe in the second and third trimesters. Ultraviolet B phototherapy is a second-line option. Last, cyclosporine, oral corticosteroids, or tumor necrosis factor alpha (TNF-α) antagonists that include adalimumab, etanercept, and infliximab are third-tier agents for pregnancy. Overall, psoriasis itself does not pose a higher risk of adverse pregnancy outcomes (Bobotsis, 2016). With severe disease, a small increased risk of low birthweight, gestational diabetes, and preeclampsia was found by some (Bröms, 2018; Yang, 2011).

Psoriasis is most commonly of the chronic plaque variety. In contrast, with *pustular psoriasis of pregnancy*, severe systemic symptoms may develop and can mimic sepsis. Formerly called *impetigo herpetiformis*, this rare pustular form has an erythematous background and pruritic plaques ringed by sterile pustules that enlarge, coalesce, and then crust (Fig. 65-3). Plaques initially involve intertriginous areas but may spread to the torso, extremities, and oral mucosa. Extensive lesions can lead to massive fluid loss with hypovolemia, placental insufficiency, and fetal compromise and may also become secondarily infected.

Testing reveals leukocytosis, elevated erythrocyte sedimentation rate, hypocalcemia, and hypoalbuminemia (Umezawa, 2003). Blood cultures and skin viral/bacterial cultures to exclude infection and a diagnostic skin biopsy are obtained. Classically, the former are sterile, and the latter reveals epidermal pustules of neutrophils.

First-line treatment is with oral prednisone (15–80 mg/d), cyclosporine (2–3 mg/kg/d), infliximab (Remicade), topical corticosteroids, or topical calcipotriene (Robinson, 2012; Trivedi, 2018). Selection of a systemic or topical agent and its dose is directed by disease severity. As needed, fluid resuscitation, electrolyte correction, and intravenous antibiotics for secondary infections are adjuncts (Huang, 2011). Pustular psoriasis of pregnancy typically resolves quickly postpartum, and thus early delivery can be considered individually. Recurrences are reported in subsequent pregnancies and with menses or oral contraceptive use (Roth, 2011).

Erythema Nodosum

This skin condition reflects subcutaneous fat inflammation and is associated with many disorders, including pregnancy. Other triggers are infections, sarcoidosis, drugs, Behçet syndrome, inflammatory bowel disease, or malignancy (Mert, 2007; Papagrigoraki, 2010). Characteristically, tender, red, warm, 1- to 6-cm nodules and plaques develop rapidly on extensor surfaces. After a few days, lesions flatten, and color evolves like a bruise—from dark red and purple to yellow green. Constitutional symptoms also may be present. Initial evaluation and treatment focuses on the underlying etiology. Symptoms spontaneously resolve in 1 to 6 weeks without scarring but may leave residual hyperpigmentation (Acosta, 2013).

Pyogenic Granuloma

This lesion is frequently seen in pregnancy (Fig. 65-4) (Bett, 2019). Poorly named, *pyogenic granuloma* is actually a lobular

FIGURE 65-3 Generalized pustular psoriasis of pregnancy displays erythematous, sometimes pruritic plaques ringed by sterile pustules that enlarge and then form a scaling crust. (Reproduced with permission from Dr. Paul Slocum.)

FIGURE 65-4 Pyogenic granuloma is characterized grossly by a lobulated red growth on a pedunculated or sessile base. With minimal trauma, these vascular lesions bleed easily. (Reproduced with permission from Dr. Sarah White.)

capillary hemangioma. Pregnancy-associated elevations in angiogenic factors that include vascular endothelial growth factor are implicated (Yuan, 2000, 2004). It commonly forms on the gingiva, other oral/nasal surfaces, or hand in response to low-grade local irritation or trauma (Cardoso 2013). Lesions grow quickly and bleed with minimal provocation. Active bleeding can be controlled with pressure and application of a silver nitrate stick or Monsel (ferric subsulfate) paste. These growths often resolve within months postpartum and thus may be observed antepartum. But, with a symptomatic antepartum growth, a persistent postpartum lesion, or an unclear diagnosis, excision is preferred. An option is scalpel excision plus suturing, electrosurgical curettage, laser photocoagulation, or cryotherapy. Oral lesions are best referred to specialists.

Miscellaneous Conditions

Hidradenitis suppurativa is a chronic inflammatory skin disease. Keratin plugging of hair follicles and recurrent inflammation lead to painful nodules and abscesses that rupture to create sinus tracts. Hurley stages I–III range from transient, widely spaced inflammatory papules to diffuse involvement with multiple deep sinus tracts between skin abscesses (Hurley, 1989). For most, symptoms during pregnancy are unchanged or improved (Kromann, 2014; Vossen, 2017).

Treatment aims to decrease cutaneous inflammation and provide antibacterial effects. For active stage I/II disease, 1-percent clindamycin is topically applied twice daily for 12 weeks (Alikhan, 2019). As alternatives, 0.75-percent metronidazole or 2-percent erythromycin gel are suitable (Perng, 2017). For stage II/III disease, a 300-mg clindamycin plus a 300-mg rifampin dose orally twice daily for 10 weeks has evidence-based support (Alikhan, 2019). Adalimumab (Humira) is an FDA-approved biological agent that targets TNF-α and offers a second-line option for advanced-stage disease in pregnancy (Jemec, 2019; Perng, 2017).

Neurofibromatosis lesions are typified by benign cutaneous neurofibromas, café-au-lait spots, axillary and inguinal freckling, benign iris nodules (Lisch nodules), and optic nerve gliomas. Neurofibromas may grow in size and number during pregnancy (Cesaretti, 2013; Dugoff, 1996). With neurofibromatosis type 1, higher rates of preeclampsia and preterm birth complicate pregnancy (Leppävirta, 2017; Terry, 2013). With type 2, some evidence suggests a risk for preeclampsia (Terry, 2015). Prenatal genetic diagnosis is available for both types (Merker, 2015).

Rosacea fulminans, also known as *pyoderma faciale,* is rare and typified by facial pustules and coalescing draining sinuses but without comedones. Its marked presentation usually merits dermatological consultation. Topical or oral antibiotics are primary treatment, and topical corticosteroids may be added. Less often, short-course oral corticosteroids or focal surgical drainage is a needed adjunct (Angileri, 2021; Fuentelsaz, 2011; Jarrett, 2010).

Other skin conditions discussed elsewhere in this book are hirsutism and melanoma (Chap. 66, p. 1176), cutaneous lupus (Chap. 62, p. 1111), hyperpigmentation (Chap. 4, p. 55), and skin lesions seen with infections (Chaps. 67 and 68, p. 1182).

DERMATOLOGICAL TREATMENT

Local skin care, oral antihistamines, and topical corticosteroids are commonly used for many dermatoses. Oral antihistamines are given for pruritus. Suitable options include first-generation agents such as diphenhydramine (Benadryl), 25 to 50 mg every 6 hours, or chlorpheniramine (Chlor-Trimeton), 4 mg every 6 hours. Second-generation agents—loratadine (Claritin) 10 mg daily or cetirizine (Zyrtec) 5 or 10 mg daily—may produce less sedation and are also safe for pregnancy.

Numerous topical corticosteroid preparations are available, and in the United States, these are categorized by potency (Table 65-2). For initial treatment of dermatological disorders, low- or moderate-potency agents are preferred. Low-potency agents include 1-percent hydrocortisone and 0.05-percent desonide (DesOwen). Moderate-potency drugs are 0.1-percent triamcinolone acetonide (Aristocort) and 0.1-percent mometasone furoate (Elocon). High-potency medications include 0.05-percent betamethasone dipropionate (Diprolene). Ultrapotent agents, such as 0.05-percent clobetasol propionate (Temovate), are best reserved for refractory disorders and used for only 2 to 4 weeks on small surface areas.

Mild and moderate strengths are not associated with adverse pregnancy outcomes, whereas high-potency and ultrapotent agents pose a small risk for fetal-growth restriction with large cumulative doses (Chi, 2013, 2015). Even then, this risk is less than that with oral corticosteroids. Importantly, with any topical agent, factors that raise systemic absorption include a large surface area treated, compromised epidermal barrier, occlusive dressing, prolonged treatment duration, and coadministration of other topical agents that enhance absorption.

TABLE 65-2. Commonly Used Topical Corticosteroids in Pregnancy

Low-Potency Agents	Moderate-Potency Agents	High-Potency Agents	Ultrapotency Agents
Hydrocortisone 0.5–1% *cream, ointment*	Triamcinolone acetonide 0.1% *cream, ointment*	Triamcinolone acetonide 0.5% *cream, ointment*	Clobetasol propionate 0.05% *cream, ointment*
Dexamethasone 0.1% *cream*	Mometasone furoate 0.1% *cream*	Mometasone furoate 0.1% *ointment*	
Desonide 0.05% *foam, cream, ointment*	Betamethasone valerate 0.1% *cream, ointment*	Betamethasone dipropionate 0.05% *cream, ointment*	

TABLE 65-3. Some Dermatological Agents and Their Suitability for Pregnancy

Group	Action	Pregnancy Recommendation
Topical Agents		
Corticosteroids	Antiinflammatory	Suitable
Benzoyl peroxide	Antiinflammatory, comedolytic, antibacterial	Suitable
Azelaic acid		Suitable
Antibiotics: Clindamycin, erythromycin	Antibacterial	Suitable
Calcineurin inhibitors: Tacrolimus, pimecrolimus	Antiinflammatory	Suitable
Calcipotriene	Antiinflammatory, vitamin D analogue	Possible poor ossification in animals; no human data Probably suitable in dermatological dosages
Coal tar	Antiinflammatory; keratinocyte regulation	Possible animal mutagen/carcinogen; no human data If used, delay until 2nd trimester
Retinoids:	Antiinflammatory, comedolytic	
Tretinoin, adapalene		Large studies show no harm, but experts suggest avoiding
Tazarotene		Teratogenic; contraindicated
Crisaborole	Antiinflammatory	Limited pregnancy data; avoidance currently suggested
Systemic Agents		
Oral antibiotics: Azithromycin, amoxicillin, cephalexin, erythromycin	Antibacterial	Suitable
Oral corticosteroids	Antiinflammatory	1st-trimester use linked to small risk of oral clefts
Cyclosporine	Immunomodulator	Low birthweight, preterm birth; nonteratogenic
TNF-α inhibitors: Infliximab, adalimumab, etanercept	TNF-α inhibition	Suitable

From Bae, 2012; Briggs, 2017; Murase, 2014; Park-Wyllie, 2000; Rademaker, 2018; Robinson, 2012; Sekhon, 2018; Vestergaard, 2019.

For use in pregnancy and lactation, Murase (2014) and Butler (2014) have compiled tables and evidence-based descriptions of most. Table 65-3 reflects more commonly encountered agents. Notable therapeutic agents to avoid during pregnancy include methotrexate, psoralen plus ultraviolet A, mycophenolate mofetil, podophyllin, and systemic retinoids. These teratogens are discussed in Chapter 8. Bacterial infections are a potential secondary complication of skin disorders and are treated promptly with oral antimicrobial agents with gram-positive coverage.

CHAPTER 66

Neoplastic Disorders

Any of the many neoplasms that affect reproductive-aged women can complicate pregnancy. Fortunately, most encountered neoplasms are benign, and uterine leiomyomas and ovarian cysts are the most frequent. Despite this, the incidence of malignancy approximates 1 case per 1000 to 2000 pregnancies (Korenaga, 2020; Ma, 2020). A third are diagnosed prenatally, and the remainder within 12 months of delivery. The distribution of some of these is shown in Figure 66-1 (de Haan, 2018). In another report from the Cancer Research Network, breast malignancies made up 25 percent and thyroid cancers, 20 percent. Melanoma and hematological and cervical cancers each contributed approximately 10 percent (Cottreau, 2019).

During pregnancy, cancer management poses unique problems related to fetal concerns, and treatment is individualized. Considerations include the type and stage of malignancy, the desire for pregnancy continuation, and inherent risks associated with modifying or delaying cancer treatment. Last, adverse pregnancy outcomes have been associated in general with gravidas with cancer (Ma, 2020; Momen, 2018).

CANCER THERAPY IN PREGNANCY

Surgery

Operative procedures may be indicated to aid cancer diagnosis, staging, or therapy. Fortunately, most surgeries that do not

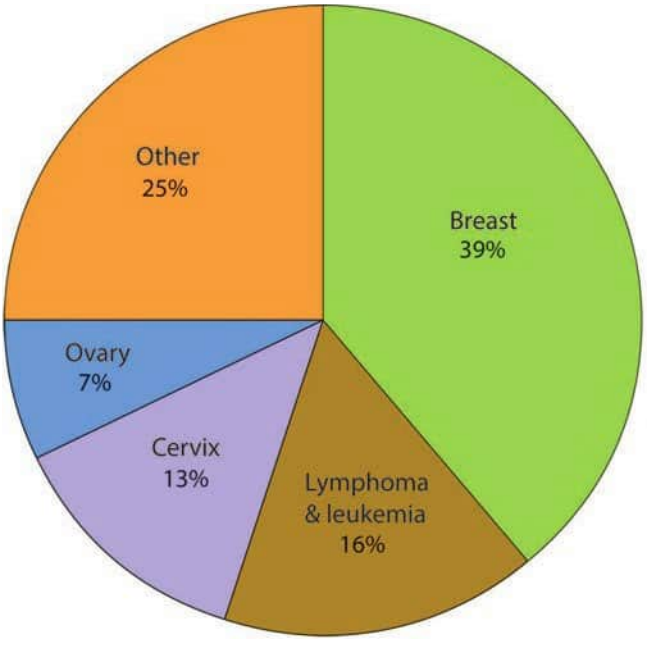

FIGURE 66-1 Distribution of cancer in 1170 pregnant women form the International Network on Cancer, Infertility, and Pregnancy (INCIP).

interfere with the reproductive tract are well tolerated by both mother and fetus (Chap. 49, p. 867). Although many operations have classically been deferred until after 12 to 14 weeks' gestation to minimize miscarriage risks, this probably is unnecessary. We believe that surgery should be performed at any gestational age if maternal well-being is imperiled.

Both pregnancy and malignancy are risk factors for venous thromboembolism (VTE). From studies of women with cancer during pregnancy, the risk of VTE is higher in pregnancy and in the postpartum period than in gravidas without a malignancy (Bleu, 2016; Greiber, 2021). Current guidelines lack specific recommendations for pregnant women undergoing surgeries for cancer. Thus, depending on the complexity of the planned procedure, it seems reasonable to consider prophylactic low-molecular-weight heparin combined with elastic stockings and/or intermittent pneumatic compression (Chap. 55, p. 989).

Diagnostic Imaging

Sonography is a preferred imaging tool during pregnancy. Even so, the American College of Obstetricians and Gynecologists (2019c) notes that most diagnostic radiographic procedures deliver very low x-ray doses and should not be delayed if they would directly affect therapy (Chap. 49, p. 872). Magnetic resonance (MR) imaging can safely be performed in any trimester, but delay until after the first trimester may lower potential risks. Gadolinium should not be used in the first trimester and should be used later in pregnancy only when the benefits overwhelmingly outweigh risks (American College of Radiology, 2021; Kanal, 2013). Computed tomography (CT) is less often selected due to ionizing radiation, and procedure-related doses are listed in Chapter 49 (p. 874). Thus, CT imaging is used in pregnancy most often to evaluate acute concerns that include pulmonary embolism, bowel or renal obstruction, and acute neurological events. To enhance CT imaging, oral and intravenous contrasts may be added. These lack known fetal harm, and postpartum breastfeeding need not be interrupted. In pregnancy, some radioisotopes are relatively safe (Table 49-10, p. 876).

Radiation Therapy

Therapeutic radiation is used to *treat* cancers and delivers a higher radiation dose than that with diagnostic imaging. Radiotherapy may significantly expose the fetus depending on the dose, tumor location, field size, and gestational age. Potential adverse effects include fetal malformation, intellectual disability, growth restriction, sterility, and carcinogenesis (Brent, 1999; Stovall, 1995). In the 2 weeks following fertilization, exposure typically leads to chromosomal damage and embryonic death. The next most susceptible period is during organogenesis in weeks 2 through 8, and exposure can create malformations. These might develop above a threshold dose of 0.1 to 0.2 Gy. During weeks 8 through 25, the fetal central nervous system is especially vulnerable. The threshold dose for intellectual disability at 8 to 15 weeks' gestation approximates 0.06 Gy, and at 16 to 25 weeks it is about 0.25 Gy (Kal, 2005; Otake, 1996). After 25 weeks' gestation, susceptibility is less, although no gestational age is considered safe for therapeutic radiation exposure. Thus, radiotherapy to the maternal abdomen is contraindicated. With some head and neck cancers, however, radiotherapy to supradiaphragmatic areas can be used relatively safely with abdominal shielding of the fetus (Amant, 2015a).

Chemotherapy

Various antineoplastic drugs may be given as primary or adjunctive therapy. Although chemotherapy often improves long-term maternal outcomes, many are reluctant to employ it during pregnancy. Concerns for the fetus include malformations, growth restriction, intellectual disability, and the risk of future childhood malignancies. Risks depend primarily on fetal age at exposure, and most agents are potentially detrimental in the first trimester during organogenesis. Indeed, in one review, 14 percent of major malformations were attributable to first-trimester exposure to cytotoxic drugs (National Toxicology Program, 2013).

After the first trimester, most antineoplastic drugs are without immediate obvious adverse fetal sequelae (Korenaga, 2020; Vercruysse, 2016). Similarly, late mutagenic effects appear limited (Amant, 2015b; Cardonick, 2015). Although not always practicable, some recommend that chemotherapy be withheld in the 3 weeks before expected delivery because neutropenia or pancytopenia might cause undue risk for maternal infection or hemorrhage. Another concern is that neonatal hepatic and renal clearance of chemotherapy metabolites is limited (Ko, 2011). For these reasons, most cytotoxic chemotherapy agents are contraindicated with breastfeeding (Pistilli, 2013).

Molecular Therapy

Biological agents designed to stimulate hemopoiesis are commonly used with cancer treatments. Some of these include the granulocyte colony-stimulating factors filgrastim (Neupogen) and pegfilgrastim (Neulasta). If required in pregnancy, limited data support the safety of these agents (Boxer, 2015). Red blood cells can be stimulated by erythropoietin alfa (Procrit), which from case reports also appears safe in pregnancy (Sienas, 2013). However, maternal hypertension is a known potential risk. Last, for chemotherapy-induced thrombocytopenia, romiplostim and eltrombopag are thrombopoietin-receptor agonists that appear to be safe in pregnancy (Chua, 2020; Michel, 2020).

Targeted Therapy

The two main types of targeted therapy are monoclonal antibodies and small-molecule inhibitors. Both block the actions of specific enzymes, proteins, or other molecules involved in cancer cell growth (Tsao, 2019). Another is nanotherapy using drugs incorporated into encapsulated nanoparticles (Pereira, 2020). These drugs are designed to treat an ever-expanding list of cancers, and some are described in later discussions of specific tumors. Most of these compounds are labeled by the Food and Drug Administration as class D, and data are limited regarding their pregnancy or breastfeeding effects.

Many of these drugs target tyrosine kinase, an important enzyme that regulates signaling pathways involved with cell division, differentiation, and apoptosis. With first-trimester

use, embryo toxicity or teratogenicity has been attributed to these. Thus, use balances potential maternal benefit and potential fetal risk (Lodish, 2013).

Of other agents, the monoclonal antibody trastuzumab (Herceptin) inhibits the human epidermal growth factor receptor type 2 (HER2), which some breast cancers express. Although not teratogenic, its use in the second and third trimesters is associated with oligohydramnios, which appears to be reversible upon stopping the drug (McCormick, 2018; Zagouri, 2013b). Because of sparse available data, other HER2 inhibitors are best avoided in pregnancy (Lambertini, 2015).

Fertility and Pregnancy after Cancer Therapy

Oncofertility is an emerging discipline to preserve fertility in young adults diagnosed with cancer (Robson, 2020). Fertility may be diminished after chemotherapy or radiotherapy. Counseling ideally takes place before cancer treatment, and guidelines have been developed by the American Society for Reproductive Medicine (ASRM) (2018) and other major groups (Oktay, 2018; van de Kooi, 2021). Prior to therapy, embryo or oocyte cryopreservation is a recognized option. Ovarian tissue cryopreservation is available in research settings (American Society for Reproductive Medicine, 2013a,b, 2014). In addition, many cancer survivors conceive by assisted reproductive technologies (ART), which by itself has associated obstetrical risks (Chap. 9, p. 169).

If pelvic radiation is planned, surgical transposition moves ovaries and their intact primary blood supply out of the pelvis. The ovary is then fixed to the lateral abdominal wall at a site 3 to 4 cm above the level of the umbilicus. Metal clips are placed to help identify the ovary in future imaging (Moawad, 2017). In one review, functional preservation was reported in 65 to 94 percent, depending on radiotherapy type (Gubbala, 2014).

In counseling cancer survivors, evidence suggests that exposure to most radiotherapy or chemotherapy agents does not significantly raise the risk of congenital anomalies or genetic disease in their offspring (Signorello, 2012; Winther, 2012). In those treated as children, chemotherapy does not show a consistent link to adverse obstetrical outcomes (Melin, 2015; Reulen, 2009). Data are limited in those with cancer treated as an adult, and some studies show slightly higher rates of preterm birth and cesarean delivery (Haggar, 2014; Stensheim, 2013).

Prior abdominopelvic radiation more convincingly affects neonatal outcomes, including elevated rates of abortion, low birthweight, stillbirth, and preterm birth (Signorello, 2006, 2010; Winther, 2008). Radiation may reduce uterine volume, thin the endometrium, and impair uterine blood flow (Critchley, 1992; van de Loo, 2019). Radiotherapy directed to the uterus and given at a younger age shows greater effects (Teh, 2014).

Placental Metastases

Tumors infrequently metastasize to the placenta. The most common types are malignant melanomas, leukemias, lymphomas, and breast cancer (Chap. 6, p. 112). Placentas from pregnancies in all women with cancer should be sent for histological evaluation. Tumor cells are usually confined within the intervillous spaces, and fetal metastases are rare (Al-Adnani, 2007; Rubrecht, 2020).

REPRODUCTIVE TRACT NEOPLASMS

Benign neoplasms of the reproductive tract are common and include leiomyomas, ovarian tumors, and endocervical polyps. Cancer in these organs may also complicate pregnancy, and of these, cervical neoplasia makes up most (de Haan, 2018).

Cervix

Endocervical Polyp

These are overgrowths of endocervical stroma covered by epithelium. They typically appear as single, red, elongated fleshy masses of variable size that extend outward from the endocervical canal. Usually benign, they can bleed and can be a source of Pap test results reported as *atypical glandular cells of undetermined significance—AGUS*. With removal and histological polyp evaluation, dysplasia is diagnosed in up to 0.5 percent, and cancer is found in approximately 0.1 percent (Park, 2020).

Few formal data guide management in pregnancy. Small asymptomatic lesions may be left alone to slough during delivery or puerperal remodeling. Removal and histological evaluation is reasonable if malignancy is suspected or if bleeding is troublesome. For most, the polyp is grasped with ring forceps and twisted repeatedly about its base to strangulate feeding vessels. With repeated twisting, the base narrows and avulses. Monsel paste, which is ferric subsulfate, can be applied with pressure to the stalk stub for hemostasis. A thick-pedicle polyp may infrequently warrant surgical ligation and excision.

Cervical Neoplasia

Pregnancy provides an opportune time to screen for cervical intraepithelial neoplasia (CIN) and invasive cervical cancer. With Pap test screening, pregnancy status should be noted on the requisition form as cytological interpretation may be influenced by normal pregnancy-associated changes. Presence of decidual cells and, less often, an Arias-Stella reaction are examples. The latter gives an appearance of endocervical gland hyperplasia, which can make differentiating this from truly atypical glandular cells difficult.

Current screening guidelines apply to both nonpregnant women and gravidas (American College of Obstetricians and Gynecologists, 2021b; U.S. Preventive Services Task Force, 2018). Recommendations for average-risk women include: (1) no screening until age 21, (2) cytology alone every 3 years in those aged 21 to 29 years, and (3) in women aged ≥30 years, three options are suitable. These are human papillomavirus (HPV) *plus* cytology, termed co-testing, every 5 years; primary HPV testing every 5 years; or cytology every 3 years.

Higher-risk women with altered immune systems include women with human immunodeficiency virus (HIV) infection, systemic lupus erythematosus, organ transplant, or immunosuppressant medication use (Perkins, 2020). Others include those with past CIN or prior early cervical cancer or in utero diethylstilbestrol (DES) exposure. Affected women are screened earlier and more often using current guidelines for HIV-affected individuals (Panel on Opportunistic Infections in Adults and Adolescents with HIV, 2020). Germane to gravidas aged ≤30 years, these guidelines recommend Pap test screening at the time of initial HIV diagnosis and then

yearly. Once three consecutive Pap test findings are normal, screening may be spaced to every 3 years. Co-testing is not recommended. For those aged >30 years, similar Pap testing is applied. Co-testing is suitable for this group, and if negative, the next test can repeated in 3 years.

Human Papillomavirus. This virus infects cervical epithelia. The infection usually clears, but in some, the virus may promote benign, premalignant, or cancerous neoplastic growth. The prevalence of HPV infection in pregnant women approximates 15 percent (Hong, 2013; Liu, 2014). Of the many HPV serotypes, several are associated with high-grade squamous intraepithelial (HSIL) lesions and invasive cancer. Serotypes 16 and 18 are preeminent. HPV testing targets only high-risk types associated with cervical neoplasia, and identification of types 16 or 18 prompts colposcopic evaluation. There is no indication for low-risk HPV testing.

Serotypes HPV 6 and 11 are linked with benign maternal genital warts. Congenital HPV infection resulting from vertical transmission, which is mother to fetus/newborn passage, beyond transient skin colonization is rare. Still, conjunctival, laryngeal, vulvar, or perianal warts present at birth in the neonate or that develop within 1 to 3 years of birth are most likely due to perinatal exposure to these maternal HPV serotypes (Chap. 68, p. 1216). Importantly, cesarean delivery does not lower the risk of neonatal laryngeal papillomatosis.

The clear link between HPV infection and cervical neoplasia led to development of approved vaccines that reduce cervical cancer risk (Lei, 2020). Only one vaccine is currently available in the United States. Gardasil 9 is a nonavalent HPV vaccine (9vHPV) against HPV types 6, 11, 16, 18, 31, 35, 45, 52, and 58. This vaccine is not administered during pregnancy and is compatible with breastfeeding (Chap. 10, p. 189).

Abnormal Cytology and Histology. The incidence of abnormal cervical cancer screening test results and their management is similar for gravidas and nonpregnant women. Current 2019 management consensus guidelines from the American Society of Colposcopy and Cervical Pathology focus on the individual's risk for CIN 3 or cervical cancer, rather than on specific screening results (Perkins, 2020).

Management has become complex and derives from large database analyses. Factors include the abnormal cytology and HPV results, age, and previous screening results. As a result, algorithms now calculate the best clinical approach to abnormal screening test results (www.asccp.org/management-guidelines). In overview, certain cytological abnormalities and HPV test results warrant colposcopy, and the main goal during pregnancy is to exclude invasive cancer. Thus, lesions suspicious for high-grade disease or cancer are biopsied. Endocervical sampling, endometrial biopsy, and treatment of preinvasive lesions are unacceptable during pregnancy.

Women with histologically confirmed CIN from biopsy during pregnancy are allowed to deliver vaginally. Further evaluation is planned at least 4 weeks postpartum. Alternatively, for clinical findings with higher cancer risk, repeat colposcopy and cytology/HPV testing are performed at intervals no more frequently than 12 weeks. Biopsy is repeated only if a lesion appears worse or invasive cancer is suspected (Perkins, 2020).

Postpartum reassessment may reveal lesions missed previously due to either cervical changes of pregnancy or advancing lesion severity. Instead, CIN regression is common during pregnancy or puerperium. In one study of 1079 pregnant women with cervical dysplasia in which biopsy correlated with colposcopic findings, 61 percent of lesions reverted to normal postpartum (Fader, 2010). In another study, lesions regressed postpartum in 70 percent of women with CIN 2 or 3. However, 7 percent of CIN 2 lesions progressed to CIN 3, but no lesion advanced to invasive cancer (Yost, 1999). In another study of 77 women with carcinoma in situ (CIS) diagnosed antepartum, a third had postpartum regression of their lesion, two thirds had persistent CIS, and only two women had microinvasive cancer on cone biopsy after delivery (Ackermann, 2006).

Adenocarcinoma in situ (AIS) is managed in a manner similar to CIN 3 (Dunton, 2008). Thus, unless invasive cancer is identified, treatment of AIS is not recommended until 6 weeks postpartum. Referral to a gynecologist with advanced colposcopic skills is recommended (Perkins, 2020).

Cervical Conization. If invasive epithelial lesions are suspected, conization is indicated and may be done with loop electrosurgical excisional procedure (LEEP) or by cold-knife conization. However, the epithelium and underlying stroma within the endocervical canal cannot be extensively excised without the risk of membrane rupture. Logically, residual disease is common. Of 376 cone biopsies during pregnancy, residual neoplasia was later found in 43 percent of subsequent specimens (Hacker, 1982). In another series, nearly 10 percent of 180 pregnant women required transfusion after conization (Averette, 1970). Thus, if possible, conization is avoided in pregnancy because of its higher risks for abortion, membrane rupture, hemorrhage, and preterm delivery.

Women with CIN treated *before* pregnancy may also encounter pregnancy complications. First, distal cervical stenosis is uncommon but may follow conization, LEEP, or laser surgery. Cervical stenosis almost always yields during labor. A so-called *conglutinated cervix* may undergo almost complete intrapartum effacement without dilation. Spontaneous dilation usually promptly follows firm pressure with a fingertip, although instrumented dilation or cruciate incisions may be required.

Second, preconceptional cold-knife conization is associated with cervical insufficiency and preterm birth. However, the relationship between preterm birth and LEEP continues to be debated (Castanon, 2012; Conner, 2014; Stout, 2015). The size of tissue excised seems to be directly related to adverse outcomes (Weinmann, 2017).

Invasive Cervical Cancer

This cancer is found in approximately 1 in 1200 to 10,000 pregnancies (Bigelow, 2017; McCormick, 2018). The diagnosis is confirmed with biopsies taken during colposcopy, with conization, or from a grossly abnormal lesion. Of the histological types, squamous cell carcinomas account for 75 percent, whereas adenocarcinomas compose the remainder (Schorge, 2017). Cancers may appear as exophytic or endophytic growth; as a polyp, papillary tissue, or barrel-shaped cervix; or as focal

ulceration or necrosis. A watery, purulent, foul, or bloody discharge may be present. The sensitivity of a single Pap test is poor. Thus, biopsy with Tischler forceps is warranted for suspicious lesions. Abnormal tumor vessels may cause heavier than expected biopsy-site bleeding, which is usually controlled by Monsel paste and pressure.

Historically, cervical cancer was solely staged clinically. The current staging system now incorporates radiological and surgical evaluation (Bhatla, 2019). Lymph node metastasis is now also included in staging**.** Allowable components of clinical staging are cold-knife conization, pelvic examination under anesthesia, cystoscopy, intravenous pyelogram (or this portion of MR imaging can be used), proctoscopy, and chest radiography. Notably, physiological pregnancy changes may limit physical assessment of cancer extent, which is more likely to be underestimated in gravidas. Specifically, induration of the broad ligament base, which characterizes tumor spread beyond the cervix, may be less prominent due to cervical, paracervical, and parametrial pregnancy-induced softening. MR imaging can be used without gadolinium contrast to ascertain involvement of the urinary tract, parametrium, and lymph nodes (Beharee, 2019).

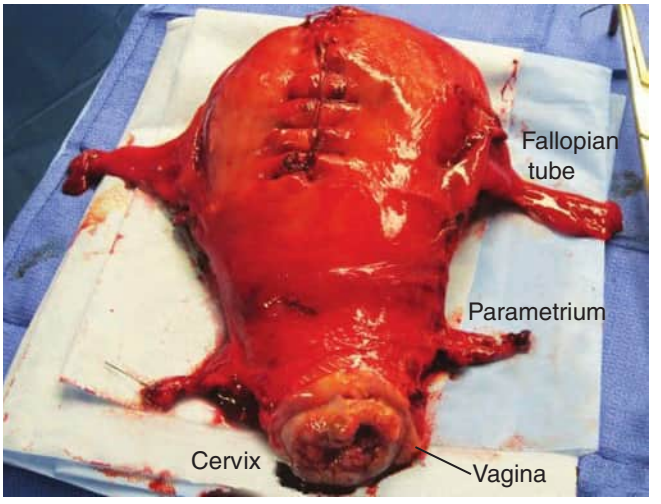

FIGURE 66-2 Radical hysterectomy specimen with invasive cervical squamous cell carcinoma. With radical hysterectomy, the parametrium and 2 to 3 cm of vagina are excised to help achieve a tumor-free resection. (Reproduced with permission from Dr. Debra L. Richardson.)

Management and Prognosis. Cervical cancer treatment in pregnant women is individualized, and factors include the clinical stage, fetal age, and individual desire to continue pregnancy. Stage IA1 is termed *microinvasive disease* and describes lesions with deepest invasion <3 mm (Bhatla, 2019). If diagnosed by cone biopsy, treatment follows guidelines similar to those for intraepithelial disease. In general, continuation of pregnancy and vaginal delivery are considered safe, and definitive therapy is reserved until 6 weeks postpartum.

In contrast, cancer with greater invasion demands relatively prompt therapy. During the first half of pregnancy, immediate treatment is advised by most, but the decision whether to continue pregnancy is a factor. During the latter half of pregnancy, the risk of early delivery versus delayed treatment are weighed (McCormick, 2018). In two studies with a total of 40 women past 20 weeks' gestation with either stage I or stage IIA carcinoma, delayed treatment was considered reasonable in women without bulky lesions (Takushi, 2002; van Vliet, 1998). Another option is to complete staging using laparoscopic lymphadenectomy and to delay treatment if metastases are excluded (Alouini, 2008; Favero, 2010). In a metaanalysis, preoperative neoadjuvant chemotherapy with platinum derivatives was found to be promising for treatment in pregnancy (Zagouri, 2013a).

Although surgical therapy and radiation are equally effective, radical hysterectomy plus pelvic lymphadenectomy is the preferred treatment for invasive cervical cancer in most young women with stage I and early stage IIA lesions. Disadvantageously, radiotherapy for cervical cancer destroys ovarian and possibly sexual function and frequently causes intestinal and urinary tract injury. In 49 women with pregnancy-associated stage IB cancer, a 30-percent severe complication rate accompanied radiotherapy compared with that of only 7 percent with radical surgery (Nisker, 1983). With surgery before 20 weeks' gestation, radical hysterectomy is usually performed with the fetus in situ. In later pregnancy, however, hysterotomy and delivery is often performed first (Fig. 66-2).

Although rarely selected during pregnancy, Ungár and colleagues (2006) performed abdominal radical trachelectomy before 20 weeks' gestation for stage IB1 cancer in five pregnant women. One cases series describes four women with stage IA1 adenocarcinoma at 16 to 23 weeks' gestation treated with laser conization, and all delivered at term (Yahata, 2008).

For more advanced-stage cancer, radiotherapy is given. External beam radiation in early in pregnancy typically leads to spontaneous abortion. If miscarriage does not ensue, curettage is performed. During the second trimester, spontaneous abortion may not promptly occur and may necessitate hysterotomy in up to a fourth of cases. This is selected because labor induction or dilation and evacuation may pose serious hemorrhage risks from the cancer.

Pregnancy does not negatively affect cervical cancer prognosis, and survival outcomes are similar for pregnant and nonpregnant women (Amant, 2014; Mogos, 2013). For both of these groups, the overall 5-year survival rate approximated 80 percent in a case-control study of 44 women with pregnancy-associated cervical cancer (van der Vange, 1995).

Delivery

Adverse prognostic effects from vaginal delivery through a cancerous cervix are unknown. For this reason, the mode of delivery is controversial, especially for small, early-stage lesions. In some cases of bulky or friable tumors, hemorrhage from the cancer may complicate vaginal delivery. Also, recurrences in the episiotomy scar have been reported (Goldman, 2003). Thus, most favor cesarean delivery.

Pregnancy after Radical Trachelectomy

Radical trachelectomy for stage IB1 and IB2 cervical cancer before conception is one fertility-sparing option. During the typically vaginal procedure, the cervix is amputated at the level of the internal os, and a permanent-suture cerclage is placed around the isthmus to support future pregnancies. The uterine

isthmus is then reconstructed to the vagina. Following this, women continue to menstruate, and conception can occur naturally. Because of the permanent cerclage, a classical cesarean incision is required for delivery. Evidence suggests that cervical length <13 mm at 20 weeks' gestation is associated with preterm birth <34 weeks (Kasuga, 2017). In a systematic review of 2566 women after radical trachelectomy for early-stage cancer, the 5-year overall maternal survival rate was 97 percent (Smith, 2020). The pregnancy rate was 24 percent, and the live-birth rate was 75 percent.

Uterus

Leiomyomas

Also known as myomas and somewhat erroneously called *fibroids*, uterine leiomyomas are common benign smooth-muscle tumors. Their incidence during pregnancy approximates 2 percent, but the cited range depends on the frequency of routine sonography and population characteristics (Qidwai, 2006; Stout, 2010). In one study of 4271 women, the first-trimester myoma prevalence was highest in black women—18 percent—and lowest in whites—8 percent (Laughlin, 2009).

Leiomyomas vary in location and may develop as submucosal, subserosal, or intramural growths. Less often, these develop in the cervix or broad ligament. Rare parasitic types obtain their blood supply from adjacent structures such as the omentum. In another rare manifestation—*leiomyomatosis peritonealis disseminata*—numerous, small, benign subperitoneal smooth-muscle tumors mimic carcinomatosis but often regress after pregnancy.

In general, progesterone is considered the critical mitogen for uterine leiomyoma growth. In turn, estrogen functions to upregulate and maintain progesterone receptors (Ishikawa, 2010). In pregnancy, progesterone's effect on myoma growth is unpredictable, and tumor size may grow, regress, or remain unchanged (Laughlin, 2009; Neiger, 2006).

Especially during pregnancy, these masses can be confused with other pelvic masses, and sonographic imaging is indispensable (Fig. 66-3). Once diagnosed, myomas do not require sonographic surveillance unless associated complications are anticipated. With unclear sonographic findings, MR imaging may be necessary and ideally performed after the first trimester.

Symptoms. Most leiomyomas are asymptomatic, but acute or chronic pain or pressure may develop, especially with large masses (Doğan, 2016). For chronic pain, nonnarcotic analgesic drugs usually suffice. More acutely, some myomas can outgrow their blood supply and hemorrhagic infarction follows, which is termed *red* or *carneous degeneration*. Clinically, acute focal abdominal pain and tenderness are preeminent and often accompanied by leukocytosis or low-grade fever. Thus, tumor degeneration may be difficult to differentiate from other sources of acute abdominal pain. Sonography aids diagnosis, but close observation is requisite because an infarcted myoma is essentially a diagnosis of exclusion. Uncommonly, preterm labor is stimulated by associated inflammation.

Symptoms from a degenerated myoma usually abate within a few days. In severe cases, observation may be needed to exclude a septic cause. Although surgery is rarely needed during pregnancy, myomectomy in highly selected cases has yielded good outcomes. Of 23 reported cases, women were 14 to 20 weeks' gestation, and in almost half, surgery was performed because of pain (Celik, 2002; De Carolis, 2001). Except for one loss immediately following surgery at 19 weeks, most underwent cesarean delivery at term. Occasionally, a pedunculated subserosal myoma will undergo torsion with subsequent painful necrosis. Laparoscopy or laparotomy can be used to ligate the stalk and resect the necrotic tumor. That said, we believe that surgery should be limited to tumors with a discrete pedicle that can be easily clamped and ligated.

Pregnancy Complications. Myomas have been associated with several complications that include preterm labor, placental

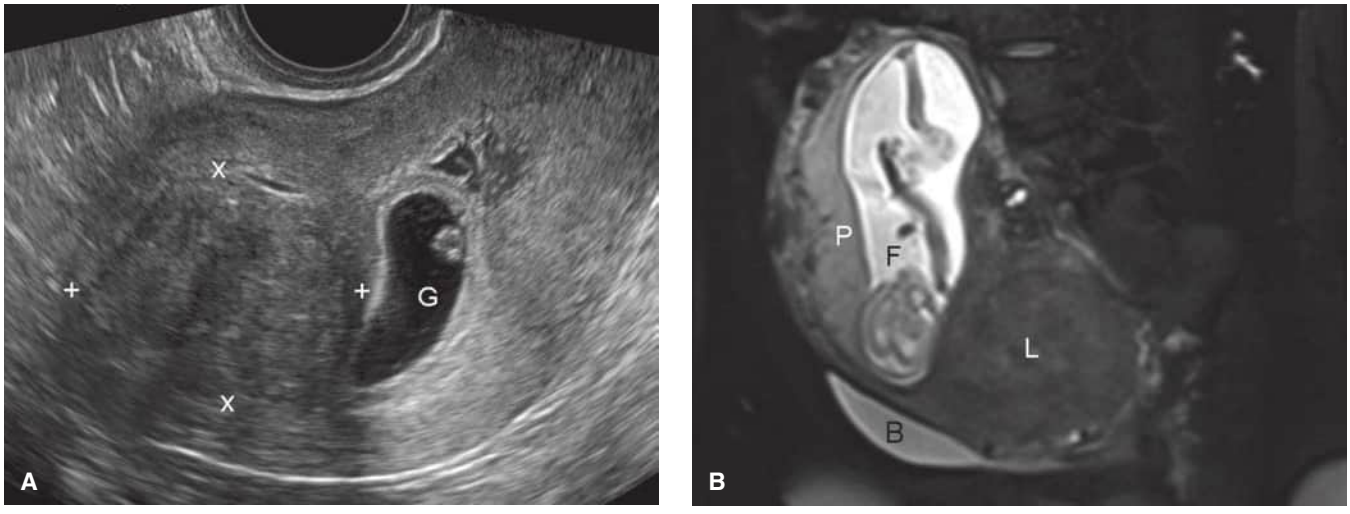

FIGURE 66-3 Leiomyoma imaging. **A.** In this sagittal view from transvaginal sonography, a large uterine leiomyoma (*calipers*) displays heterogeneous echoes and occupies the fundus. This mass lies adjacent to an early first-trimester gestational sac (*G*) that shows a yolk sac. **B.** MR imaging at 16 weeks' gestation shows a large leiomyoma (*L*) in the posterior uterine segment and cervix, which fills the pelvis. Associated ureteral compression and hydronephrosis required placement of a percutaneous nephrostomy tube. At term, planned cesarean delivery was done due to obstruction of the birth canal. B = bladder; F = fetus; P = placenta.

abruption, fetal malpresentation, obstructed labor, cesarean delivery, and postpartum hemorrhage. In a review of pregnancy outcomes in 2065 women with myomas compared with unaffected gravidas, placental abruption and breech presentation were each increased fourfold; first-trimester bleeding and dysfunctional labor, twofold; and cesarean delivery, sixfold (Coronado, 2000). In a report of 301 women with myomas, the preterm birth risk was 2.5-fold higher than in unaffected women (Girault, 2018). Another study reported an eightfold increased second-trimester abortion risk in affected women (Salvador, 2002).

Factors most important in determining morbidity in pregnancy are myoma number, size, and location (Ciavattini, 2015; Jenabi, 2018; Lam, 2014). If the placenta is adjacent to or implanted over a leiomyoma, the risks for abortion, preterm labor, placental abruption, and postpartum hemorrhage are all increased. Retroplacental myomas are also associated with fetal-growth restriction (Knight, 2016). Myoma-related bleeding may stem from miscarriage, preterm labor, placenta previa, and placental abruption. Rarely, bleeding results from a submucous myoma that has prolapsed from the uterus and into the cervix or vagina. In this case, although heavy or persistent bleeding may require earlier intervention, the stalk, if accessible, can be ligated vaginally near term to avoid avulsion during delivery.

Tumors in the cervix or lower uterine segment may obstruct labor (Fig. 66-4). Despite these complications, Qidwai and associates (2006) reported a 70-percent vaginal delivery rate even in women in whom myomas measured ≥10 cm. These data argue against empirical cesarean delivery, and we allow a trial of labor unless myomas clearly obstruct the birth canal. If cesarean delivery is indicated, uterine malrotation, which can be caused by a bulky lateral myoma, should be excluded by palpation of the fundus prior to hysterotomy (Chap. 3, p. 46). Myomas are generally left alone. Specifically, because of enucleation-associated hemorrhage, myomectomy during cesarean delivery is discouraged. Exceptions include recalcitrant intraoperative bleeding or a myoma that prohibits hysterotomy closure. With cesarean delivery in one study, mean hemoglobin levels dropped in those with myomas, but the transfusion rate was not increased (Pergialiotis, 2017). Importantly, cesarean hysterectomy may be technically difficult because of lateral ureteral displacement by the masses.

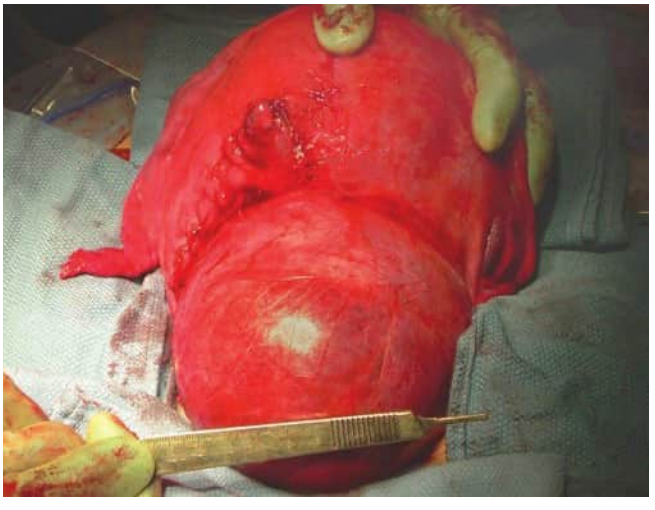

FIGURE 66-4 Cesarean delivery performed because of a large leiomyoma in the lower uterine segment. A classical vertical uterine incision, seen to the left of the myoma, was required for delivery of the fetus.

Fortunately, myomas rarely become infected (Genta, 2001). When infection develops, it usually is postpartum, especially if the tumor is located immediately adjacent to the implantation site (Lin, 2002). They also may become infected with an associated septic abortion or with myoma perforation by a sound, dilator, or curette.

Fertility Considerations. Despite their relatively high prevalence in young women, their negative effect on fertility is unclear. Moreover, evidence from one systematic review was inconclusive to support myomectomy for intramural or subserosal myomas to improve fertility (Metwally, 2020). As an exception, the American Society for Reproductive Medicine (2017) describes fair evidence for hysteroscopic myomectomy of submucous myomas to improve clinical pregnancy rates. In a systematic review of nearly 1400 pregnancies, myomas were not associated with a higher miscarriage rate (Sundermann, 2017).

Instead of an infertility indication, some women may elect myomectomy to treat bleeding or pressure symptoms yet still desire fertility preservation. Importantly, after myomectomy, the gravid uterus can rupture either before or during labor (American College of Obstetricians and Gynecologists, 2021a). Management is individualized, and review of the prior operative report is prudent. If resection resulted in a defect into or immediately adjacent to the endometrial cavity, cesarean delivery is usually done before labor. Timing of cesarean delivery is individualized, and the American College of Obstetricians and Gynecologists (2021b) cites between $37^{0/7}$ and $38^{6/7}$ weeks' gestation.

Uterine artery embolization of myomas is another option for women seeking symptom relief yet desiring fertility preservation (Ludwig, 2020). Women so treated have higher rates of miscarriage, cesarean delivery, and postpartum hemorrhage. The Society of Interventional Radiology considers myoma embolization relatively contraindicated in women who plan future pregnancies (Dariushnia, 2014). Even so, myoma embolization does not harm ovarian reserve (Shamy, 2020).

Endometrial Lesions

With *endometriosis*, studies have recently focused on a link with adverse obstetrical outcomes (Stephansson, 2009; Zullo, 2017). However, data are complicated by heterogeneity regarding disease stage and location, use of ART, and analysis methodologies (Leone Roberti Maggiore, 2016). Despite this, an association with placenta previa is the most consistent.

Occasionally, an *endometrioma* can develop after delivery from endometrial tissue implanted within laparotomy or episiotomy scars. Pfannenstiel incisions carry greater susceptibility than vertical ones (Ecker, 2014). These form a palpable mass and can cause cyclical localized pain. Endometriomas within an ovary are discussed in the next section.

Adenomyosis is traditionally found in late reproductive life and beyond. Its acquisition may be at least partially related to

disruption of the endometrial-myometrial border during sharp curettage for abortion (Curtis, 2002). In one systematic review, miscarriage, poor fetal growth, preeclampsia, placenta previa, and preterm delivery were associated risks (Nirgianakis, 2021).

Endometrial carcinoma is an estrogen-dependent neoplasia also usually found in women aged >40 years and thus seen only rarely with pregnancy (Korenaga, 2020). Of 27 cases that were identified during pregnancy or within the first 4 months postpartum, most were found in first-trimester curettage specimens (Hannuna, 2009). These are usually early-stage, well-differentiated adenocarcinomas for which treatment consists primarily of total abdominal hysterectomy and bilateral salpingo-oophorectomy.

For nonpregnant women, surgical management of early endometrial cancer is also the standard. However, to preserve fertility potential in a well-counseled woman with early-stage, well-differentiated, endometrioid endometrial cancer, treatment with oral or intrauterine progestin therapy can be used to prompt tumor regression (Hamilton, 2021). Notably, live birth rates are low, and a large percentage requires ART for conception (Harrison, 2019). Moreover, recurrences and deaths have been reported (Erkanli, 2010).

Ovary

Ovarian masses found during pregnancy are common. Incidences vary depending on the frequency of prenatal sonography, the ovarian size threshold, and study site designation as tertiary or primary care. Thus, the incidence of ovarian masses not surprisingly ranges from 1 in 100 to 2000 pregnancies (Bacalbaşa, 2020; Korenaga, 2020). Of ovarian malignancies, the incidence in the California Cancer Registry was 1 case in 19,000 pregnancies (Smith, 2003).

The most frequent types of ovarian masses are corpus luteum cysts, endometriomas, benign cystadenomas, and mature cystic teratomas (dermoid cysts). In one series of 53 endometriomas diagnosed in the first trimester, a fourth each remained stable or increased in size, and a third shrank (Bailleux, 2017).

Mature cystic teratomas enlarge infrequently during pregnancy. Rarely, a teratoma may express N-methyl-D-aspartate (NMDA) receptors within the tumor's neural-tissue component. Antibodies form against these receptors within the tumor and then attack similar-looking receptors in the brain. In one case, a pregnant woman developed encephalitis from these antibodies (Mizutamari, 2016).

Because pregnant women are usually young, malignant tumors and those of low malignant potential are proportionately uncommon. One study found that 1 percent of 9375 ovarian masses were frankly malignant and that another 1 percent were of low malignant potential (Leiserowitz, 2006). In surgically excised masses, rates of malignancy are higher, vary from 4 to 13 percent, and probably reflect a greater preoperative concern for cancer (Sherard, 2003).

Diagnosis

Most ovarian masses are asymptomatic. Some cause pressure or chronic pain, and acute abdominal pain may be due to torsion, rupture, or hemorrhage. Rarely, blood loss is sufficient to cause hypovolemia.

Ovarian masses are usually detected during routine prenatal sonography or during imaging for other indications, including symptom evaluation. For complicated anatomy, MR imaging can be used without contrast.

Cancer antigen 125 (CA125) is a tumor marker, and levels are frequently elevated with ovarian malignancy. Importantly, in early pregnancy and early puerperium, CA125 levels are normally elevated, possibly from the decidua. From the second trimester until term, levels are not normally higher than those in the nonpregnant woman (Appendix, p. 1229) (Korenaga, 2020; Szecsi, 2014). With severe preeclampsia, however, concentrations are abnormally elevated (Karaman, 2014). Other tumor markers that have been used for diagnosis or posttreatment surveillance in pregnancy include human chorionic gonadotropin (hCG), alpha-fetoprotein (AFP), inhibins A and B, carcinoembryonic antigen (CEA), and the multimarker OVA1 test (Liu, 2011).

Complications

Torsion and hemorrhage are significant complications of adnexal masses. Torsion usually causes acute constant or episodic lower abdominal pain and tenderness that is accompanied frequently by nausea and vomiting. Transvaginal sonography (TVS) often aids diagnosis, and an adnexal mass is typically comorbid. With color Doppler, absent flow strongly correlates with torsion. However, minimal or early twisting may compromise only venous flow, thus leaving the arterial supply intact. Other sonographic signs are ovarian stromal edema; follicle displacement to the ovarian periphery; free cul-de-sac fluid; the whirlpool sign, which displays twisted vessels of the involved pedicle; and the follicular ring sign (Moro, 2020; Yatsenko, 2021). This last sign is a 1- to 2-mm echogenic rim around antral follicles and may reflect edema and engorged capillaries.

If torsion is suspected, laparoscopy or laparotomy is warranted. Contrary to prior teaching, most now recommend untwisting to save the ovary (Fig. 66-5). Concerns for thrombus release and pulmonary embolism have been allayed (McGovern, 1999). A grossly necrotic adnexum is removed. With a salvageable

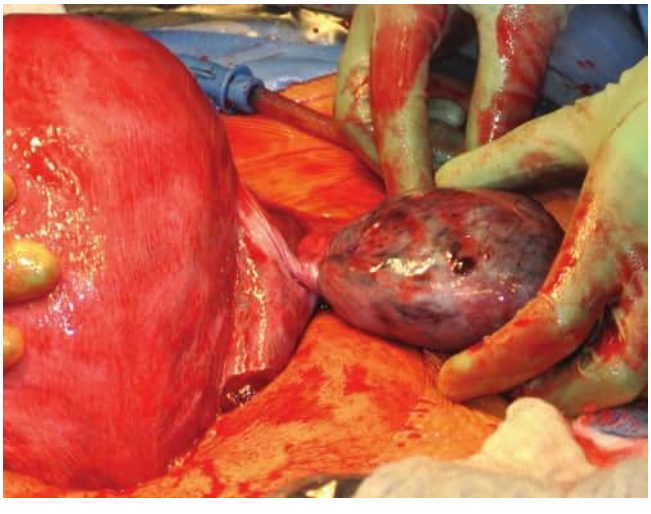

FIGURE 66-5 Ovarian torsion at term. The patient underwent cesarean delivery, and the left uteroovarian pedicle was untwisted. (Reproduced with permission from Dr. C. Edward Wells.)

ovary, within minutes of untwisting, congestion is relieved but the blue-black color typically persists.

If the adnexum is deemed viable, there are options. First, an associated neoplasm is resected. However, ovarian cystectomy in an edematous ovary may be technically difficult, and adnexectomy may be necessary. Less often, cystectomy may be delayed for low-risk lesions to allow easier enucleation following edema resolution (Adeyemi-Fowode, 2019). Second, oophoropexy, especially for a second case of torsion, can minimize recurrence risk (Djavadian, 2004). Techniques described include shortening of the uteroovarian ligament with a running stitch or fixing the uteroovarian ligament to the posterior uterus, the lateral pelvic wall, or the round ligament (Fuchs, 2010).

The most common cause of ovarian hemorrhage follows rupture of a corpus luteum cyst. Symptoms mirror those of hemoperitoneum, and diffuse lower abdominal pain is usual. TVS shows blood in the cul-de-sac and a collapsed ovarian cyst remnant (Fig. 12-5, p. 224). If the diagnosis is certain and symptoms abate, observation and surveillance is usually sufficient. Concern for ongoing bleeding will typically prompt surgical evaluation. If the corpus luteum is removed before 10 weeks' gestation, progestational support is recommended to maintain the pregnancy. Suitable regimens include: (1) micronized progesterone (*Prometrium*), 200 or 300 mg orally once daily; (2) 8-percent progesterone vaginal gel (*Crinone*), one premeasured applicator vaginally daily, plus micronized progesterone, 100 or 200 mg orally once daily; or (3) intramuscular 17-hydroxyprogesterone caproate, 150 mg. The first two regimens are given until 10 completed weeks. For the last, if given between 8 and 10 weeks' gestation, only one injection is required immediately after surgery. If the corpus luteum is excised between 6 and 8 weeks' gestation, two additional doses should be given 1 and 2 weeks after the first.

Asymptomatic Adnexal Mass During Pregnancy

Most of these are incidentally found, and decisions include necessity and timing of resection. A cystic benign-appearing mass measuring <5 cm often requires no additional antepartum surveillance. Early in pregnancy, this is likely a corpus luteum cyst, which typically resolves by the early second trimester. For cysts ≥10 cm, the risk of malignancy, torsion, or labor obstruction is substantial, and surgical removal is reasonable.

Tumors between 5 and 10 cm are carefully evaluated by TVS coupled with color Doppler and possibly MR imaging. Simple-appearing cysts can be managed expectantly with sonographic surveillance (Fig. 66-6) (American College of Obstetricians and Gynecologists, 2016; Schmeler, 2005). Resection is done if cysts grow, display malignant qualities, or become symptomatic. Those with classic findings of endometrioma or mature cystic teratoma may be resected postpartum or during cesarean delivery for obstetrical indications.

On the other hand, if sonographic findings suggest cancer, prompt resection is indicated (Caspi, 2000). Nodules, papillary excrescences, solid components, or thick, vascular septa within the mass or ascites are suggestive findings (Andreotti, 2020). In one review of 563 masses in pregnancy, approximately half were simple, and the other half complex (Webb, 2015). Among simple masses, 1 percent were malignant, and of complex masses, 9 percent were cancerous.

Approximately 1 in 1000 pregnant women undergoes surgical exploration for an adnexal mass (Boulay, 1998). In general, we plan resection at 14 to 20 weeks' gestation because most masses that will regress will have done so by this time. Laparoscopic removal is ideal (Chap. 49, p. 867) (Naqvi, 2015; Sisodia, 2015). Importantly, the American College of Obstetricians and Gynecologists (2016) recommends consultation with a gynecological oncologist for elements implicating cancer that include a very elevated CA125 level, a nodular or fixed pelvic mass, ascites, evidence of metastasis, or ultrasound findings suggesting malignancy.

Pregnancy-Related Ovarian Tumors

One group of ovarian masses results directly from the stimulating effects of various pregnancy hormones on ovarian stroma. These include pregnancy luteoma, hyperreactio luteinalis, and ovarian hyperstimulation syndrome.

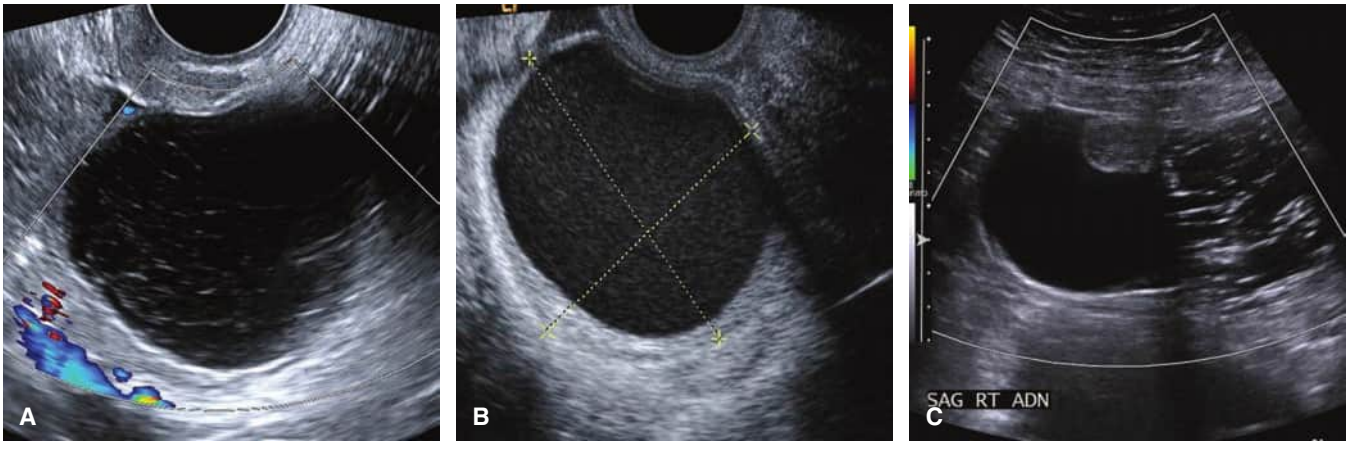

FIGURE 66-6 Sonographic characteristics of common adnexal masses in pregnancy. **A.** A simple hemorrhagic cyst with smooth walls and an internal reticular pattern is characteristic of a physiological corpus luteum cyst. **B.** Homogeneous cystic mass with diffuse internal low-level echoes suggestive of an endometrioma or hemorrhagic corpus luteum. **C.** Mature cystic teratoma (dermoid cyst) appears as a complex adnexal cyst. On the right side, hyperechoic lines and dots represent hair in both longitudinal and transverse planes. At the central superior aspect of this cyst, a mural nodule—the Rokitansky protuberance—is seen. A fat (*right side*)-fluid (*left side*) level is another common finding with these tumors.

Pregnancy Luteoma. This is a rare, benign ovarian neoplasm that arises from luteinized stromal cells and classically raises testosterone levels (Hakim, 2016; Irving, 2011). Up to 25 percent of affected women will be virilized, and of these affected women, nearly half of their female fetuses will have some degree of virilization. However, most mothers and their fetuses may be unaffected because the placenta rapidly converts testosterone to estrogen (Kaňová, 2011).

In typical cases, an adnexal mass along with maternal virilization will prompt sonography and measurement of testosterone and CA125 levels. Luteomas are variably sized, appear solid, may be multiple or bilateral, and may be complex because of internal hemorrhage (Choi, 2000). Concerns for malignancy may be further investigated with MR imaging (Kao, 2005; Tannus, 2009).

Total testosterone levels are increased, but notably, levels in normal pregnancy can be substantially elevated (Appendix, p. 1231). Differential diagnoses include granulosa cell tumors, thecomas, Sertoli-Leydig cell tumors, Leydig cell tumors, stromal hyperthecosis, and hyperreactio luteinalis.

Generally, luteomas do not require surgical intervention unless torsion, rupture, or hemorrhage complicate these (Masarie, 2010). Tumors spontaneously regress during the first few months postpartum, and androgen levels drop precipitously following delivery (Wang, 2005). Lactation may be delayed a week by hyperandrogenemia (Dahl, 2008). Recurrence in subsequent pregnancies is rare.

Hyperreactio Luteinalis. In this condition, one or both ovaries develop multiple, large theca-lutein cysts, typically after the first trimester. Cysts are caused by luteinization of the follicular theca interna layer, and most are stimulated by exceptionally high hCG levels (Russell, 2009). Thus, they are more common with gestational trophoblastic disease, twins, fetal hydrops, and other conditions with increased placental mass (Nassr, 2018). Maternal but not fetal virilization may develop (Malinowski, 2015). Serum testosterone levels are not predictive of maternal virilization (Condic, 2021).

Sonographically, these ovarian tumors have a "spoke wheel" pattern (Fig. 13-3, p. 238) (Baxi, 2014). If the diagnosis is confident, and unless complicated by torsion or hemorrhage, surgical intervention is not required. These masses resolve after delivery. Few data allow prediction of recurrence in a subsequent pregnancy, but in one case report, a woman had hyperreactio with three pregnancies (Bishop, 2016).

Ovarian Hyperstimulation Syndrome. This is typified by multiple ovarian follicular cysts accompanied by increased capillary permeability. It most often is a complication of ovulation-induction therapy for infertility, although it rarely may develop in an otherwise normal pregnancy. Its etiopathogenesis is thought to involve hCG stimulation of vascular endothelial growth factor (VEGF) expression in granulosa-lutein cells (Soares, 2008). This causes greater vascular permeability that can lead to ascites, pleural or pericardial effusion, hypovolemia with acute kidney injury, and hypercoagulability. Serious complications are renal dysfunction, adult respiratory distress syndrome, ovarian rupture with hemorrhage, and VTE. Unlike hyperreactio luteinalis, virilization is absent (Suzuki, 2004).

Management is outlined by the American Society for Reproductive Medicine (2016). Treatment is primarily supportive to maintain vascular volume and prevent VTE. In severe cases, paracentesis can be helpful.

Ovarian Cancer

Malignancies of the ovary are the leading cause of death from genital-tract cancers in all women (American Cancer Society, 2021). Still, the incidence of ovarian malignancy only ranges from 1 case in 20,000 to 50,000 births (Eibye, 2013; Smith, 2003). Of those found in pregnancy, 75 percent are early-stage cancers that carry a 5-year survival rate between 70 and 90 percent (Brewer, 2011). The types of malignancy are also markedly different in gravidas compared with those in older women. In pregnant women, these are, in decreasing order of frequency, germ cell and sex cord-stromal tumors, low-malignant-potential tumors, and epithelial cancers (Morice, 2012).

Pregnancy apparently does not alter the prognosis of most ovarian malignancies. Management is similar to that for nonpregnant women, with the usual proviso that it may be modified depending on gestational age. Thus, if frozen-section histopathological analysis verifies malignancy, surgical staging is done with careful inspection of all accessible peritoneal and visceral surfaces (Bacalbaşa, 2020). Peritoneal washings are taken for cytology, biopsies are obtained from the diaphragmatic surface and peritoneum, omentectomy is completed, and pelvic and infrarenal paraaortic lymph nodes are sampled, if accessible.

If disease is advanced, bilateral adnexectomy and omentectomy will decrease most tumor burden. In early pregnancy, hysterectomy and aggressive surgical debulking procedures may be elected. In other cases, minimal debulking described in the previous paragraph is done, and the operation is terminated. In some cases of aggressive or large-volume disease, chemotherapy can be given during pregnancy while awaiting pulmonary maturation. Monitoring maternal CA125 serum levels during chemotherapy is not accurate in pregnancy (Morice, 2012).

Preventively, increasing parity is one known factor (Fortner, 2019; Huang, 2020). A metaanalysis also found that prior miscarriage or abortion lowered risk (Lee, 2021). Of modifiable factors, combination oral contraceptives and breastfeeding lower ovarian cancer rates (Babic, 2020; Havrilesky, 2013; Iversen, 2018). Discussed in Chapter 39 (p. 682), rates of some ovarian cancers may decline following tubal interruption and perhaps salpingectomy.

■ Adnexal Cysts

Paratubal and paraovarian cysts either are distended remnants of the paramesonephric ducts or are mesothelial inclusion cysts. One autopsy series in nonpregnant women cited an incidence of 5 percent (Dorum, 2005). The most common paramesonephric cyst is the hydatid of Morgagni, which is pedunculated and typically dangles from one of the fimbria. Although these may undergo torsion, other complications are rare, and most are identified during cesarean delivery or puerperal sterilization. In these instances, they can simply be excised or drained by creating a large window in the cyst wall. Neoplastic paraovarian cysts are rare, sonographically and histologically resemble

tumors of ovarian origin, and rarely are of borderline potential or frankly malignant (Korbin, 1998).

Vulva and Vagina

Preinvasive disease in young women—vulvar intraepithelial neoplasia (VIN) and vaginal intraepithelial neoplasia (VAIN)—are seen more often than invasive disease and are commonly associated with HPV infection. As with cervical neoplasia, these premalignant conditions are treated after delivery.

Cancer of the vulva or vagina is generally a malignancy of older women, and thus, these are rarely associated with pregnancy (Amant, 2019; Korenaga, 2020). Even so, any suspicious lesion is biopsied. Most are squamous cell cancers, and treatment is individualized according to the clinical stage and depth of invasion. In a review of 23 cases, investigators concluded that radical surgery for stage I disease was feasible during pregnancy—including in the last trimester (Heller, 2000). It appears that vaginal delivery is not contraindicated if vulvar and inguinal incisions are well healed. In late pregnancy, resection and definitive therapy can often be delayed due to these tumors' typically slow progression (Anderson, 2001). Other vulvar cancer types and vaginal malignancies are rare in pregnancy and mainly the subjects of case reports (Korenaga, 2020; Matsuo, 2009).

BREAST CARCINOMA

Breast cancer incidence in women aged 25 to 40 years has been rising since the 1930s (American Cancer Society, 2021; Lima, 2020). It has an overall relatively high frequency in younger women and is the most frequent cancer complicating pregnancy (see Fig. 66-1) (Alfasi, 2019; de Hann, 2018). From the Nationwide Inpatient Sample, the incidence approximated 1 case in 15,000 births (Maor, 2017). Postponed childbearing was considered partially responsible for the increase in pregnancy-associated breast cancer in Sweden and Denmark (Andersson, 2015; Eibye, 2013). And, as more women choose to delay childbearing, the frequency of associated breast cancer is certain to rise. Genetic mutations underlie some breast cancer cases, and these are discussed in that section (p. 1174).

Diagnosis

More than 90 percent of gravidas with breast cancer have a palpable mass, and greater than 80 percent of cases are self-reported (Brewer, 2011). In pregnancy, clinical assessment, diagnostic procedures, and treatment of women with breast tumors are often slightly delayed (McCormick, 2018). This is partially attributed to pregnancy-induced growth of breast tissue that obscures masses.

Breast mass evaluation does not differ from that for nonpregnant women (Loibl, 2015; McCormick, 2018). Thus, any suspicious breast mass should be pursued to diagnosis. Pragmatically, a palpable discrete mass can be biopsied or excised. To distinguish between a solid and cystic lesion, sonography has high sensitivity and specificity (Navrozoglou, 2008). Mammography is appropriate if indicated, and the fetal radiation risk is negligible—0.04 mGy—with appropriate shielding (Krishna, 2013). But, because breast tissue is denser in pregnancy, mammography has a false-negative rate of 35 to 40 percent (Woo, 2003). If the decision to biopsy is uncertain, MR imaging may be used.

To better classify imaging findings for breast masses, the American College of Radiology (2013) developed the Breast Imaging-Reporting and Data System—BI-RADS. Suitable for sonography, mammographic, and MR imaging results, the intent is to communicate an individual woman's risk of developing breast cancer (Table 66-1).

Cystic breast lesions are simple, complicated, or complex. Simple cysts do not require special management or monitoring, but they may be aspirated if symptomatic. Complicated cysts

TABLE 66-1. American College of Radiology: Breast Imaging Reporting and Data Systems—BI-RADS[a]

BI-RADS Category	Interpretation	
0	Addition mammography views or sonography required	Focal asymmetry, microcalcifications, or a mass identified on a screening mammogram
1	No abnormalities identified	Normal fat and fibroglandular tissue
2	Not entirely normal, but definitely benign	Fat necrosis from a prior excision, stable biopsy-proven fibroadenoma, stable cyst
3	Probably benign <2% probability of malignancy	Circumscribed mass that has been followed for <2 years
4A	Low suspicion for malignancy (2–9%), but intervention required	Probable fibroadenoma, complicated cyst
4B	Moderate suspicion for malignancy (10–49%), intervention required	Partially indistinctly marginated mass otherwise consistent with a fibroadenoma
4C	High suspicion (50–94%), but not classical for carcinoma	New cluster of fine pleomorphic calcifications, ill-defined irregular solid mass
5	Almost certainly malignant (>95% probability)	Spiculated mass, fine linear and branching calcifications
6	Biopsy-proven carcinoma	Biopsy-proven carcinoma

[a]Mammography, sonography, or magnetic resonance imaging.

show internal echoes during sonography, and they sometimes are indistinguishable from solid masses. These are typically aspirated, and if the sonographic abnormality does not resolve completely, a core-needle biopsy is usually performed. Complex cysts have septa or intracystic masses seen sonographically. Because some breast cancer may form complex cysts, excision is usually recommended.

For solid breast masses, evaluation uses the *triple test*, that is, clinical examination, imaging, and core needle biopsy. If all three suggest a benign lesion or if all three suggest a breast cancer, the test is considered *concordant*. A concordant benign triple test is ≥99-percent accurate, and breast lumps in this category can be followed by clinical examination alone. Most masses in pregnancy have these three reassuring features. In contrast, if any of the three assessments suggests malignancy, the mass should be excised.

Management

With breast cancer, a limited search of the most common metastatic sites is completed. For most, this includes a chest radiograph, liver sonography, and skeletal MR imaging (Becker, 2016; Krishna, 2013). MR imaging can also evaluate the abdomen, pelvis, and brain.

Treatment of breast cancer includes an obstetrician, breast surgeon, and medical oncologist. Initially, desires for pregnancy continuation are addressed, and data indicate that pregnancy interruption does not influence the course or prognosis of breast cancer (Cardonick, 2010). With pregnancy continuation, treatment in general mirrors that for nonpregnant women. Important caveats are that chemotherapy and surgery are postponed to the second trimester, and adjuvant radiotherapy is withheld until after delivery (Brewer, 2011). Delay should be avoided as the risk of metastases increases with every few months by 5 to 10 percent (McCormick, 2018).

Surgical treatment may be definitive. In the absence of metastatic disease, either a wide excision or a modified or total mastectomy—each with axillary node staging—can be performed (Rosenkranz, 2006). Staging by sentinel lymph node biopsy and lymphoscintigraphy with technetium-99m is safe. Breast reconstruction, if desired, is typically delayed until after delivery (Viswanathan, 2011). That said, one small series showed good results in 10 pregnant women who underwent immediate reconstruction after mastectomy (Caragacianu, 2016).

Chemotherapy is usually given with both positive- and negative-node breast cancers. In premenopausal women, survival rates with this approach are improved, even if lymph nodes are cancer free. For node-positive disease, multiagent chemotherapy is begun if delivery is not anticipated within several weeks. Cyclophosphamide, doxorubicin, and cisplatin are currently used (Euhus, 2016). If an anthracycline-based agent such as doxorubicin is used, pretherapy maternal echocardiography is performed because of associated cardiotoxicity (Brewer, 2011). Good maternal and perinatal results have been reported (Freret, 2020; McCormick, 2018).

Immunotherapy for breast cancers is now commonplace. Trastuzumab (*Herceptin*) is a monoclonal antibody to the HER2/neu receptor, which is found in approximately a third of invasive breast cancers (Hudis, 2007). The drug is not recommended in pregnancy. This is because HER2/neu is strongly expressed in fetal renal epithelium, and trastuzumab has been linked with miscarriage, fetal renal failure and related oligohydramnios, and preterm birth (Amant, 2010; Azim, 2010).

The effects of pregnancy on the course of breast cancer and its prognosis are complex. Breast cancer is more aggressive in younger women, but whether it is more aggressive during pregnancy in these same women is debatable (Azim, 2014). Clinically, most studies indicate little difference in overall survival rates with pregnancy-associated breast cancer compared with similarly aged and staged nonpregnant women (Beadle, 2009). Other reports note worse overall survival rates with pregnancy-associated breast cancer (Rodriguez, 2008). These investigators do conclude, however, that later disease stages are more prevalent in pregnant women.

Because breast cancer is usually found at a more advanced stage in pregnant women, the overall prognosis is diminished (Andersson, 2015). The aggregate of studies published after 1990 indicate that up to 60 percent of pregnant women have concomitant axillary node involvement at diagnosis. And although, stage for stage, the 5-year survival rate is comparable in pregnant and nonpregnant women, the more advanced stages that are typical of pregnant women worsen their prognosis (Kuo, 2019; Zemlickis, 1992).

Pregnancy Following Breast Cancer

After breast cancer treatment, chemotherapy will render some women infertile, but childbearing options were noted earlier (p. 1164). For those who become pregnant, long-term maternal survival rates are not adversely affected (Averette, 1999; Lambertini, 2019). One metaanalysis found that for women with early breast cancer, pregnancy that occurs 10 months after diagnosis may, in fact, confer a survival benefit (Valachis, 2010). Breastfeeding does not adversely alter the course.

In women successfully treated for breast cancer, recurrence is a concern. Because recurrences are more common soon after treatment, it seems reasonable to delay conception for 2 to 3 years. Hormonal contraceptive methods are contraindicated, and a copper-containing intrauterine device is an excellent method for many. That said, women with breast cancer who subsequently conceive do not appear to have diminished survival rates (Ives, 2006). Those who developed breast cancer within 10 years of delivery have and increased risk for metastases (Goddard, 2019). Importantly, tamoxifen, which may be used long-term following initial therapy, is a teratogen. Discontinuation 2 months prior to conception is recommended (Zydus Pharmaceuticals, 2020).

BRCA1/2 MUTATIONS

Hereditary breast and ovarian cancer (HBOC) syndrome yields a susceptibility to either one or both of these two cancers in individuals with recognized gene mutations (Table 66-2). *BRCA1* and *BRCA2* mutations are preeminent, but others are associated.

Preventively, cancer screening, chemoprevention, prophylactic surgery, and preimplantation testing are options. First,

TABLE 66-2. Some Genes Associated with Hereditary Cancers

Genes with established association with breast cancer										
BRCA1	*BRCA2*	*STK11*	*CDH1*	*PALB2*	*CHEK2*	*ATM*	*TP53*	*PTEN*	*NF1*	*NBN*
Genes with established association with epithelial ovarian cancer[a]										
BRCA1	*BRCA2*	*BR1P1*	*MSH2*	*MSH6*	*MLH1*	*RAD51C*	*RAD51D*			
Genes with established association with uterine cancer										
			MSH2	*MSH6*	*MLH1*	*PMS2*				

[a]*STK11* mutation is associated with ovarian sex-cord stromal tumors but not epithelial types.

American College of Obstetricians and Gynecologists, 2019d; Amin, 2020; Easton, 2015; Menon, 2018; Peters, 2017; Tamura, 2019.

ovarian cancer screening with TVS or serum CA125 levels is not routinely recommended (Daly, 2021). For breast cancer, surveillance in those aged 25 to 29 years is clinical breast examination (CBE) performed by a provider once or twice yearly plus annual breast MR imaging. For older individuals, yearly MR imaging and mammography are alternated every 6 months.

For women with *BRCA1* and *BRCA2* gene mutation, combination oral contraceptives (COC) are recognized chemoprevention for ovarian cancer (Chen, 2019). COC effects on breast cancer risk are conflicting, and studies show no risk or modest increased risk (Daly, 2021). For breast cancer chemoprevention, tamoxifen can lower cancer risk in those with *BRCA2* defects (King, 2001).

Prophylactic bilateral salpingo-oophorectomy (BSO) is recommended after childbearing in those aged 35 to 40 years with *BRCA1* defects and aged 40 to 45 years in those with *BRCA2* mutations (Chen, 2019). BSO or mastectomy also decreases breast cancer risk in these women (Kotsopoulos, 2016; Li, 2016; Rebbeck, 2009).

BRCA1/2 genes are transmitted in an autosomal dominant fashion. In those planning pregnancy, affected women may elect *preimplantation genetic testing* of blastocysts (Chen, 2019). However, with an established pregnancy, *prenatal testing* poses ethical concerns regarding pregnancy termination for a mutation that may not lead to cancer. Currently, testing for conditions that do not accrue until adulthood are discouraged by the American College of Obstetricians and Gynecologists (2020a,b).

Regarding parity, protective benefits for breast cancer in women with either *BRCA* defect show conflicting data (Kotsopoulos, 2018; Pan 2014; Rieder, 2015; Toss, 2017). For ovarian cancer, parity lowers rates for women with *BRCA1* but not *BRCA2* mutations (Kotsopoulos, 2015). Women with either *BRCA* mutation who undergo induced abortion do not have an elevated breast cancer risk (Friedman, 2006). Breastfeeding conveys a protective effect against breast cancer in those with *BRCA1* defects but not *BRCA2* mutations. It lowers ovarian cancer rates for those with either mutation (Kotsopoulos, 2012; 2020).

Among those with either *BRCA* mutation, a breast cancer diagnosis during pregnancy does not lower survival rates compared with similarly affected but not pregnant women (Valentini, 2013). After breast cancer treatment, women with either *BRCA* defect who pursue pregnancy do not experience increase pregnancy complication rates. Moreover, disease-free or overall survival rates are not worsened (Lambertini, 2020; Valentini, 2013).

THYROID CANCER

Palpable thyroid nodules are detected in 4 to 7 percent of the population, and management is found in Chapter 61 (p. 1098). Approximately 10 percent are malignant (Burman, 2015). In pregnancy, thyroid cancer incidence approximates 10 cases per 100,000 births (Spiegel, 2019; Sullivan, 2019). With this diagnosis, pregnancy termination is not necessary. Primary therapy is partial or subtotal thyroidectomy ideally done during the second trimester. Most lesions are well differentiated, and delayed treatment is acceptable (Angell, 2019). For aggressive tumors, however, prompt surgical treatment is recommended. Postoperatively, replacement thyroxine is given. A higher risk for VTE is reported for these women (Spiegel, 2019).

In some thyroid cancer types, radioiodine is used for primary or postoperative treatment. This is contraindicated in both pregnancy and lactation for several reasons. First, iodine-131 transferred transplacentally is avidly trapped by the fetal thyroid gland to cause hypothyroidism. Second, during lactation, the breast also concentrates a substantial amount of iodide. This may pose neonatal risk due to radioiodine-contaminated milk ingestion and raise maternal cancer risk from significant breast irradiation. To limit maternal exposure, a delay of 3 months between lactation and thyroid ablation will more reliably ensure complete breast involution (Sisson, 2011). In women with thyroid cancer who ultimately receive iodine-131 doses, pregnancy should be avoided for 6 months to 1 year. This time ensures thyroid function stability and permits confirmation of cancer remission (Abalovich, 2007).

LYMPHOMAS

Hodgkin Disease

This lymphoma is probably B-cell derived and is cytologically distinguished from other lymphomas by Reed–Sternberg cells.

TABLE 66-3. Lugano Classification Staging System for Hodgkin and Other Lymphomas

Stage	Findings
I	Involvement in a single lymph node region or lymphoid site—e.g., spleen or thymus
II	Involvement of two or more lymph node groups on the same side of the diaphragm or cancer extends from one node group to a nearby organ
III	Involvement of lymph nodes on both sides of the diaphragm 1. Limited to spleen or splenic hilar, celiac, or portal nodes 2. Includes paraaortic, iliac, or mesenteric nodes plus those in II
IV	Extralymphatic involvement—e.g., liver, bone marrow, or lungs

Substage A = no symptoms; substage B = fever, sweats, or weight loss; substage E = extralymphatic involvement excluding liver and bone marrow; X = bulky disease.

Of cancers in pregnancy, lymphomas are common, and gestational rates are rising because of delayed childbearing (see Fig. 66-1) (Horowitz, 2016). In one review from the Nationwide Inpatient Sample, the incidence of Hodgkin lymphoma approximates 1 case in 12,400 births (El-Messidi, 2015).

In more than 70 percent of these cases, lymph nodes painlessly enlarge at sites above the diaphragm, that is, in the axillary, cervical, or submandibular chains. Approximately one third of patients have fever, night sweats, malaise, weight loss, or pruritus. Diagnosis is by histological examination of involved nodes (McCormick, 2018).

The Lugano staging system is applied to Hodgkin and other lymphomas (Table 66-3). For staging, pregnancy limits the use of some radiographic studies, but at minimum, chest radiography, abdominal imaging with sonography or MR imaging, and bone marrow biopsy are completed (Shah, 2020). MR imaging is excellent for evaluating thoracic and abdominal paraaortic lymph nodes.

The current trend for nonpregnant individuals is to administer chemotherapy for all stages of Hodgkin disease. In pregnancy, for early-stage disease in the first trimester, options include pregnancy termination or observation until after 12 weeks' gestation and then multiagent chemotherapy (Eyre, 2015; McCormick, 2018). For most advanced-stage disease after the first trimester, cycles of doxorubicin, bleomycin, vinblastine, and dacarbazine are given. In general, postponement of therapy until fetal maturity is achieved seems justifiable only when the diagnosis is made late in pregnancy.

Women with Hodgkin lymphoma have a higher incidence of VTE (El-Messidi, 2015; Horowitz, 2016). Also, in our experiences, the gravidas—even after they are "cured"—are inordinately susceptible to infection and sepsis. Active antineoplastic therapy only raises this vulnerability.

The overall prognosis with Hodgkin lymphoma is similar to that for nonpregnant women, and 5-year survival rates exceed 90 percent (Maggen, 2019). Pregnancy does not adversely affect the cancer course of this lymphoma, and pregnancy outcomes are not generally adversely affected. For women with disease in remission, pregnancy does not stimulate relapse (Weibull, 2016).

Non-Hodgkin Lymphomas

Although usually B-cell tumors, non-Hodgkin lymphomas can also be T-cell or natural-killer-cell neoplasms. Their biology, classification, and treatment are complex. They are associated with viral infections, and their incidence has risen sharply at least partly because 5 to 10 percent of persons with HIV infection develop lymphoma. Other associated viruses include Epstein-Barr and hepatitis C viruses and human herpes virus 8. Some of these lymphomas are aggressive, and survival rates vary with the type of cell line involved.

Non-Hodgkin lymphomas are infrequent during pregnancy (Pinnix, 2016). They also are staged according to the Lugano system. If diagnosed in the first trimester, pregnancy termination followed by multiagent chemotherapy is recommended for all but indolent or very early disease. These less aggressive forms may be observed in the first trimester, and then full treatment given in the second. One regimen is rituximab plus the CHOP combination of cyclophosphamide, doxorubicin (hydroxydaunorubicin), vincristine [Oncovin], and prednisone. In a study of 80 pregnant women with this regimen, the 3-year survival rate was 73 to 96 percent (Maggen, 2021).

Burkitt lymphoma is an aggressive B-cell tumor associated with Epstein-Barr virus infection. Prognosis is poor, and treatment is multiagent chemotherapy. In an earlier review of 19 women whose pregnancies were complicated by this lymphoma, 17 died within a year of diagnosis (Barnes, 1998).

Leukemias

These malignancies generally arise either from lymphoid tissues—lymphoblastic or lymphocytic leukemias, or from bone marrow—myeloid leukemias. They can be acute or chronic. Adult leukemias are more prevalent after age 40 but still are among the most common malignancies of young women (see Fig. 66-1). In two large registries, the incidence was 1 case in 40,000 to 50,000 births (Nolan, 2020; Smith, 2003). In a review of 72 pregnancies complicated by leukemia from 1975 until 1988, 44 had acute myelogenous leukemia; 20 had acute lymphocytic leukemia; and eight had one of the chronic leukemias (Caligiuri, 1989). Nolan and colleagues (2020) cite similar proportions.

Acute leukemias almost always cause marked peripheral blood count abnormalities, and often the white blood cell count is elevated with readily recognizable circulating blast cells. The diagnosis is made from bone marrow biopsy.

With current multiagent chemotherapy, remission during pregnancy is common, and termination does not further improve the prognosis. In some cases, pregnancy termination before

viability may simplify management of an acutely ill woman. Abortion is a consideration in early pregnancy to avoid potential chemotherapy teratogens. One is all-*trans*-retinoic acid, also known as *tretinoin*, which causes retinoic acid syndrome (Chap. 8, p. 154) (Li, 2020; Santolaria, 2020). Tyrosine kinase inhibitors are another teratogenic group (p. 1163) (Palani, 2015).

Other than these caveats, treatment of gravidas with leukemia is similar to that for nonpregnant women. Acute myeloid leukemia is treated without delay (Ali, 2015). After induction chemotherapy, postremission maintenance therapy is mandatory to prevent a relapse, which is then usually treated with stem-cell transplantation. If allogeneic stem-cell transplantation is indicated, early delivery is considered. With some chronic leukemias, it may be possible to delay therapy until after delivery (Fey, 2008). As with lymphoma, infection and hemorrhage are significant complications that should be anticipated in women with active disease.

Most descriptions of leukemia treatment in pregnancy are single cases or small series (Routledge, 2018; Sanz, 2015). In one review of 58 cases, 75 percent were diagnosed after the first trimester (Reynoso, 1987). Half were acute myelogenous leukemia, which had a remission rate of 75 percent with chemotherapy. Only 40 percent of these pregnancies resulted in a live birth (Caligiuri, 1989). In a more recent report of 92 pregnant women with acute promyelocytic leukemia, 91 percent had a complete remission (Santolaria, 2020).

MALIGNANT MELANOMA

These most often originate from melanocytes in a preexisting nevus. Lesions most often develop in fair-skinned whites and commonly in childbearing-aged women. Pigmented lesions that change in contour or height or show discoloration, bleeding, or ulceration should prompt biopsy (Richtig, 2017).

In some population studies, melanoma is the most frequent malignancy complicating pregnancy (Andersson, 2015; Bannister-Tyrrell, 2015). The reported incidence ranges from <1 to 3 cases per 1000 births (Cottreau, 2019; Eibye, 2013). Many are treated outpatient and thus not entered into tumor registries.

Staging is clinical. Stage I is a melanoma with no palpable lymph nodes; in stage II, lymph nodes are palpable; and in stage III, distant metastases are identified. For patients with stage I, tumor thickness is the single most important predictor of survival. The Clark classification includes five levels of involvement by depth into the epidermis, dermis, and subcutaneous fat. The Breslow scale measures tumor thickness and size, in addition to invasion depth.

Primary surgical treatment for melanoma is determined by the stage and includes wide local resection, sometimes with extensive regional lymph node dissection. The American Academy of Dermatology recommends sentinel lymph node mapping and biopsy using technetium-99m–sulfur colloid, which has a calculated fetal dose of 0.014 mSv or 0.014 mGy (Swetter, 2019). Routine regional node dissection reportedly improves survival rates in nonpregnant patients with microscopic metastases. For gravidas, an algorithm is proposed that begins with resection of the primary tumor under local anesthesia but postpones sentinel lymph node biopsy until postpartum (Broer, 2012). Although prophylactic chemotherapy or immunotherapy is usually avoided during pregnancy, it may be given if indicated by tumor stage and maternal prognosis. In most cases of distant metastatic melanoma, treatment is at best palliative.

Stage-for-stage, survival is equivalent between pregnant and nonpregnant women (Driscoll, 2016; Johansson, 2014). In two studies, half of pregnant women presented with an advanced stage (de Haan, 2017; Sawyers, 2020). Placentas are submitted for histological evaluation to exclude metastasis (p. 1164). Therapeutic abortion does not improve maternal survival rates. Clinical stage is the strongest determinant of survival, and women with deep cutaneous invasion or regional node involvement have the worst prognosis. Approximately 60 percent of recurrences will manifest within 2 years, and 90 percent by 5 years. Thus, most recommend that pregnancy be avoided for 3 to 5 years after surgical resection. Interim contraception can include combination oral contraceptives, as they do not appear to have adverse cancer effects (Still, 2017).

GASTROINTESTINAL TRACT CANCER

Carcinomas of the colon and rectum are the third most frequent cancer in all women in the United States (American Cancer Society, 2021). Their incidence in pregnancy is rising because of delayed childbearing (Murphy, 2018). Even so, colorectal tumors are uncommon before age 40. An approximate incidence of 1 case in 150,000 deliveries was derived from the California Cancer Registry (Smith, 2003). In another report, however, the incidence approximated 1 case in 13,000 pregnancies (Salani, 2014). Of colorectal carcinomas in pregnant women, 80 percent arise from the rectum. In one review, only 41 cases in pregnancy were colon cancers located above the peritoneal reflection (Chan, 1999).

The most frequent symptoms are abdominal pain, distention, nausea, constipation, and rectal bleeding. If symptoms of colon disease persist, digital rectal examination, stool tests for occult blood, and colonoscopy are done. Some gastrointestinal (GI) tract cancers are found because of metastases to the ovary. These *Krukenberg tumors* are tumor-laden ovaries from another, often GI, primary and carry a bleak prognosis (Kodama, 2016).

Colon cancer treatment in gravidas mirrors that for nonpregnant women. Without evidence of metastatic disease, surgical resection is preferred, but most pregnant women have advanced lesions (Al-Ibrahim, 2014). During the first half of pregnancy, hysterectomy is not necessary to perform colon or rectal resection, and thus, therapeutic abortion is not mandated. During later pregnancy, therapy may be delayed until fetal maturation. However, bowel hemorrhage, obstruction, or perforation may force surgical intervention.

Gastric and esophageal cancers are rare in pregnancy. Despite this, persistent unexplained upper GI symptoms should be prompt upper abdominal sonography and perhaps endoscopy.

CHAPTER 67

Infectious Diseases

Infections remain a major cause of maternal and fetal morbidity and mortality worldwide. The unique maternal–fetal vascular interface in some cases serves to protect the fetus from infectious agents, but in other instances it provides a conduit for transmission. Maternal serological status, acquisition mode, gestational age at the time of infection, and immunological status of mother and fetus all influence disease outcome.

The TORCH acronym reflects the infections toxoplasmosis, others, rubella, and cytomegalovirus and herpesvirus infections. These can cross the placenta to cause fetal infection and substantial neonatal sequelae. Of members in the "others" category, parvovirus B19 infection is discussed here. Herpesvirus and syphilis infections are described in Chapter 68.

MATERNAL AND FETAL IMMUNOLOGY

Maternal Immunological Changes

Despite significant advances, many of the maternal immunological adaptations to pregnancy remain unclear. Successful pregnancy results from a complex interplay between the innate and adaptive immune systems to establish fetal tolerance (Chap. 5, p. 93) (Liu, 2017). Within the innate system, decidual natural killer (dNK) cells interact with and aid invasion of fetal extravillous trophoblasts via human leukocyte antigen (HLA)-G (Fig. 21-8, p. 404). Also, cytokines produced during viral infection activate dNK cells to induce protective cytotoxicity (Tilburgs, 2015).

Within the adaptive immune system, a CD4+ subset of T helper cells called regulatory T cells (Tregs) express *forkhead box P3 (FOXP3)*. This is an immune-suppressive transcription factor that plays a critical role in inducing maternal immune tolerance to the fetus (Kahn, 2010). However, this same mechanism compromises maternal defense against bacterial pathogens. Noncoding microRNAs, whose roles are incompletely defined, regulate activation and proliferation of both innate and adaptive immune cells (Robertson, 2017).

In describing infections, *horizontal transmission* is the spread of an infectious agent from one individual to another. *Vertical transmission* is passage of an infectious agent from the mother to her fetus through the placenta, during labor or delivery, or by breastfeeding. Thus, preterm rupture of membranes or prolonged labor may enhance the risk of some neonatal infections (American College of Obstetricians and Gynecologists, 2020b). Table 67-1 shows specific infections by mode and acquisition timing. A final term, the *secondary attack rate*, is the probability that infection develops in a susceptible individual following known contact with an infectious person.

Fetal and Newborn Immunology

The active immunological capacity of the fetus and neonate is compromised compared with that of older children and adults. That said, fetal innate and adaptive immunity begin to develop by 9 to 15 weeks' gestation (McGovern, 2017). The primary fetal response to infection is mediated by innate immunity—macrophages and dendritic cells—and to a lesser extent, by adaptive immunity—B and T cells (Chougnet, 2018). Passive immunity

TABLE 67-1. Specific Causes of Some Fetal and Neonatal Infections

Intrauterine
Transplacental
Viruses: varicella-zoster, coxsackie, rubella, CMV, human parvovirus B19, HIV, Zika, SARS-CoV-2
Bacteria: *Listeria*, syphilis, *Borrelia*
Protozoa: toxoplasmosis, malaria
Ascending infection
Bacteria: GBS, coliforms
Viruses: HIV
Intrapartum
Maternal exposure
Bacteria: gonorrhea, chlamydia, GBS, tuberculosis, mycoplasmas
Viruses: HSV, HPV, HIV, hepatitis B, hepatitis C, Zika
External contamination
Bacteria: staphylococcus, coliforms
Viruses: HSV, varicella zoster
Neonatal
Human transmission: staphylococcus, HSV, influenza, SARS-CoV-2
Respirators and catheters: staphylococcus, coliforms

CMV = cytomegalovirus; GBS = group B *Streptococcus*; HIV = human immunodeficiency virus; HPV = human papillomavirus; HSV = herpes simplex virus; SARS-CoV-2 = severe acute respiratory syndrome coronavirus-2.

is provided by maternal immunoglobulin G (IgG) transferred across the placenta. By 16 weeks' gestation, this transfer begins to rise rapidly, and by 26 weeks, fetal concentrations are equivalent to those of the mother. Evidence suggests maternal vaccination also primes the fetal cell-mediated immune response independent of passive immunity (Wilcox, 2018).

Neonatal infection, especially in its early stages, may be difficult to diagnose because these newborns often fail to express classic clinical signs. If the fetus was infected in utero, it may be depressed and acidotic at birth for no apparent reason. The neonate may suck poorly, vomit, or show abdominal distention. Respiratory insufficiency can develop, which may present similarly to idiopathic respiratory distress syndrome. The neonate may be lethargic or jittery. The response to sepsis may be hypothermia rather than hyperthermia, and the total leukocyte and neutrophil counts can be depressed.

VIRAL INFECTIONS

Cytomegalovirus

The most common perinatal infection in the developed world is caused by cytomegalovirus (CMV). It is a ubiquitous DNA herpesvirus that eventually infects most humans, and some evidence of fetal infection is found in 0.2 to 2.2 percent of all neonates (American College of Obstetricians and Gynecologists, 2020a). The virus is secreted into all body fluids, and person-to-person contact with viral-laden saliva, semen, urine, blood, and nasopharyngeal and cervical secretions can transmit infection. The fetus may become infected by transplacental viremia, but amniocentesis does not result in iatrogenic fetal transmission (Revello, 2008). The neonate is infected at delivery or during breastfeeding and acquisition continues to accrue. Day-care centers, for example, are a frequent source.

Up to 85 percent of women from lower socioeconomic backgrounds are seropositive by the time of pregnancy, whereas only half of women in higher income groups have detectable IgG antibodies to CMV. Following primary CMV infection, and behaving similarly to other herpesvirus infections, the virus becomes latent but undergoes periodic reactivation characterized by viral shedding. This occurs despite high serum levels of anti-CMV IgG antibody. These antibodies do not prevent maternal recurrence, reactivation, or reinfection, nor do they totally mitigate fetal or neonatal infection.

Maternal Infection

Pregnancy does not increase the risk or severity of maternal CMV infection. Most primary infections are asymptomatic, but 10 to 15 percent of infected adults have a mononucleosis-like syndrome characterized by fever, pharyngitis, lymphadenopathy, and polyarthritis. Immunocompromised women may develop myocarditis, pneumonitis, hepatitis, retinitis, gastroenteritis, or meningoencephalitis. Most women with primary infection have elevated serum aminotransferase levels or lymphocytosis. Reactivated disease usually is asymptomatic, although viral shedding is common.

Because most primary maternal infections are clinically silent, they are detected by IgG seroconversion. The rate of seroconversion during pregnancy may reach 20 percent. Rates are higher in regions with greater seroprevalence (Mussi-Pinhata, 2018). Women who are seronegative before pregnancy and then acquire primary CMV infection during pregnancy are at highest risk of having a congenitally infected fetus. Vertical transmission rates for primary infection are 30 to 36 percent in the first trimester, 34 to 40 percent in the second, and 40 to 72 percent in the third (American College of Obstetricians and Gynecologists, 2020a**;** Picone, 2017). Approximately 23 percent of congenital CMV infections in the United States are from primary maternal infection (Wang, 2011).

In contrast, recurrent or reactivated maternal infection infects the fetus in only 0.15 to 2 percent of pregnancies. However, up to 90 percent of congenitally infected neonates in high-prevalence areas are born to women with recurrent infection (Mussi-Pinhata, 2018). The diagnosis of recurrent or reactivated maternal CMV infection remains a challenge (Tanimura, 2017).

Congenital Infection

Newborns with apparent sequelae of intrauterine-acquired CMV infection are described as having *symptomatic CMV infection*. Congenital CMV infection is a syndrome that may include growth restriction, microcephaly, intracranial calcifications, chorioretinitis, mental and motor delays, sensorineural deficits, hepatosplenomegaly, jaundice, hemolytic anemia, and thrombocytopenic purpura. An example of periventricular calcifications is shown in Figure 67-1. Of the estimated 40,000

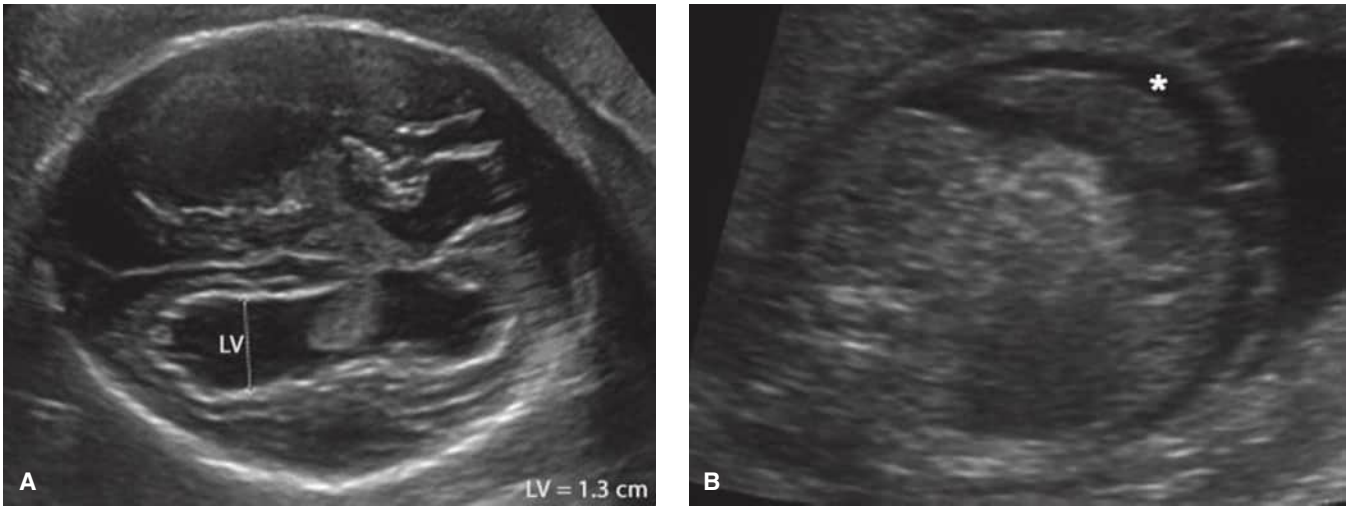

FIGURE 67-1 Congenital cytomegalovirus infection. **A.** Transverse view of the fetal head demonstrates ventriculomegaly (*LV*) and periventricular calcifications. **B.** Transverse image of the fetal abdomen with ascites (*asterisk*) and echogenic bowel.

CMV-infected neonates born each year, only 5 to 10 percent demonstrate this syndrome (Fowler, 1992). Thus, most infected newborns are asymptomatic at birth, but some develop late-onset sequelae. These may include hearing loss, neurological deficits, chorioretinitis, psychomotor delay, and learning disabilities. Infections in dichorionic twins most likely are nonconcordant (Egaña-Ugrinovic, 2016).

Prenatal Diagnosis

Routine prenatal CMV serological screening is not recommended. Pregnant women undergo serological testing for CMV if they present with a mononucleosis-like illness or if congenital infection is suspected based on abnormal sonographic findings (Fig. 67-2) (American College of Obstetricians and Gynecologists, 2020a; Society for Maternal-Fetal Medicine, 2016). If

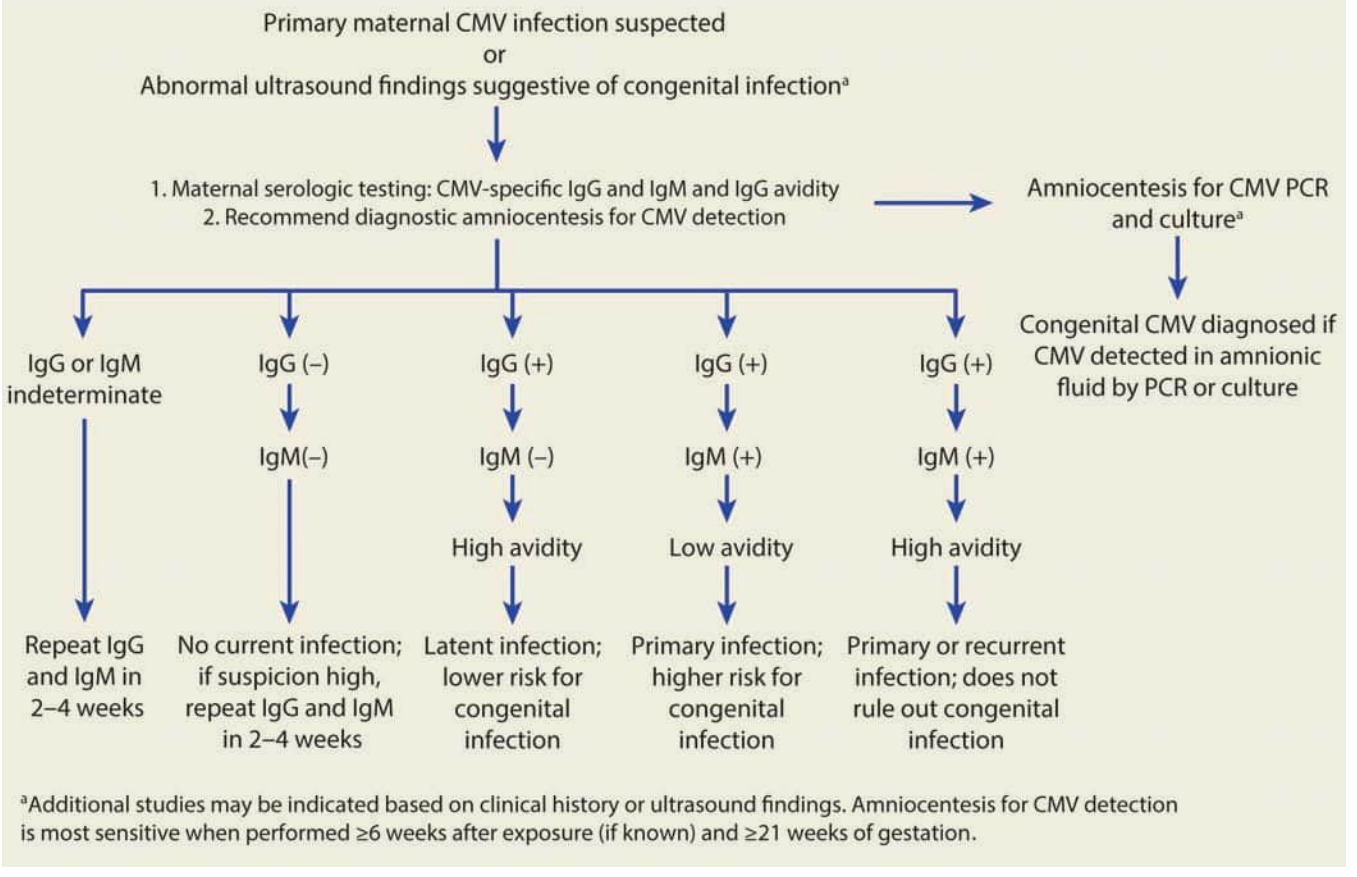

FIGURE 67-2 Diagnostic algorithm for evaluation of cytomegalovirus (CMV) infection in pregnancy. IgG = immunoglobulin G; IgM = immunoglobulin M; PCR = polymerase chain reaction.

either ultrasound or serological results indicate infection, diagnostic amniocentesis is pursued.

Serum levels of CMV IgM alone do not accurately diagnose primary infection because antibodies may persist for more than a year after infection and may rise again following reactivation or reinfection. To help clarify a primary infection from a past one, serological CMV-specific IgG avidity assays measure the "avidity" or binding strength between IgG antibodies and virus. Following primary infection, IgG antibodies have low avidity, which during the next 2 to 4 months matures to high avidity. Low IgG avidity indicates primary CMV infection within the preceding 3 to 4 months, and high IgG avidity excludes primary infection within the previous 3 months. Thus, primary infection during the first trimester may not be excluded if maternal avidity testing is performed in the second or third trimesters (Prince, 2014). In this case, diagnostic amniocentesis is still recommended if ultrasound findings suggest congenital infection. In other cases, early primary infection may be so recent that IgM is not yet detectable. If suspicion is high, serological assays are repeated in 2 to 4 weeks.

More commonly, numerous sonographic fetal findings may prompt CMV testing. Fetal abnormalities associated with CMV infection include microcephaly, ventriculomegaly, and cerebral calcifications; ascites, hepatomegaly, splenomegaly, and hyperechoic bowel; hydrops; early growth restriction; and oligohydramnios. Findings will prompt maternal serological CMV testing and diagnostic amniocentesis (see Fig. 67-2).

CMV polymerase chain reaction (PCR) testing of amnionic fluid is considered the gold standard for the diagnosis of fetal infection. Sensitivities range from 70 to 99 percent and depend on amniocentesis timing. Sensitivity is highest when amniocentesis is performed at least 6 weeks after maternal infection and after 21 weeks' gestation (Guerra, 2000). Abnormal sonographic findings seen in combination with positive findings in amnionic fluid samples are predictive of an approximate 75-percent risk of symptomatic congenital infection (Leruez-Ville, 2016a). A negative result from amnionic fluid PCR testing does not exclude fetal infection and may need to be repeated if suspicion for fetal infection is high. Diagnostic viral culture of amnionic fluid is also suitable although sensitivity is somewhat lower. Isolation of virus from cell culture allows detection of actively replicating virus, and rapid shell vial culture methods enable detection within 24 hours (Saldan, 2017).

Management and Prevention

The management of the immunocompetent pregnant woman with primary, reactivated, or recurrent CMV is limited to symptomatic treatment. If primary CMV infection is diagnosed serologically or if fetal sonographic abnormalities suggest congenital infection, amnionic fluid analysis should be offered (see Fig. 67-2). Counseling regarding fetal outcome depends on the gestational age during which primary infection is documented. Lipitz and associates (2013) reported hearing loss or neurodevelopmental delay in 15 to 25 percent of infants following primary maternal infection in the first trimester compared with 2 to 16 percent after second-trimester infection. Despite the high infection rate with primary infection in the first half of pregnancy, most fetuses develop normally. That said, pregnancy termination may be an option for some.

Currently, no curative treatments are available for CMV infection. One study group reported that treating pregnant women with high-dose oral valacyclovir, 8 g daily, apparently mitigated adverse outcomes for 80 percent of moderately asymptomatic fetuses compared with a historical cohort (Leruez-Ville, 2016b). Kimberlin and colleagues (2015) previously showed that oral valganciclovir administered for 6 weeks to neonates with symptomatic central nervous system (CNS) disease prevented hearing deterioration at 6 months and possibly later. In a recent randomized trial, CMV-specific hyperimmune globulin given to pregnant women with primary infection was ineffective in lowering perinatal CMV infection rates (Hughes, 2021).

For the CMV-affected fetus, a detailed anatomical sonographic evaluation is performed. Referral to a maternal–fetal medicine specialist is warranted, and serial sonography is indicated to identify poor growth, oligohydramnios, or fetal hydrops, which confers a worse prognosis. Antenatal surveillance is typically implemented after a shared discussion about the goals of surveillance in a fetus with known congenital infection. Delivery at term is the goal, although consultation with maternal–fetal medicine and neonatology experts is warranted to determine whether earlier delivery is indicated.

Prevention of congenital infection relies on avoiding maternal primary infection, especially in early pregnancy. Basic hygiene measures such as hand washing and not sharing food or utensils have been promoted, particularly in women with toddlers in day care (Rawlinson, 2017). CMV may be sexually transmitted among infected partners, but no data address the efficacy of preventive strategies. Several clinical trials of a CMV vaccine are underway (Gerna, 2019).

Varicella-Zoster Virus

Maternal Infection

Varicella-zoster virus (VZV) is a double-stranded DNA herpesvirus acquired predominantly during childhood, and 90 percent of adults have serological evidence of immunity. The incidence of varicella infection declined by approximately 95 percent after the introduction of varicella vaccination. Maternal and fetal varicella rates subsequently dropped (Baxter, 2014). In the United States between 2003 and 2010, the incidence of maternal varicella among 7.7 million pregnancy admissions was 1.21 cases in 10,000 (Zhang, 2015).

Primary infection—*varicella* or *chickenpox*—is transmitted by respiratory droplets or through direct contact with an infected individual. The incubation period is 10 to 21 days, and a nonimmune woman has a 70- to 90-percent risk of becoming infected after exposure (Whitley, 2018). Primary varicella has a 1- to 2-day flu-like prodrome, which is followed by pruritic vesicular lesions that crust after 3 to 7 days. Affected patients are contagious from 1 day before the rash onset until all lesions become crusted.

In adults, mortality risk rises with age and is predominantly due to secondary infection or VZV pneumonia (Leung, 2018). Risk factors for severe pneumonitis include immunosuppression and early bacterial co-infection (Mirouse, 2017). Although

the incidence was once thought to be higher in gravidas, only 2.5 percent develops VZV pneumonia (Zhang, 2015).

Symptoms of VZV pneumonia usually appear 3 to 5 days into the illness course. Fever, tachypnea, dry cough, dyspnea, and pleuritic pain are characteristic. Nodular infiltrates are similar to other viral pneumonias. Although resolution of pneumonitis parallels that of skin lesions, fever and compromised pulmonary function may persist for weeks.

If primary varicella is reactivated years later, it causes *herpes zoster* or *shingles*. The associated unilateral dermatomal vesicular eruption often produces severe pain. Zoster does not appear to be more frequent or severe in gravidas. Congenital varicella syndrome rarely develops in cases of maternal herpes zoster (Ahn, 2016). Zoster is contagious if there is direct contact with broken blisters.

Fetal and Neonatal Infection

In women with primary varicella during the first half of pregnancy, the fetus may develop *congenital varicella syndrome*. Some features include chorioretinitis, microphthalmia, cerebral cortical atrophy, growth restriction, hydronephrosis, limb hypoplasia, and cicatricial skin lesions (Ahn, 2016; Auriti, 2009). Among 1373 pregnant women with primary varicella infection in one study, only 0.4 percent with a rash before 13 weeks' gestation had neonates with congenital varicella syndrome (Enders, 1994). The highest risk period for vertical transmission was between 13 and 20 weeks, during which 2 percent of exposed fetuses had evidence of infection. After 20 weeks' gestation, the researchers found no clinical evidence of congenital varicella. Others described similar findings (Ahn, 2016). That said, fetuses that do develop congenital varicella in the third trimester may have CNS abnormalities and skin lesions (Koren, 2005).

If the fetus or neonate is exposed to active infection just before or during delivery, and therefore before maternal antibody has formed, the newborn faces a serious threat. Attack rates range from 25 to 50 percent, and mortality rates approach 30 percent. In some instances, neonates develop disseminated visceral and CNS disease, which is commonly fatal. For this reason, *varicella-zoster immune globulin (VariZIG)* should be administered to neonates born to mothers who have clinical evidence of varicella 5 days before and up to 2 days after delivery (Centers for Disease Control and Prevention, 2013).

Diagnosis

Prior maternal varicella is usually confirmed clinically based on reported history of prior illness or vaccination. Infection is confirmed by PCR-based testing of vesicular fluid or of a crust that is lifted from the skin. Congenital varicella may be diagnosed using PCR-based testing of amnionic fluid, although a positive result does not correlate well with the development of congenital infection (Mendelson, 2006). A detailed anatomical sonographic evaluation performed at least 5 weeks after maternal infection may disclose abnormalities, but the sensitivity is low (Mandelbrot, 2012).

Management and Prevention

Maternal Viral Exposure. *Any patient diagnosed with primary varicella infection or herpes zoster should be isolated from pregnant women.* Several aspects of maternal VZV exposure and infection in pregnancy affect management. Exposed gravidas with a negative clinical history for prior chickenpox or vaccination should undergo VZV serological testing. At least 70 percent of these women will be seropositive and thus immune. Seronegative women should be given intramuscular VariZIG, 125 units per 10 kg body weight, up to a maximum dose of 625 units (5 vials). Although best given within 96 hours of exposure, its use is approved for up to 10 days to prevent or attenuate varicella infection (Centers for Disease Control and Prevention, 2013). This passive immunization appears to be highly effective (Jespersen, 2016). In women with a reported history of chickenpox or varicella vaccination, VariZIG is not indicated.

Maternal and Fetal Infection. For women with primary varicella, a chest radiograph is recommended by many because VZV pneumonia often presents with few symptoms. Most women require only supportive care, but those who require intravenous fluids and especially those with pneumonia are hospitalized. Acyclovir therapy is given to women requiring hospitalization—10 to 15 mg/kg intravenously every 8 hours until afebrile. This is followed by oral acyclovir, 800 mg five times daily to complete 7 days and until lesions have crusted. For uncomplicated primary varicella without hospitalization or for herpes zoster, treatment is oral acyclovir, 800 mg five times daily for 7 days.

For the VZV-affected fetus, greater antenatal surveillance is typically implemented. Serial sonography may help identify poor growth. Delivery at term is the norm unless fetal findings prompt earlier timing.

Vaccination. An attenuated live-virus vaccine is recommended for nonpregnant adolescents and adults with no history of varicella. Two doses are needed and are separated by 4 to 8 weeks. The vaccine is not recommended for gravidas or for those who may become pregnant within one month following each vaccine dose. However, a registry of more than 1000 vaccine-exposed pregnancies reports no cases of congenital varicella syndrome or other associated congenital malformations (Peppa, 2020). The attenuated vaccine virus is not secreted in breast milk. Thus, postpartum vaccination should not be delayed because of breastfeeding (American College of Obstetricians and Gynecologists, 2019e).

■ Influenza Virus

Influenza A and B belong to the Orthomyxoviridae family of RNA viruses, and both cause epidemic human disease (Wright, 2018). Influenza A viruses are subclassified further by hemagglutinin (H) and neuraminidase (N) surface antigens. Influenza outbreaks occur annually, and severity is determined by the number of outpatient visits, hospitalizations, and deaths (Xu, 2019).

Maternal Infection

Fever, dry cough, and systemic symptoms characterize this infection, which usually is not life-threatening in otherwise healthy adults. However, pregnant women in general are more susceptible to serious complications, particularly pulmonary

involvement (Mertz, 2017; Rasmussen, 2012). Severe infection during the 2009 to 2010 pandemic had a maternal mortality rate of 1 percent and caused 12 percent of pregnancy-related deaths (Callaghan, 2015).

No firm evidence links influenza A virus and congenital malformations. Rather, the increased rates of neural-tube defects seen in neonates born to women with influenza may be associated with hyperthermia. Viremia is infrequent, and transplacental passage is rare (Rasmussen, 2012). Stillbirth, preterm delivery, and first-trimester abortion have all been reported, but these usually correlate with maternal infection severity (Fell, 2017; Meijer, 2015; Wang, 2021).

Influenza may be detected by nasopharyngeal swab of symptomatic patients using rapid molecular or viral antigen detection assays known as rapid influenza diagnostic tests (RIDTs). Recently, commercially available multiplex molecular assays have allowed nucleic acid detection and differentiation of both influenza and severe acute respiratory syndrome (SARS)-CoV-2 respiratory viruses. Molecular tests are more sensitive and specific than RIDTs, which have sensitivities of 50 to 70 percent. *Decisions to administer antiviral medications for influenza treatment or chemoprophylaxis should be based on clinical symptoms and epidemiological factors*. Namely, the start of therapy should not be delayed pending testing results.

Management

Of available agents, *neuraminidase inhibitors* are highly effective for the treatment of early influenza A and B. These include *oseltamivir* (Tamiflu), which is taken orally for treatment and for chemoprophylaxis; *zanamivir* (Relenza), which is inhaled for treatment; and *peramivir* (Rapivab), which is administered intravenously. A newer agent, *baloxavir marboxil* (Xofluza), was approved by the U.S. Food and Drug Administration in 2018 for acute uncomplicated influenza, although data in pregnancy are limited.

In pregnancy, experience is most robust with oseltamivir. The American College of Obstetricians and Gynecologists (2019a) and the Infectious Diseases Society of America recommend oral oseltamivir—75 mg twice daily for 5 days—for pregnant women with suspected or confirmed influenza, ideally within 48 hours of symptom onset (Uyeki, 2019). Early administration may reduce length of hospital stays (Oboho, 2016). For prophylaxis following exposure to a contact with confirmed infection, oseltamivir, 75 mg orally once daily for 7 days, is recommended. Antibacterial medications are added when a secondary bacterial pneumonia is suspected (Chap. 54, p. 962).

Vaccination

Effective vaccines against influenza are formulated annually and encouraged for all women who will be pregnant during the influenza season, which extends from October through March. Vaccination throughout the influenza season, but optimally before the end of October, is recommended (American College of Obstetricians and Gynecologists, 2019c; Grohskopf, 2020). This is especially important for those affected by chronic medical disorders such as diabetes, heart disease, asthma, or human immunodeficiency virus (HIV) infection. Influenza vaccination was associated with a 40-percent reduction in influenza-associated hospitalizations in pregnant women (Thompson, 2019).

Importantly, no evidence shows teratogenicity or developmental problems in children exposed to maternal vaccination (Conlin, 2018; Ludvigsson, 2016). Moreover, for mothers vaccinated during pregnancy, their infants are protected from lower respiratory tract infections for the first 3 months of life (Nunes, 2017). All inactivated or recombinant influenza vaccines may be used in gravidas (Grohskopf, 2020). However, a live attenuated influenza virus vaccine available for intranasal use is not recommended for pregnant women. Inactivated or recombinant influenza vaccines may be administered concomitantly or sequentially with other vaccines including COVID-19 and tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) vaccines.

Coronavirus

These single-stranded RNA viruses are named for the "crown" of surface proteins covering the particles. Seven coronaviruses infect humans, four of which cause upper respiratory disease characterized by rhinorrhea, sneezing, and congestion (Cui, 2019). Three newer coronaviruses of zoonotic origin have emerged in the past two decades and may cause serious lower respiratory tract illness in humans. These are SARS-CoV, Middle East respiratory syndrome (MERS-CoV), and the novel coronavirus of 2019 (SARS-CoV-2).

The first SARS-CoV emerged from China in 2003 and infected more than 8000 people. In a cohort of 12 pregnant women with confirmed infection, the predominant symptoms were myalgia, chills, and cough (Wong, 2004). All women had radiographic evidence of atypical pneumonia, 33 percent required mechanical ventilation, and 80 percent of women diagnosed after 24 weeks' gestation delivered preterm. Although no vertical transmission occurred, the maternal fatality rate was 25 percent.

MERS-CoV emerged in the Middle East in 2012 and can cause respiratory illness, acute kidney injury, and gastrointestinal illness (Hui, 2018). Although experience with MERS-CoV in pregnancy is limited, the mortality rate in a small series was 40 percent (Assiri, 2016).

SARS-CoV-2

This virus causes the clinical illness known as coronavirus disease 2019 (COVID-19). The SARS-CoV-2 pandemic began in China in late 2019, and by mid-2021 it had caused respiratory illness in more than 151 million people and 3 million deaths globally (World Health Organization, 2021). The mortality rate is between 1 and 2 percent in adults, and it increases sharply with age (Verity, 2020). Compared with MERS-CoV and SARS-CoV, SARS-CoV-2 is more infectious but less deadly. Variants with increased transmissibility are emerging, and the Delta (B.1.617.2) variant has recently predominated (Centers for Disease Control and Prevention, 2020a). Evidence suggests increased disease severity in gravidas who acquire this variant (Adhikari, 2021).

SARS-CoV-2 is predominantly transmitted via respiratory droplets. Asymptomatic or presymptomatic individuals account for 40 to 50 percent of transmissions (He, 2020; Kimball, 2020). The immune response to natural infection appears to require both humoral and cell-mediated immunity (Hartley, 2020). Because of the potential for asymptomatic transmission,

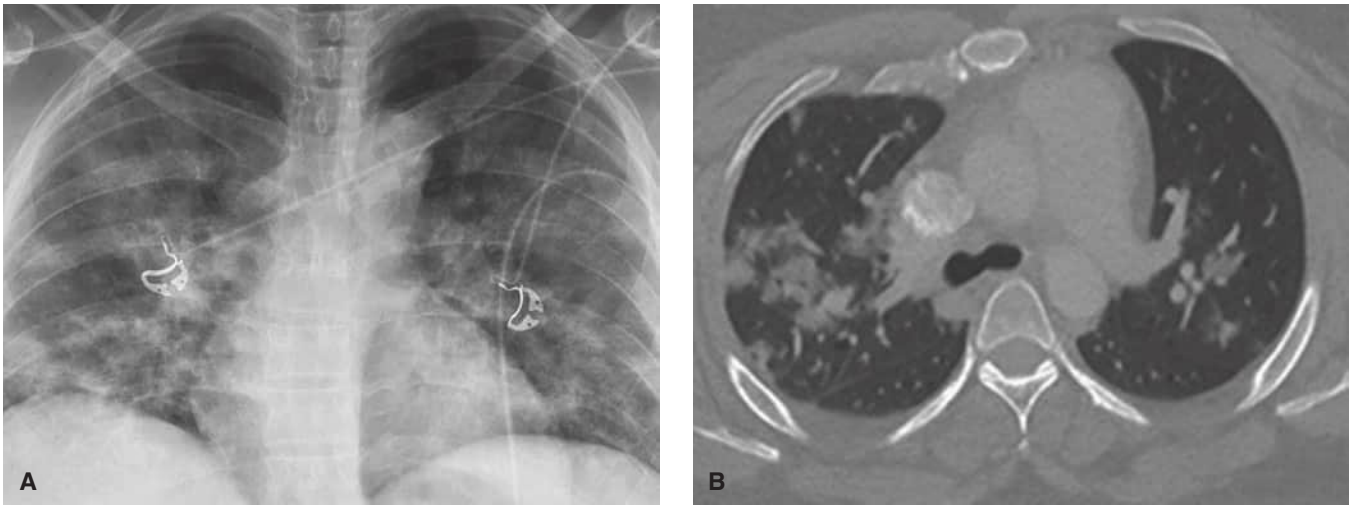

FIGURE 67-3 **A.** Chest radiograph of a critically ill pregnant woman at 26 weeks' gestation demonstrating diffuse bilateral pulmonary opacities with peripheral predominance. **B.** Axial image of the chest from a computed tomographic scan demonstrates advanced COVID-19 disease with multiple peripheral lobular consolidations and ground glass opacities.

interventions such as masking and social distancing are recommended (Centers for Disease Control and Prevention, 2021b).

Maternal Infection

COVID-19 symptoms in gravidas do not differ from those in nonpregnant individuals. An incubation period of approximately 5 to 14 days is followed by fever, cough, and myalgia. Loss of smell (anosmia) and taste (ageusia) are reported in more than half of patients (Patel, 2020). Diarrhea, nausea, and vomiting are somewhat less common. Lower respiratory involvement develops in some individuals approximately 8 days after symptom onset (Huang, 2020). Signs of worsening of disease include dyspnea, tachypnea, decreased oxygen saturation, and rarely, acute respiratory distress syndrome. Imaging indicative of moderate to severe viral pneumonia reveals multifocal opacities in a predominantly peripheral distribution and ground glass opacities on computed tomography (Fig. 67-3). Pregnant women may be at higher risk for intensive care unit admission, invasive ventilation, and death (Zambrano, 2020). A study from Parkland Hospital demonstrated that 5 percent of infected gravidas developed severe or critical illness, and diabetes may be a risk factor (Adhikari, 2020). Although COVID-19 was not associated with adverse pregnancy outcomes, women with severe illness experienced a higher rate of preterm birth. In a surveillance program of COVID-19 in pregnant women, the rate of preterm birth was higher than the general population—13 percent compared with 10 percent (Woodworth, 2020).

Fetal Infection

Infection of the placenta by SARS-CoV-2 has been demonstrated, but transmission to the fetus is rare (Schwartz, 2020). Microscopic examination of the placenta may demonstrate inflammation and syncytiotrophoblast necrosis (Fig. 67-4). Standardized criteria have been proposed for determining definite, probable,

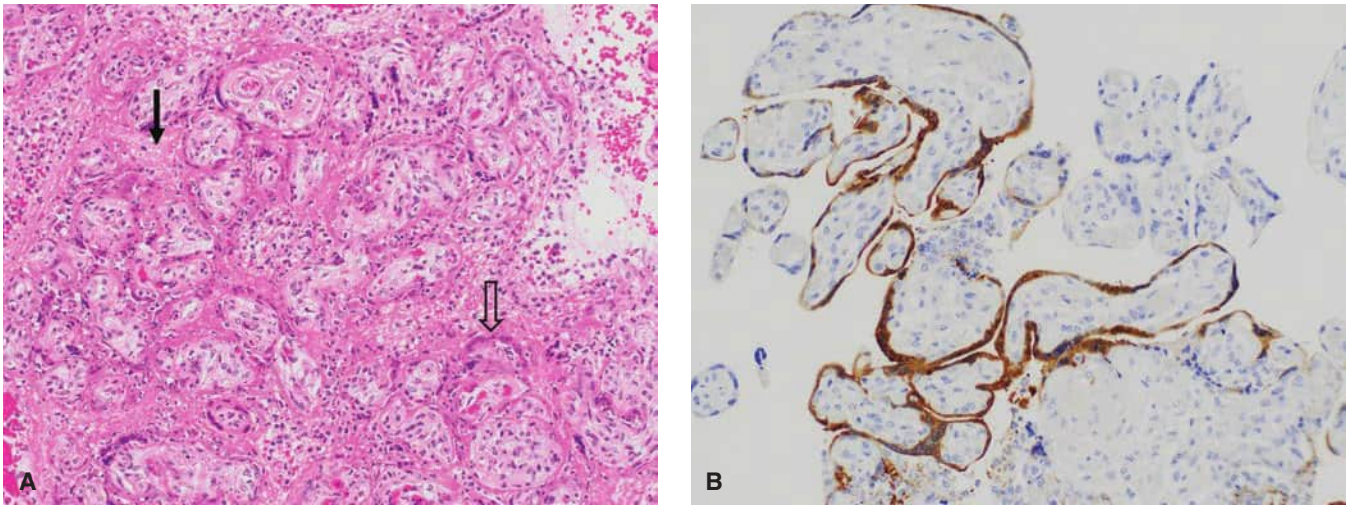

FIGURE 67-4 Placental SARS-CoV-2 infection. **A.** Histologic slide of a placenta with known maternal SARS-CoV-2 infection. Large, discrete areas of the placenta showed increased perivillous fibrin (*solid arrow*), focal trophoblast necrosis (*open arrow*), and marked histiocytic inflammation. **B.** Anti-SARS-CoV-2 viral nucleocapsid antibody is positive in villous trophoblast (*brown immunostaining*), confirming placental infection. (Reproduced with permission from Dr. Rebecca Collins.)

or possible placental infection by SARS-CoV-2 (Roberts, 2021). When vertical transmission does occur, infected neonates may have asymptomatic, mild, or severe illness (Raschetti, 2020; Sisman, 2020). Adhikari and associates (2020) demonstrated infection in 3 percent of neonates tested at 24 and 48 hours after birth. Mechanisms of vertical transmission are poorly understood. No evidence suggests transmission of SARS-CoV-2 through breastmilk (Centeno-Tablante, 2021). Newborns with SARS-CoV-2 do not need to be separated from their mothers but are isolated from the general newborn nursery population.

Diagnosis

Active maternal infection can be diagnosed from nasopharyngeal, nasal, or saliva specimens. Reverse transcriptase–polymerase chain reaction (RT-PCR) testing identifies viral RNA, whereas rapid antigen testing detects viral antigen. Several commercial tests are available and listed on the Centers for Disease Control and Prevention (CDC) (2021a) website. Rapid antigen tests are inexpensive but less sensitive in asymptomatic individuals. Thus, test result interpretation depends on pretest probability, epidemiological risk factors, and intended use for diagnostic or screening purposes in health-care or congregate settings. The latter include dormitories, correctional facilities, nursing homes, and housing shelters providing social services. Serological screening for IgG is used for epidemiological and seroprevalence studies rather than diagnosis of acute infection.

Management

For mild to moderate illness, supportive care is indicated and delivery is reserved for obstetric indications. For those with mild illness at high risk for clinical progression, anti-SARS-CoV-2 monoclonal antibodies may be administered within 10 days of symptom onset and according to variant predominance (National Institutes of Health, 2021). Pregnancy is considered a high-risk criterion, and use of monoclonal antibodies can be considered in consultation with specialists. Inpatient observation may be considered for moderate illness, as up to 40 percent may worsen (Adhikari, 2020). For pregnant women with severe to critical illness, inpatient management includes supporting respiratory function, managing comorbid conditions, and, when indicated, coordinating safe delivery with subspecialists (Society for Maternal-Fetal Medicine, 2021). The goal of respiratory support is to maintain oxygen saturation ≥95 percent and reduce dyspnea and tachypnea (Pacheco, 2020). Prone positioning of gravidas to improve oxygenation in severe cases of COVID-19 pneumonia has been described (Tolcher, 2020).

With severe infection, a dysregulated inflammatory response contributes to lung injury and hypoxia. A United Kingdom trial found decreased mortality rates at 28 days with intravenous or oral dexamethasone, 6 mg daily for up to 10 days in patients requiring supplemental oxygen or mechanical ventilation, compared with usual care (RECOVERY Collaborative Group, 2021). In the ACTT-1 trial, intravenous remdesivir, a broad-spectrum antiviral agent, was associated with shortened time to recovery among patients requiring low-flow supplemental oxygen (Beigel, 2020). Remdesivir is approved by the Food and Drug Administration for treatment of COVID-19 in hospitalized adults. Data on efficacy and safety of antiviral and biological agents for COVID-19 in pregnancy are limited. In a study of remdesivir in hospitalized gravidas with COVID-19, no serious adverse events were reported, but elevated serum aminotransaminase levels were common (Burwick, 2020). Decisions to use currently available therapeutic agents under Emergency Use Authorization are made in consultation with experts and should balance potential benefits and theoretical risks (National Institutes of Health, 2021). Antibiotics for respiratory illness are rarely necessary unless bacterial co-infection is suspected.

Prevention

Non-pharmaceutical interventions are mainstays for reducing the spread of SARS-COV-2. These include universal masking, maintaining physical distance of at least 6 feet, and hand hygiene. In healthcare settings, airborne and contact isolation precautions are used, particularly when invasive procedures are planned (Centers for Disease Control and Prevention, 2021c).

Currently available vaccines are highly protective against viral transmission and clinical disease in nonpregnant adults (Baden, 2021; Polack, 2020). In one study, the BNT162b2 mRNA vaccine was associated with a reduction in COVID-19 diagnosed in pregnancy (Goldshtein, 2021). The American College of Obstetricians and Gynecologists and the Society for Maternal-Fetal Medicine (2021) recommend that pregnant and lactating women receive the COVID-19 vaccine. Individuals who accept vaccination are counseled to anticipate common reactions such as injection-site pain, headache, fatigue, myalgia, and low-grade fever (Shimabukuro, 2021). Recent evidence from national experts suggests no greater miscarriage rate in gravidas receiving the vaccine (Zauche, 2021).

■ Mumps Virus

This is an RNA paramyxovirus that primarily infects the salivary glands but also may involve the gonads, meninges, pancreas, and other organs. It is transmitted by direct contact with respiratory secretions, saliva, or fomites. Most transmission occurs before and within 5 days of parotitis onset, and droplet isolation is recommended during this time (Kutty, 2010). Treatment is symptomatic, and mumps during pregnancy is no more severe than in nonpregnant adults.

An increased risk of spontaneous abortion has been observed in women who acquire mumps in the first trimester. Infection is not associated with congenital malformations, and fetal infection is rare (McLean, 2013).

Recent outbreaks in previously vaccinated young adults prompted the recommendation of a third dose of measles-mumps-rubella (MMR) vaccine for at-risk nonpregnant individuals during any outbreak (Marin, 2018). The MMR vaccine is a live-virus vaccine. Thus, it is contraindicated in pregnancy, although fetal risk from inadvertent administration is theoretical (McLean, 2013). Pregnancy should be avoided for 30 days after vaccination. The vaccine is encouraged for susceptible postpartum women, and breastfeeding is not contraindicated.

■ Measles Virus (Rubeola)

This is a highly contagious RNA virus of the family Paramyxoviridae that infects only humans. In endemic areas, annual

outbreaks of measles occur in late winter and early spring, with larger epidemic cycles every 2 to 5 years. Although once declared eliminated in the United States, recent outbreaks raise concerns regarding waning population immunity (Patel, 2019; Strebel, 2019). Transmission is by respiratory droplets, and the secondary attack rate among susceptible contacts exceeds 90 percent (Rainwater-Lovett, 2018).

Typical symptoms include fever, coryza, conjunctivitis, and cough. *Koplik spots*, small white lesions with surrounding erythema, appear on the buccal mucosa. A characteristic erythematous maculopapular rash develops on the face and neck and then spreads to the back, trunk, and extremities. Diagnosis of acute infection is made by detection of measles-specific IgM antibodies in serum. Additionally, measles RNA may be detected by RT-PCR testing of a throat swab, nasopharyngeal swab, or urine specimen. Treatment of measles is supportive, and evaluation for secondary infections may be necessary.

For pregnant women without evidence of measles immunity, postexposure prophylaxis is intravenous immune globulin (IVIG), and a 400-mg/kg dose is ideally given within 6 days of exposure (Centers for Disease Control and Prevention, 2020d). Human immune globulin (IG) is a blood product used to provide antibodies for short-term prevention of infectious diseases and is prepared from plasma pools derived from thousands of donors.

Measles in pregnancy is associated with increased risk for pregnancy loss, pneumonia, and death (Eberhart-Phillips, 1993; Ogbuanu, 2014). If a woman develops measles shortly before delivery, risk of serious infection developing in the neonate is considerable, and neonatal chemoprophylaxis is warranted.

As a live-virus vaccine, MMR vaccine is not provided during pregnancy as prevention. However, MMR vaccination is not an indication for pregnancy termination. Susceptible women are vaccinated routinely postpartum, and breastfeeding is not contraindicated.

Rubella Virus

Also called German measles, rubella is caused by an RNA togavirus and is of minor importance in the absence of pregnancy. Transmission is via nasopharyngeal secretions, and the transmission rate is 80 percent to nonimmune individuals. The peak incidence is late winter and spring in endemic areas (Lambert, 2015).

In 2018, more than 26,000 cases of rubella virus were reported worldwide (Grant, 2019). In the United States, ongoing or sustained transmission was eliminated in 2004, and large epidemics of rubella have virtually disappeared here because of immunization. However, up to 10 percent of women are susceptible, and cases are also imported each year from countries with incomplete vaccine coverage (Al Hammoud, 2018).

Maternal rubella is usually a mild febrile illness that follows an incubation of 12 to 23 days. A generalized maculopapular rash begins on the face and spreads to the trunk and extremities. Other symptoms may include arthralgias or arthritis, head and neck lymphadenopathy, and conjunctivitis. However, 25 to 50 percent of infections are asymptomatic. Viremia usually precedes clinical signs by approximately a week, and adults are infectious during viremia and through 7 days after the rash appears. Up to half of maternal infections are subclinical despite viremia that may cause spontaneous abortion or devastating fetal infection, described subsequently.

Diagnosis

Rubella virus may be isolated from the urine, blood, nasopharynx, and cerebrospinal fluid for up to 2 weeks after rash onset. However, the diagnosis is usually made with serological analysis. Specific IgM antibody can be detected using enzyme-linked immunoassay for 4 to 5 days after onset of clinical disease, but antibody can persist for up to 6 weeks after appearance of the rash. Importantly, rubella virus reinfection can give rise to transient low levels of IgM. With this, no adverse fetal effects have been described. A false-positive IgM result is also possible in populations with low prevalence of disease.

Serum IgG antibody titers peak 1 to 2 weeks after rash onset. These may fail to distinguish between recent infection and preexisting immunity if the specimen is obtained more than a week after symptoms. IgG avidity testing aids differentiation, and high-avidity IgG antibodies indicate an infection at least 2 months prior.

Fetal Effects

Rubella virus is one of the most complete teratogens, and its effects are worst during organogenesis. Up to 90 percent of pregnant women with rubella and a rash during the first 12 weeks of gestation have an affected fetus (Miller, 1982). At 13 to 14 weeks' gestation, this incidence is 50 percent, and by the end of the second trimester, it is 25 percent. Defects are rare after 20 weeks' gestation.

Features of congenital rubella syndrome are cardiac septal defects, pulmonary stenosis, microcephaly, cataracts, microphthalmia, and hepatosplenomegaly (Yazigi, 2017). Other abnormalities include sensorineural deafness, intellectual disability, neonatal purpura, and radiolucent bone disease. *Neonates born with congenital rubella may shed the virus for many months and thus be a threat to other infants and to susceptible adults who contact them.*

Management and Prevention

Rubella has no specific treatment. Droplet precautions for 7 days after the onset of the rash are recommended. Postexposure passive immunization with IVIG may be of benefit if given within 5 days of exposure (Young, 2015).

When rubella infection is diagnosed in the mother, targeted sonographic examination is performed to evaluate for fetal structural anomalies described in the last section. Referral to and counseling by a maternal–fetal medicine specialist is warranted. If ultrasound findings suggest congenital infection or growth delay, diagnostic amniocentesis is recommended to detect rubella virus by PCR and to test for other congenital infections.

As prevention, MMR vaccine should be offered to nonpregnant women of childbearing age who lack evidence of immunity. Vaccination of all susceptible hospital personnel who might be exposed to patients with rubella or who might have contact with pregnant women is important. Rubella

vaccination is avoided 1 month before or during pregnancy because the vaccine contains attenuated live virus, although the fetal malformation risk is theoretical. MMR vaccination is not an indication for pregnancy termination. Prenatal serological screening for rubella is indicated for all pregnant women. Women found to be nonimmune are offered the MMR vaccine postpartum.

■ Parvovirus B19

This virus causes *erythema infectiosum* or *fifth disease*. It is a small, single-stranded DNA virus that replicates in rapidly proliferating cells such as erythroblast precursors. This can lead to anemia, which is its primary fetal effect. In individuals with increased red cell turnover, such as with sickle-cell disease, parvovirus infection may cause an aplastic crisis.

The primary mode of parvovirus transmission is respiratory secretions, although infection through blood transfusion or organ donation has been reported. Most infections occur in late winter to early spring. The maternal infection rate is highest in women with school-aged children and in day-care workers. Viremia develops 4 to 14 days after exposure, and a rash follows several days later. An otherwise immunocompetent individual is no longer infectious at the onset of the rash. By adulthood, only 40 percent of women are susceptible. The annual seroconversion rate is 1 to 2 percent, and the secondary attack rate approaches 50 percent.

Maternal Infection

In 20 to 30 percent of adults, infection is asymptomatic. In others, fever, headache, and flu-like symptoms may begin in the last few days of the viremic phase. Several days later, a bright red rash with erythroderma affects the face and gives a slapped-cheek appearance. The rash becomes lacelike and spreads to the trunk and extremities. Adults often have milder rashes and develop symmetrical polyarthralgia that may persist for several weeks. No evidence suggests that parvovirus infection is altered by pregnancy. With recovery, IgM antibody is generated 7 to 10 days postinfection, and production persists for 3 to 4 months. Several days after IgM is produced, IgG antibody is detectable and persists for life with natural immunity (American College of Obstetricians and Gynecologists, 2020a).

Fetal Infection

There is vertical transmission to the fetus in up to a third of maternal parvovirus infections (de Jong, 2011; Lamont, 2011). Fetal infection is associated with abortion, nonimmune hydrops, and stillbirth (Fig. 67-5). The fetal loss rate with serologically proven parvovirus infection is 8 to 17 percent before 20 weeks' gestation, and 2 to 6 percent after midpregnancy (American College of Obstetricians and Gynecologists, 2020a). Currently, no data support screening asymptomatic mothers or evaluating stillborn fetuses for parvovirus infection.

Fetal hydrops develops in approximately 4 percent of gravidas infected with parvovirus (Enders, 2004). Still, it is the most frequent infectious cause of nonimmune hydrops in autopsied fetuses (Rogers, 1999). Hydrops usually stems from infection in the first half of gestation. In one report, more than 80 percent of cases of fetal infection developed within 10 weeks of maternal infection. The mean interval was 6 to 7 weeks (Yaegashi, 2000). The critical period for maternal infection leading to fetal hydrops is estimated to be between 13 and 16 weeks' gestation, which coincides with the period in which fetal hepatic hemopoiesis is greatest (Chap. 7, p. 128).

FIGURE 67-5 Stillborn, hydropic fetus and characteristically large placenta resulting from intrauterine parvovirus B19 infection. (Reproduced with permission from Dr. April Bleich.)

Diagnosis and Management

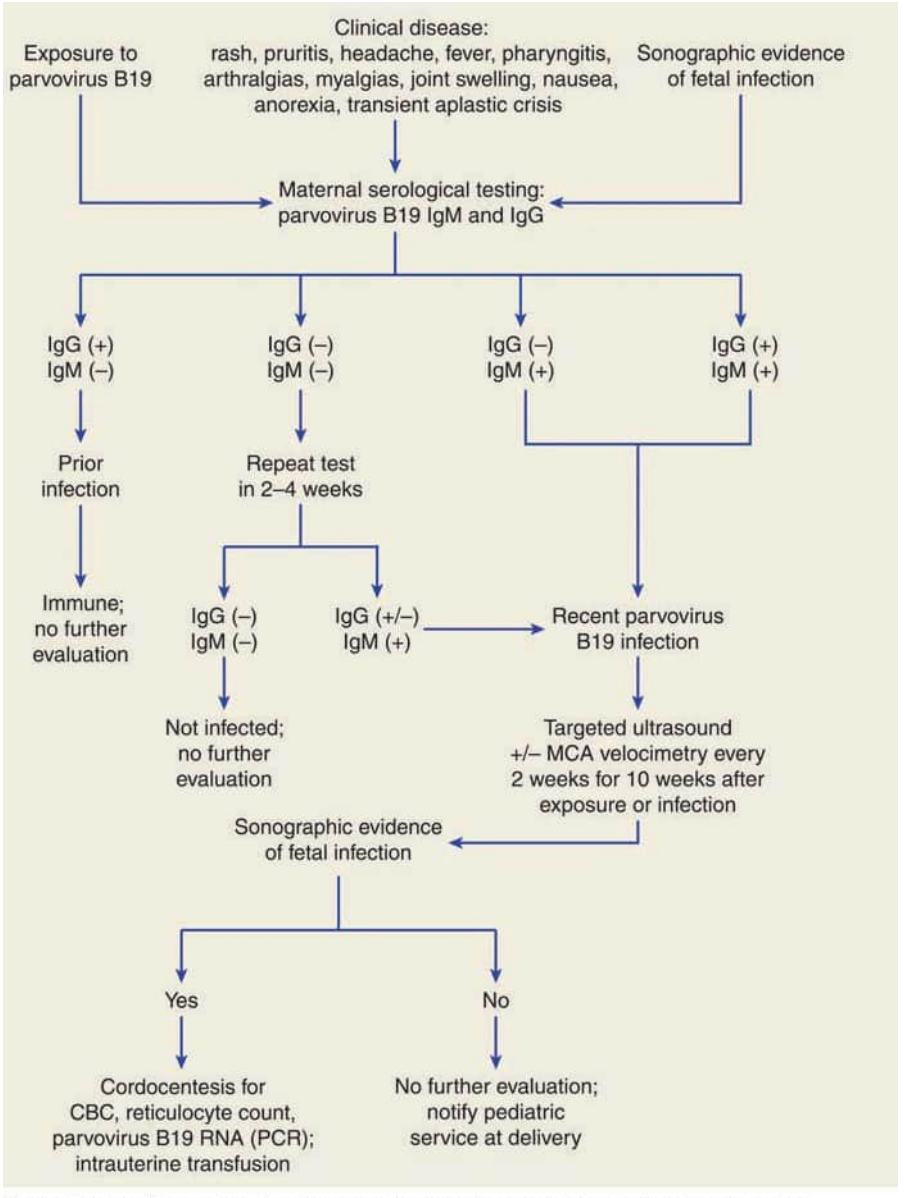
An algorithm for diagnosis of maternal parvoviral infection is illustrated in Figure 67-6. Diagnosis is generally made by maternal serological testing for specific IgG and IgM antibodies. Viral DNA may be detectable by PCR testing in maternal serum during the prodrome and persist for months to years after infection. Fetal infection is diagnosed by detection of B19 viral DNA in amnionic fluid (American College of Obstetricians and Gynecologists, 2020a). Fetal and maternal viral loads do not predict fetal morbidity and mortality (de Haan, 2007).

Most cases of parvovirus-associated hydrops develop in the first 10 weeks after infection. Thus, sonography should be performed every 2 weeks in women with recent infection. As discussed in Chapter 14 (p. 262), middle cerebral artery (MCA) Doppler interrogation is used to predict fetal anemia. MCA Doppler findings that suggest anemia may warrant fetal blood sampling followed by transfusion.

In hydropic fetuses without transfusion, mortality rates up to 30 percent have been reported. With transfusion, 94 percent of hydrops cases resolve within 6 to 12 weeks, and the overall mortality rate is <10 percent. Most fetuses require only one transfusion because hemopoiesis resumes as infection resolves.

Long-term Prognosis

Neurodevelopmental outcomes in fetuses transfused for B19 infection-induced anemia have varied. In one review of 24 transfused hydropic fetuses, abnormal neurodevelopment was noted in 5 of 16 survivors—32 percent—at 6 months to 8 years (Nagel, 2007). Outcomes were not related to severity of fetal anemia or acidemia, and these investigators hypothesized that the infection



[a]Hydrops fetalis, hepatomegaly, splenomegaly, placentomegaly, elevated MCA peak systolic velocity

FIGURE 67-6 Algorithm for evaluation and management of human parvovirus B19 infection in pregnancy. CBC = complete blood count; IgG = immunoglobulin G; IgM = immunoglobulin M; MCA = middle cerebral artery; PCR = polymerase chain reaction; RNA = ribonucleic acid.

itself induced cerebral damage. In another study of 28 children treated with intrauterine transfusion, 11 percent had neurodevelopmental impairment during evaluation at a median age of 5 years (de Jong, 2012). Conversely, Dembinski (2003) found no significant neurodevelopmental delay despite severe fetal anemia.

Prevention

Currently, no parvovirus vaccine is available, and no antiviral agent is recommended for prevention or treatment of maternal or fetal infection. Decisions to avoid higher-risk work settings are complex and require assessment of exposure risks. Pregnant women should be counseled that risks for infection approximate 5 percent for casual, infrequent contact; 20 percent for intense, prolonged work exposure such as for teachers; and 50 percent for close, frequent interaction such as in the home. Workers at day-care centers and schools need not avoid infected children because infectivity is greatest before clinical illness. Last, infected children do not require isolation.

Other Respiratory Viruses

More than 200 antigenically distinct respiratory viruses cause the common cold, pharyngitis, laryngitis, bronchitis, and pneumonia. The DNA-containing adenovirus is more likely to produce cough and lower respiratory tract involvement, including pneumonia. The RNA-containing rhinovirus, respiratory enterovirus, and nonpandemic common coronavirus usually produce a trivial illness characterized by rhinorrhea, sneezing, and congestion. An enterovirus named EV-D68 caused large outbreaks of respiratory illness in several countries and was linked to clusters of polio-like illness in children, known as *acute flaccid myelitis* (Sejvar, 2016).

The teratogenic risks of respiratory viruses are low. In one study, amnionic fluid viral PCR testing was done on samples from 1191 women undergoing amniocentesis for fetal karyotyping (Adams, 2012). Viral PCR was positive in 6.5 percent, and adenovirus was the virus most frequently identified. There was an association with fetal-growth restriction, nonimmune hydrops, foot/hand abnormalities, and neural-tube defects. Adenoviral infection is a known cause of childhood myocarditis and has been reported in cases of fetal myocarditis and nonimmune hydrops (Towbin, 1994).

Other Enteroviruses

Characterized by a clinical phenotype distinct from that of respiratory enteroviruses, these viruses are a major subgroup of RNA picornaviruses that include nonrespiratory enterovirus species, coxsackievirus, poliovirus, and echovirus. They are trophic for intestinal epithelium but can also cause widespread maternal, fetal, and neonatal infections that may include the CNS, skin, heart, and lungs. Most maternal infections are subclinical yet can be fatal to the fetus-neonate (Tassin, 2014). Hepatitis A is an enterovirus discussed in Chapter 58 (p. 1036).

Coxsackievirus infections with group A and B are usually asymptomatic. Symptomatic infections—usually with group B—include aseptic meningitis; polio-like illness; hand, foot, and mouth disease; rashes; respiratory disease; pleuritis; pericarditis;

and myocarditis. No treatment or vaccination is available (Cohen, 2018). Coxsackievirus may be transmitted by maternal secretions to the fetus at delivery in up to half of mothers who seroconverted during pregnancy (Modlin, 1988). Transplacental passage also has been reported, which may cause neonatal skin lesions, myocarditis, pneumonia, or encephalitis (Ornoy, 2006). Some have reported higher rates of cardiac anomalies and of low-birthweight, preterm, and growth-restricted newborns (Chen, 2010).

Polioviruses are highly contagious and cause subclinical or mild infections. The virus is trophic for the brain, and it can cause paralytic poliomyelitis (Cohen, 2018). Siegel (1955) demonstrated that pregnant women not only were more susceptible to polio but also had a higher death rate. Perinatal transmission has been observed, especially when maternal infection developed in the third trimester (Bates, 1955). Inactivated subcutaneous polio vaccine is recommended for susceptible pregnant women who must travel to endemic areas or are placed in other high-risk situations. Live oral polio vaccine has been used for mass vaccination during pregnancy without harmful fetal effects (Harjulehto, 1989).

■ Mosquito-borne Viruses

West Nile Virus

This mosquito-borne RNA flavivirus is a human neuropathogen. It is the most common cause of arthropod-borne disease in the United States (McDonald, 2019). West Nile viral infection is typically acquired through mosquito bites and is rarely transmitted through donated blood or organs. The incubation period is 2 to 14 days, and most persons have mild or no symptoms. Less than 1 percent of infected adults develop meningoencephalitis or acute flaccid paralysis. With these, presenting symptoms may include fever, mental status changes, muscle weakness, and coma (Stewart, 2013).

West Nile infection is diagnosed based on clinical symptoms and detection of viral IgG and IgM in serum and IgM in cerebrospinal fluid (Centers for Disease Control and Prevention, 2018). Management is supportive, and no effective antiviral treatment is available. The primary strategy for preventing exposure in pregnancy is use of insect repellant containing *N*,*N*-diethyl-*m*-toluamide (DEET), which is considered safe (Wylie, 2016). Avoiding outdoor activity and stagnant water and wearing protective clothing also are recommended.

Adverse effects of West Nile viremia on pregnancy are unclear. Animal data suggest that embryos are susceptible, and one case report of human fetal infection at 27 weeks' gestation described chorioretinitis and severe cerebral leukomalacia (Alpert, 2003; Julander, 2006). However, data from the West Nile Virus Pregnancy Registry show no increased risk for miscarriage, preterm birth, or major malformations (O'Leary, 2006; Pridjian, 2016). No evidence suggests that maternal West Nile virus infection is harmful to a breastfeeding infant.

Zika Virus

This RNA flavivirus is the first major mosquito-borne teratogen recognized (Rasmussen, 2016). Zika virus is primarily transmitted by mosquito bite, but sexual transmission is possible. The virus may be detected in body fluids for months following acute infection (Joguet, 2017; Paz-Bailey, 2017). It was first introduced to a nonimmune Brazilian population in 2014, but as of 2020, no countries had reported active Zika transmission.

Maternal-Fetal Infection. Zika infection is asymptomatic in approximately 80 percent of adults. It may cause mild rash, fever, headache, arthralgia, and conjunctivitis lasting a few days. The fetus can be severely infected whether or not the mother is symptomatic. In one report of 134 women with positive RT-PCR results, the fetal mortality rate was 7 percent (Brasil, 2016). Among live births with first-trimester exposure, the rate of fetal birth defects ranges from 5 to 15 percent (Reynolds, 2017). In the most severely affected fetuses, a *congenital Zika syndrome* has been described that includes microcephaly, lissencephaly, ventriculomegaly, intracranial calcifications, ocular abnormalities, and congenital contractures (Honein, 2017).

Diagnosis and Management. Zika virus is typically detectable in blood around the time of symptom onset and may persist days to months in pregnant women (Meaney-Delman, 2016). Serum IgM antibodies typically become detectable within the first 2 weeks and may persist for months. IgG antibodies develop shortly after IgM ones and confer long-lived immunity (Centers for Disease Control and Prevention, 2019).

Laboratory testing for Zika infection is recommended only in *symptomatic* gravidas with residence in or recent travel to areas with active dengue transmission and risk for Zika transmission (Centers for Disease Control and Prevention, 2019). For a pregnant woman within 12 weeks of symptom onset, PCR testing of serum and urine specimens for both dengue and Zika virus RNA is recommended. For women with prenatal ultrasound findings suggesting congenital Zika syndrome, Zika virus PCR and IgM are initially performed on serum and urine. Amnionic fluid PCR may be performed, although less is known about its diagnostic accuracy for congenital infection.

Currently, no specific treatment or vaccine is available for Zika infection, although several vaccines are in development (Shan, 2018). Prophylaxis includes protective netting, insect spray to control the vector mosquito, personal DEET spray use, and avoidance of sexual contact with partners recently exposed.

■ Ebola Virus

A member of the RNA Filoviridae family, the Ebola virus is transmitted by direct person-to-person contact (Kuhn, 2018). Infection produces a severe hemorrhagic fever with pronounced immunosuppression and disseminated intravascular coagulopathy. Treatment is supportive. Data are few concerning Ebola viral infection in gravidas (Money, 2015; Oduyebo, 2015). Henwood and associates (2017) described an approximate 50-percent risk of death among pregnant and nonpregnant women with Ebola virus disease, and universally poor fetal and neonatal outcomes. That said, no evidence suggests that pregnant women are more susceptible to Ebola virus infection. In survivors, persistent Ebola virus has been detected months after recovery in "sanctuary sites" such as the eyes and gonads.

A live-attenuated Ebola virus vaccine, rVSV-ZEBOV, was approved in 2019 in the United States for individuals studying or treating Ebola virus. Among 84 health-care workers

who inadvertently received vaccination in early pregnancy or who became pregnant soon after vaccination, pregnancy loss or congenital anomalies were not associated with the vaccine (Legardy-Williams, 2020).

BACTERIAL INFECTIONS

Group A Streptococcus

Streptococcus pyogenes is the most frequent bacterial cause of acute pharyngitis. In most cases, streptococcal pharyngitis, scarlet fever, and erysipelas are not life threatening. Treatment, usually with penicillin, is equivalent for pregnant and nonpregnant women. *S pyogenes* produces numerous toxins and enzymes responsible for its local and systemic toxicity. Pyrogenic exotoxin-producing strains are usually associated with severe disease (Wessels, 2018). In the United States, *S pyogenes* infrequently causes puerperal infection. Still, it remains the most common cause of severe maternal postpartum infection and death worldwide, and their incidence is rising (Hamilton, 2013; Wessels, 2018). Puerperal infections are discussed in detail in Chapter 37 (p. 649).

Group B Streptococcus

Streptococcus agalactiae colonizes the gastrointestinal and genitourinary tract in 10 to 25 percent of gravidas (Kwatra, 2016). Group B *Streptococcus* (GBS) is isolated in a transient, intermittent, or chronic fashion during pregnancy. Although the organism is more likely always present in these same women, its isolation is not always consistent.

Maternal and Perinatal Infection

Maternal and fetal GBS effects range from asymptomatic colonization to septicemia. *S agalactiae* can cause maternal bacteriuria, pyelonephritis, osteomyelitis, postpartum mastitis, and puerperal infections. GBS may also have the ability to overcome normally protective cervical mucus barriers during pregnancy to cause ascending antenatal infection (Vornhagen, 2018). As such, GBS has also been implicated in preterm labor, prelabor rupture of membranes, chorioamnionitis, fetal infections, and stillbirth (Randis, 2014; Seale, 2017).

Among newborns in the United States, GBS remains the leading infectious cause of morbidity and mortality (Nanduri, 2019). Infection <7 days after birth is defined as *early-onset disease*, although many investigators recognize a threshold of <72 hours of life as most compatible with intrapartum acquisition of disease (Stoll, 2011). Tudela and associates (2012) reported that newborns with early-onset GBS infection often had clinical evidence of fetal infection during labor or at delivery.

In many neonates, septicemia involves signs of serious illness that usually develop within 6 to 12 hours of birth. These include respiratory distress, apnea, and hypotension. At the outset, therefore, neonatal infection must be differentiated from respiratory distress syndrome caused by insufficient surfactant production (Chap. 34, p. 615). The mortality rate with early-onset disease has declined to approximately 4 percent, and preterm newborns are disparately affected.

Late-onset disease caused by GBS is noted in 0.28 per 1000 live births and usually manifests as meningitis 1 week to 3 months after birth (Centers for Disease Control and Prevention, 2020a). The mortality rate, although appreciable, is lower for late-onset meningitis than for early-onset sepsis. Unfortunately, it is not uncommon for surviving infants of both early- and late-onset disease to exhibit devastating neurological sequelae.

Prophylaxis for Perinatal Infections

Maternal intrapartum antibiotic administration is the main prevention of early-onset GBS disease. In the United States, rates of early-onset neonatal sepsis decreased from 3 cases per 1000 live births in the early 1990s to 0.25 cases in the years following widespread prophylaxis (Centers for Disease Control and Prevention, 2020a). Both culture- and risk-based criteria to identify candidates for intrapartum prophylaxis have been proposed and debated (Table 67-2) (Braye, 2019; Hughes, 2017).

TABLE 67-2. Indications for Intrapartum Group B Streptococcal Infection Prophylaxis[a]

Intrapartum Prophylaxis Indicated	Intrapartum Prophylaxis Not Indicated
GBS bacteriuria	Negative vaginal–rectal culture obtained at ≥36 weeks' gestation during current pregnancy
Previous infant with invasive GBS disease	Cesarean delivery before labor onset or membrane rupture, regardless of GBS status or gestational age
Positive GBS screening culture during current pregnancy (unless cesarean delivery is performed before labor onset and with intact membranes)	Negative vaginal–rectal GBS culture in late gestation during the current pregnancy, regardless of intrapartum risk factors
Unknown GBS status at labor onset and any of the following:	Unknown GBS status and intrapartum NAAT result negative and no intrapartum risk factors present
Birth at <$37^{0/7}$ weeks' gestation	
Membrane rupture ≥18 hr	
Intrapartum temperature ≥100.4° F (38.0°C)	
Intrapartum NAAT result positive for GBS	
Positive GBS status in prior pregnancy	

[a]Perform vaginal and rectal GBS culture at 36–38 weeks' gestation for all pregnant women, unless intrapartum antibiotic prophylaxis indicated for current pregnancy based on bacteriuria or prior infant with invasive GBS disease.
GBS = group B *Streptococcus*; NAAT = nucleic acid amplification test.

Culture-based Prevention. The American College of Obstetricians and Gynecologists (2020b) recommends universal vaginal-rectal culture screening for GBS at 36 to 38 weeks' gestation. This is followed by intrapartum antibiotic prophylaxis for women identified to be carriers. Selective enrichment of the vaginal-rectal culture to favor GBS growth and then subculture improves detection. GBS isolates can also be tested for inducible clindamycin resistance in women with reported penicillin allergy. Updated guidance also recommends consideration of antenatal maternal penicillin-allergy testing in GBS-colonized women at high risk for anaphylaxis or IgE-mediated hypersensitivity (American College of Obstetricians and Gynecologists, 2020b). In a recent surveillance study of neonates with early-onset sepsis, 53 percent of those diagnosed with GBS disease were born to mothers with negative antenatal screening results (Stoll, 2020).

In women with heavy colonization, GBS may be specifically identified in a routine prenatal urine culture obtained to exclude asymptomatic bacteriuria (ASB). Cultures with $\geq 10^5$ colony-forming units (cfu) should prompt treatment of ASB to reduce the risk of acute pyelonephritis in pregnancy. Values $<10^5$ do not require acute antepartum antibiotics for ASB. However, women are given GBS prophylaxis in labor (see Table 67-2). As a surrogate, we also consider a urine culture result that identifies gram-positive cocci, without further speciation, to be a presumptive positive result for GBS.

Risk-based Prevention. This approach is recommended for women in labor and whose GBS culture results are not known. It relies on risk factors associated with intrapartum GBS transmission. Intrapartum chemoprophylaxis is then given to candidates with criteria listed in Table 67-2.

At Parkland Hospital we use the risk-based approach for intrapartum prophylaxis. Additionally, all term neonates who were not given intrapartum prophylaxis are treated in the delivery room with aqueous penicillin G, 50,000 to 60,000 units intramuscularly. With this strategy, early-onset neonatal sepsis rates in our predominantly minority population decreased to levels similar to those reported by national surveillance data (Stafford, 2012; Wendel, 2002).

Nucleic Acid–based Testing. Approximately 20 percent of laboratories now offer PCR testing for maternal GBS screening (Fay, 2019). Additionally, a rapid point-of-care PCR test has been evaluated for intrapartum identification of maternal GBS (El Helali, 2019). One major limitation is cost, which is currently several times greater than that of culture-based techniques. A second is the inability to determine antibiotic sensitivities using current PCR techniques.

GBS Vaccine

Serotype-specific capsular antibody concentrations clinically correlate with reduced rates of GBS neonatal disease. However, vaccine development is challenged by the diversity of GBS serotypes. Another hurdle is the bacterium's ability to undergo serotype switching by altering its capsular polysaccharide (Dangor, 2016). No vaccines are clinically available at this time.

Intrapartum Antimicrobial Prophylaxis

Penicillin remains the first-line agent for prophylaxis, and ampicillin is an acceptable alternative (Table 67-3) (American College of Obstetricians and Gynecologists, 2020b). Women with a penicillin allergy and at low risk for anaphylaxis are given cefazolin (Briody, 2016). Those at high risk for anaphylaxis or other life-threatening reaction, such as Stevens-Johnson syndrome, should have antimicrobial susceptibility testing for erythromycin and clindamycin performed on GBS isolates. Clindamycin-sensitive but erythromycin-resistant isolates should undergo inducible clindamycin resistance testing. If clindamycin resistance is confirmed, vancomycin should be administered. *Erythromycin is no longer used for penicillin-allergic patients*.

Management of spontaneous preterm labor, threatened preterm delivery, or preterm prelabor rupture of membranes includes obtaining a GBS culture. Intrapartum chemoprophylaxis is initiated until the culture results. Women undergoing cesarean delivery before labor onset with intact membranes do not need GBS chemoprophylaxis, regardless of colonization status or gestational age.

TABLE 67-3. Regimens for Intrapartum Antimicrobial Prophylaxis for Perinatal GBS Disease

Regimen	Treatment[a]
Recommended	Penicillin G, 5 million units IV initial dose, then 2.5 to 3.0 million units IV every 4 hr
Alternative	Ampicillin, 2 g IV initial dose, then 1 g IV every 4 hr or 2 g every 6 hr
Penicillin allergic	
Patients not at high risk for anaphylaxis	Cefazolin, 2 g IV initial dose, then 1 g IV every 8 hr
Patients at high risk for anaphylaxis and with GBS resistant to clindamycin or susceptibility unknown	Vancomycin, 1 g IV every 12 hr *or* 20 mg/kg IV every 8 hr with a maximum of 2 g per single dose
Patients at high risk for anaphylaxis and with GBS susceptible to clindamycin	Clindamycin, 900 mg IV every 8 hr until delivery

[a]Following initial dose, subsequent doses are continued until delivery.
GBS = group B *Streptococcus*; IV = intravenous.
Data from the American College of Obstetricians and Gynecologists, 2020; Verani, 2010.

Methicillin-resistant *Staphylococcus Aureus* (MRSA)

Staphylococcus aureus is a pyogenic gram-positive organism and is considered the most virulent staphylococcal species. It primarily colonizes the nares, skin, genital tissues, and oropharynx. Although approximately 30 percent of adults carry *S aureus*, MRSA colonizes 2 percent of adults (Gorwitz, 2008). MRSA colonization is considered the greatest risk factor for subsequent infection (Marzec, 2016).

MRSA infection may be hospital- or community-acquired MRSA (CA-MRSA). CA-MRSA is diagnosed in an outpatient setting or within 48 hours of hospitalization in a person without health-care exposures in the past year. Exposures include prior hospitalization, dialysis or surgery, or indwelling catheters or devices (Dantes, 2013). In pregnant women, most cases are CA-MRSA, which disproportionately affects persons in lower socioeconomical strata (See, 2017).

MRSA and Pregnancy

Skin and soft tissue infections are the most common presentation of MRSA in pregnant women. Mastitis and breast abscesses have been reported in up to a fourth of MRSA cases in pregnancy (Laibl, 2005; Lee, 2010). Perineal or episiotomy abscess, abdominal surgical site infection, and rare placental abscess and chorioamnionitis have been associated with MRSA (Maeda, 2018; Pimentel, 2009). Last, osteomyelitis and spinal-epidural abscess have been topics of case reports (Tanamai, 2016; Vakili, 2017).

Vertical transmission of MRSA is rare. Postnatal colonization and infection in the newborn are associated with maternal and health-care worker colonization or infection near the time of delivery (Jimenez-Truque, 2012; Reich, 2016).

Management

Uncomplicated superficial infections are primarily managed by drainage and local wound care. Although historically de-emphasized, evidence suggests benefit from antibiotic therapy added to incision and drainage of smaller abscesses (Daum, 2017; Forcade, 2012). Severe superficial infections, especially those that fail to respond to local care or those in patients with medical comorbidities, are treated with MRSA-appropriate antibiotics. Purulent cellulitis should be treated empirically for MRSA until culture and sensitivity results are available.

Most CA-MRSA strains are sensitive to trimethoprim-sulfamethoxazole or clindamycin (Miller, 2015; Talan, 2016). Rifampin rapidly develops resistance and should not be used as monotherapy. Linezolid, although effective against MRSA, is expensive, and little information guides its use in pregnancy. Although effective for MRSA infections, doxycycline, minocycline, and other tetracyclines should not be used in pregnancy. Vancomycin remains a first-line therapy for inpatient treatment of serious MRSA infections.

The control and prevention of MRSA infection relies on appropriate hand hygiene and prevention of skin-to-skin contact. Routine screening of obstetrical patients for MRSA colonization is not recommended (American College of Obstetricians and Gynecologists, 2020c. That said, for women with culture-proven MRSA colonization or infection, we add a single dose of vancomycin to routine beta-lactam perioperative prophylaxis for cesarean deliveries and deep perineal lacerations. Decolonization is not effective in the general obstetrical population (Huang, 2019). Breastfeeding in women colonized with MRSA is not prohibited, but optimal hygiene and attention to minor skin breaks is encouraged.

Listeriosis

Listeria monocytogenes is a facultative intracellular gram-positive bacillus that causes 100 to 200 infections requiring hospitalization each year in the United States (Tack, 2020). Nearly all cases are thought to be foodborne. Outbreaks have been caused by contaminated dairy products, fruits and vegetables, and undercooked or processed meats and deli foods.

Invasive listerial infections are more common in pregnant women, immunocompromised patients, and the very old or young. For unclear reasons, infection during pregnancy is 10 to 20 times more common than in the general population (Craig, 2019). Although pregnancy losses linked to listeriosis are more likely to be reported, another hypothesis is that pregnant women are more susceptible because of decreased cell-mediated immunity (Baud, 2011).

Maternal and Fetal Infection

Infections with *Listeria* may result in noninvasive, febrile gastroenteritis, sepsis, or CNS infection after a 2- to 4-week incubation. Listeriosis during pregnancy may be asymptomatic or may cause a febrile illness that is confused with influenza, pyelonephritis, or meningitis. The diagnosis usually is not apparent until blood cultures are reported as positive. Occult or clinical infection also may stimulate labor. Transplacental bacterial invasion leads to fetal infection, which can result in stillbirth or clinical illness similar to early-onset GBS sepsis. A classic description of overwhelming fetal infection is that of disseminated microabscesses and granulomas known as *granulomatosis infantiseptica*. Chorioamnionitis is common, and placental macroabscesses may be seen. Late-onset neonatal infection can also follow exposure at delivery. In a review of 222 cases, infection with *Listeria* resulted in abortion or stillbirth in 20 percent, and neonatal sepsis developed in 68 percent of surviving newborns (Mylonakis, 2002). In one prospective cohort study, 24 percent of mothers experienced fetal loss, but none after 29 weeks' gestation (Charlier, 2017). However, a neonatal case fatality rate of 21 percent has been reported (Sapuan, 2017).

Treatment with ampicillin plus gentamicin is usually recommended because of its synergism against *Listeria* species (Rouse, 2016). Trimethoprim-sulfamethoxazole can be given to penicillin-allergic women. Maternal treatment in most cases is also effective for fetal infection. No vaccine is available. Prevention is by washing raw vegetables, cooking all raw food, and avoiding the implicated foods listed previously (American College of Obstetricians and Gynecologists, 2019d).

Salmonellosis

Infections from *Salmonella* species continue to be a major cause of foodborne illness. Six serotypes, including *Salmonella* subtypes *typhimurium* and *enteritidis*, account for most cases in the

United States. Nontyphoid *Salmonella* gastroenteritis is contracted through contaminated food. Symptoms that include nonbloody diarrhea, abdominal pain, fever, chills, nausea, and vomiting begin 6 to 48 hours after exposure. Diagnosis is made by stool studies (Chap. 57, p. 1018).

Treatment is with intravenous crystalloid solutions given for rehydration. Antimicrobials are not given in uncomplicated infections because they do not commonly shorten illness and may prolong the convalescent carrier state. If gastroenteritis is complicated by high fever or bacteremia, antimicrobials are given (Angelo, 2016). Rare case reports have linked *Salmonella enteritidis* bacteremia with septic abortion (Delcourt, 2019).

Typhoid fever caused by *Salmonella typhi* remains a global health problem. Infection is spread by oral ingestion of contaminated food, water, or milk. Although uncommon in the United States, an outbreak in Central America in 2017 involved almost 300 cases (Pan American Health Organization, 2018). Severe complications among patients requiring hospitalization include gastrointestinal bleeding—11 percent; intestinal perforation—9 percent; encephalopathy—8 percent; renal failure—6 percent; and cardiovascular collapse—7 percent (Bano-Zaidi, 2018). In pregnant women, the disease is more likely to be encountered during epidemics and in those with recent travel (Engsbro, 2019). Septic abortion is rare but reported (Jena, 2017).

Fluroquinolones and third-generation cephalosporins are the preferred empirical treatment for enteric (typhoid) fever and invasive nontyphoidal *Salmonella* infection (Shane, 2017). Antimicrobial susceptibility testing is important to tailor the course of therapy, which typically lasts 1 to 2 weeks. Two licensed vaccines for prevention of typhoid fever are available in the United States (Milligan, 2018). From limited evidence, typhoid vaccine administration to pregnant women before travel is not linked to adverse outcomes.

■ Shigellosis

Transmitted via the fecal–oral route, shigellosis is a common cause of diarrheal outbreaks in children attending day-care centers and in adults following international travel. Bacillary dysentery caused by *Shigella* species can range from mild diarrhea to severe dysentery with fever, bloody stools, abdominal cramping, and tenesmus. In immunosuppressed individuals, severe infection may lead to toxic megacolon, seizures or meningitis, or hemolytic uremic syndrome (Kotloff, 2018).

Although mild infection is typically self-limited, treatment of dehydration is essential. Antimotility drugs are avoided, and meticulous hygiene is recommended to avoid transmission. Antimicrobial therapy during pregnancy includes fluoroquinolones, ceftriaxone, or azithromycin. Resistance is rapidly emerging, and antibiotic susceptibility testing can help guide appropriate therapy (Centers for Disease Control and Prevention, 2020e). Shigellosis can stimulate uterine contractions and cause preterm birth (Parisot, 2016).

■ Lyme Disease

Caused by the spirochete *Borrelia burgdorferi*, Lyme disease is the most commonly reported vector-borne illness in the United States (Centers for Disease Control and Prevention, 2021g). Lyme borreliosis results from tick bites of the genus *Ixodes*. There are three stages (Steere, 2018). Early infection—stage 1—causes a distinctive local skin lesion, *erythema migrans*, which may be accompanied by a flu-like syndrome and regional adenopathy. If untreated, early disseminated infection—stage 2—follows in days to weeks. Multisystem involvement is frequent, but skin lesions, neuropathies, myalgia, carditis, and meningitis predominate. If still untreated after months, late or persistent infection—stage 3—manifests in perhaps half of patients as a migratory arthritis. Native immunity is acquired, and the disease enters a chronic phase in approximately 10 percent. Some patients remain asymptomatic, but others in the chronic phase develop various skin, joint, or neurological manifestations.

Clinical diagnosis is important because serological and PCR testing have many pitfalls (Steere, 2016). IgM and IgG serological testing is recommended in early infection and is followed by a second test—either a second immunoassay or western blot—for confirmation (Mead, 2019). Ideally, acute and convalescent serological evaluation is completed if possible, however, rates of false-positive and -negative results are high.

Treatment is recommended by the Infectious Diseases Society of America (Lantos, 2021). For erythema migrans, doxycycline for 10 days or amoxicillin or cefuroxime axetil for 14 days is recommended. However, doxycycline is usually avoided in pregnancy. Azithromycin for 7 days is a second-line regimen. For other manifestations, a 14- to 28-day oral or intravenous course of the same first-line drugs is recommended. No vaccine is commercially available. Avoiding areas with endemic Lyme disease and improving tick control in those areas is the most effective prevention. Self-examination with removal of unengorged ticks within 36 hours of attachment reduces infection risk. For tick bites recognized within 72 hours, a single 200-mg oral dose of doxycycline may reduce infection development (Lantos, 2021).

Several reports describe Lyme disease in pregnancy, although large series are lacking. Transplacental transmission has been confirmed, but no congenital effects of maternal borreliosis have been conclusively identified (Shapiro, 2014). Prompt treatment of early maternal infection should prevent most adverse pregnancy outcomes. In the northeast United States, between 2 and 40 percent of women with early Lyme disease may be co-infected with *Babesia microti*, which is another parasite transmitted by same tick. *Babesiosis* has been reported to cause congenital infection (Saetre, 2018).

■ Tuberculosis

Diagnosis and management of tuberculosis during pregnancy is discussed in Chapter 54 (p. 965).

PROTOZOAL INFECTIONS

■ Toxoplasmosis

The obligate intracellular parasite *Toxoplasma gondii* has a life cycle with two distinct stages (Kim, 2018). The *feline* stage takes place in cats—the definitive host—and their prey. Unsporulated oocysts are excreted in feces. In the *nonfeline* stage, tissue cysts containing bradyzoites or oocysts are ingested by

the intermediate host, including humans. Gastric acid digests the cysts to release bradyzoites, which infect small-intestinal epithelium. Here, they are transformed into rapidly dividing tachyzoites, which can infect all cells within the host mammal. Humoral and cell-mediated immune defenses eliminate most of these, but tissue cysts develop. Their lifelong persistence is the chronic form of toxoplasmosis.

Human infection is acquired by eating raw or undercooked meat infected with tissue cysts or by ingesting soil or water contaminated with oocysts from cat feces. Prior infection is confirmed by serological testing, and its prevalence depends on geographical locale and parasite genotype. The incidence of congenital toxoplasmosis in the United States has declined and now approximates 0.23 cases in 10,000 live births (Maldonado, 2017).

Maternal and Fetal Infection

Most acute maternal infections are subclinical and are detected only by prenatal or newborn serological screening. In some cases, maternal symptoms may include a flu-like illness with lymphadenopathy. In immunocompetent adults, initial infection confers immunity, and prepregnancy infection nearly eliminates any risk of vertical transmission. Infection in immunocompromised women, however, may be severe, and reactivation may cause encephalitis, chorioretinitis, or mass lesions.

Vertical transmission can cause fetal infection and then congenital toxoplasmosis. The latter is a fetopathy characterized by ocular or intracranial lesions and growth delay. Congenital toxoplasmosis is also associated with an increased risk for preterm delivery (Freeman, 2005).

The estimated rate of vertical transmission rises with gestational age. In one metaanalysis, the rate was 15 percent at 13 weeks, 44 percent at 26 weeks, and 71 percent at 36 weeks (SYROCOT Study Group, 2007). Although transmission risk is lower in early pregnancy, sequelae of congenital toxoplasmosis are more likely to be severe (American College of Obstetricians and Gynecologists, 2020a).

Notably, most infected fetuses are born without obvious toxoplasmosis stigmata. Clinically affected neonates usually have generalized disease expressed as low birthweight, hepatosplenomegaly, jaundice, and anemia. Some primarily have neurological disease with intracranial calcifications, hydrocephaly, or microcephaly (Dhombres, 2017). Many eventually develop chorioretinitis and exhibit learning disabilities. This classic triad—chorioretinitis, intracranial calcifications, and hydrocephalus—is often accompanied by convulsions. Infected neonates with clinical signs are at risk for long-term complications (Abdoli, 2014).

Screening and Diagnosis

With IgG antibody confirmed before pregnancy, there is no risk for fetal infection in immunocompetent hosts. The American College of Obstetricians and Gynecologists (2020a) does not recommend prenatal screening for toxoplasmosis in low-prevalence areas, including the United States. Screening IgG serology tests should be performed in immunocompromised gravidas, including those with HIV infection.

Pregnant women with suspected toxoplasmosis also should be tested. The parasite is rarely detected in tissue or body fluids. IgG antibodies against *Toxoplasma* develop within 2 to 3 weeks after infection, peak at 1 to 2 months, and usually persist for life—sometimes in high titers. Although IgM antibodies appear by 10 days after infection and usually become negative within 3 to 4 months, they may remain detectable for years. Thus, IgM antibodies are not used alone to diagnose acute toxoplasmosis. Best results are obtained with the Toxoplasma Serologic Profile performed at the Dr. Jack S. Remington Laboratory for Specialty Diagnostics (www.sutterhealth.org). Toxoplasma IgG avidity increases with time. Thus, if a high-avidity IgG result is found, infection in the preceding 3 to 5 months is excluded. Multiple tests are available that allow high-avidity results to confirm latent infection with a 100-percent positive predictive value (Villard, 2013).

Congenital toxoplasmosis is suspected when sonography reveals findings such as hydrocephaly, intracranial or hepatic calcifications, ascites, placental thickening, hyperechoic bowel, and growth restriction. These are similar to abnormalities that may be seen with congenital CMV. If these are found incidentally, diagnostic amniocentesis with PCR testing for toxoplasma as well as cytomegalovirus DNA is recommended, along with maternal serologic testing for both infections. The sensitivity of PCR for detection of toxoplasma DNA varies with gestational age and is lowest before 18 weeks' gestation (Filisetti, 2015; Yamamoto, 2017).

Management

Prenatal treatment of acute maternal toxoplasmosis is based on two regimens. Spiramycin may be given alone, or a pyrimethamine plus sulfonamide combination is taken with folinic acid (American College of Obstetricians and Gynecologists, 2020a). These two regimens have also been used consecutively. Most experts will use spiramycin in women with acute infection early in pregnancy to reduce the risk of vertical transmission. Because it does not cross the placenta, spiramycin may not be used to treat fetal infection. Pyrimethamine plus sulfadiazine with folinic acid is selected for maternal infection after 18 weeks' gestation or if fetal infection is suspected. The SYROCOT study group (2007) reviewed data from 1438 treated pregnancies and found weak evidence for early treatment to reduce congenital toxoplasmosis risks. Treatment has been associated with a reduced rate of serious neurological sequelae and neonatal demise (Cortina-Borja, 2010).

Prevention

No vaccine is available to prevent toxoplasmosis. Strategies to avoid infection include: (1) cooking meat to safe temperatures; (2) peeling or thoroughly washing fruits and vegetables; (3) cleaning all food preparation surfaces and utensils that have contacted raw meat or unwashed fruits and vegetables; (4) wearing gloves when changing cat litter or delegating this duty; and (5) avoiding feeding cats raw or undercooked meat and keeping cats indoors. Although these preventive steps are recommended, no robust data support their effectiveness (American College of Obstetricians and Gynecologists, 2020a; Di Mario, 2015).

■ Malaria

This protozoan infection remains a global health crisis. In 2018, it caused 260,000 deaths, and most occurred among children

younger than 5 years (World Health Organization, 2019). Sub-Saharan Africa and India carry the largest burden of cases. Malaria had been effectively eradicated in Europe and in most of North America, but some cases are imported in returning military personnel or recent immigrants from endemic areas (Mace, 2017). Transmitted by infected *Anopheles* mosquitoes, six species of *Plasmodium* cause human disease.

Pregnant women have increased susceptibility (Kourtis, 2014). After infection, antibodies to the parasite surface antigen VAR2CSA help mediate placental accumulation of infected erythrocytes and lead to the harmful effects of malaria (Mayor, 2015). Through this mechanism, some immunity accrues with parity and is termed *pregnancy-specific antimalarial immunity*. Ironically, malaria treatment dampens this immunity.

Maternal and Fetal Infection

Clinical manifestations are fever, chills, and flu-like symptoms, which may occur episodically. Symptoms are less severe with recurrences. Malaria may be associated with anemia and jaundice, and infections with *Plasmodium falciparum* may cause kidney failure, coma, and death. That said, many otherwise healthy but infected adults in endemic areas are asymptomatic because of partial immunity. Pregnant women, although often asymptomatic, are said to be more likely to develop traditional symptoms.

Malarial infections in pregnancy—either symptomatic or asymptomatic—are associated with higher rates of perinatal morbidity and mortality (Rogerson, 2018). Adverse outcomes include stillbirth, preterm birth, low birthweight, and maternal anemia. These correlate with high levels of placental parasitemia. The maternal anemia and low birthweight are documented most frequently (Machado Filho, 2014; McClure, 2013). Approximately 16 percent of low-birthweight neonates born to women in Africa are attributable to maternal malaria infection (World Health Organization, 2019). Effects stem from parasitized erythrocytes, monocytes, and macrophages that accumulate in the vascular areas of the placenta (Fig. 67-7). Infections with *P falciparum* are the worst, and early infection raises the risk for abortion. The incidence of malaria increases significantly in the latter two trimesters and postpartum (Diagne, 2000). Despite this, congenital malaria develops in <5 percent of neonates born to infected mothers.

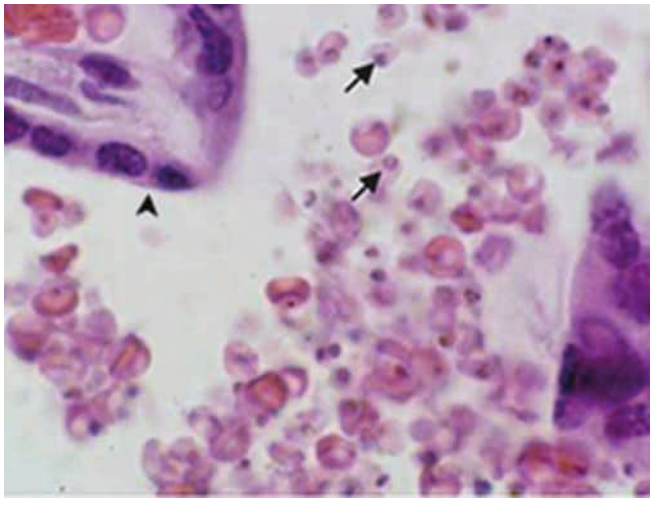


FIGURE 67-7 Photomicrograph of placental malaria. Multiple infected erythrocytes are seen, and two are identified (*arrows*). Cross section of nearby chorionic villus is shown (*arrowhead*).

Diagnosis and Management

Identification of parasites by microscopic evaluation of a blood smear remains the diagnostic gold standard. In women with low parasite densities, however, the sensitivity of microscopy is poor. Malaria-specific antigens are now being used for rapid testing, which has become the diagnostic standard (Cunningham, 2019).

For treatment, the most frequently used antimalarial drugs are not contraindicated in pregnancy. The World Health Organization recommends that all infected patients living in or traveling from endemic areas be treated with an artemisinin-based regimen for uncomplicated falciparum malaria (Tarning, 2016). The CDC (2020c) recommends that initial treatment be determined by where the infection was acquired.

Pregnant women diagnosed with uncomplicated malaria caused by *P vivax*, *P malariae*, *P ovale*, and chloroquine-sensitive *P falciparum* should be treated with hydroxychloroquine or chloroquine (Centers for Disease Control and Prevention, 2020c). For women infected with multidrug-resistant *P falciparum*, the first-line agent for gravidas in the second and third trimesters is a drug containing both artemether and lumefantrine. The PREGACT Study Group (2016) compared four artemisinin-based drugs in 3428 pregnant women with falciparum malaria and reported no serious maternal or perinatal adverse effects. Chloroquine-resistant *P vivax* should be treated with mefloquine. Chloroquine-sensitive *P vivax* or *P ovale* should be treated with chloroquine throughout pregnancy and then primaquine postpartum. Resistance to all the antimalarial drugs has been reported, including the recently added artemisinin-based compounds.

Treatment regimens for uncomplicated and severe malarial infections in pregnancy are detailed at: www.cdc.gov/malaria/diagnosis_treatment. The CDC also maintains a malaria hotline for treatment recommendations (855-856-4713).

Prevention and Chemoprophylaxis

Malaria control and prevention relies on chemoprophylaxis when traveling to or living in endemic areas. Vector control also is important. Insecticide-treated netting, pyrethroid insecticides, and DEET-based insect repellent lower malarial rates in endemic areas. These are well tolerated in pregnancy. If travel is necessary, chemoprophylaxis is recommended.

Chloroquine or hydroxychloroquine prophylaxis is safe and well tolerated in pregnancy. One evaluation compared prophylaxis during pregnancy with either sulfadoxine-pyrimethamine or dihydroartemisinin-piperaquine and found the latter to be more effective in preventing placental infection (Kakuru, 2016). Atovaquone/proguanil use is approved for gravidas, however, primaquine and doxycycline are contraindicated (Briggs, 2022). The latest chemoprophylaxis regimens for pregnancy can be obtained from the CDC *Travelers' Health* website at: www.cdc.gov/malaria/travelers/. The CDC also publishes *Health Information for International Travel* (The Yellow Book) at: www.cdc.gov/yellowbook. For women living in endemic areas, intermittent preventive treatment with sulfadoxine-pyrimethamine

is superior to intermittent screening plus indicated treatment, although resistance is a growing concern (Desai, 2018).

Amebiasis

Approximately 10 percent of the world population is infected with *Entamoeba histolytica*, and most are asymptomatic (Andrade, 2018). Amebic dysentery, however, may take a fulminant course during pregnancy. Symptoms are fever, abdominal pain, and bloody stools. Prognosis is worse if complicated by a hepatic abscess. Identifying *E histolytica* cysts or trophozoites within a stool sample is diagnostic. Therapy is similar to that for nonpregnant woman. For amebic colitis and invasive disease, tinidazole may be preferred over metronidazole, (Gonzales, 2019).

MYCOTIC INFECTIONS

Disseminated fungal infection—usually pneumonitis—during pregnancy is uncommon with coccidiomycosis, blastomycosis, cryptococcosis, or histoplasmosis. Their identification and management are considered in Chapter 54 (p. 965). Vulvovaginal candidiasis is described in Chapter 68 (p. 1218).

TRAVEL PRECAUTIONS DURING PREGNANCY

Pregnant travelers face general medical, obstetrical, and potentially hazardous destination risks. Several sources provide travel information (Freedman, 2016). The International Federation for Tropical Medicine has comprehensive information available at www.iftm-hp.org, and the International Society of Travel Medicine publishes information at www.istm.org. Also, *The Yellow Book* from the CDC has extensive travel information regarding pregnancy and breastfeeding.

BIOTERRORISM

The concept of bioterrorism involves the deliberate release of bacteria, viruses, or other infectious agents to cause illness or death. These natural agents are often altered to raise their infectivity or their resistance to medical therapy. Health-care providers should be alert for significant increases in the number of persons with febrile illnesses accompanied by respiratory symptoms or with rashes not easily associated with common illnesses. Clinicians are urged to contact their state health department or the CDC for current information and recommendations. In their Committee Opinion, the American College of Obstetricians and Gynecologists (2019b) has addressed disaster preparedness for obstetricians.

Smallpox

The variola virus causes smallpox and is considered a serious weapon. The virus is highly transmissible and carries an overall 30-percent case fatality rate. The last case of smallpox in the United States was reported in 1949, and worldwide it was reported in Somalia in 1977. Nishiura (2006) has reviewed the severe perinatal and maternal morbidity and mortality caused by smallpox. The case fatality rate of smallpox is 61 percent if the pregnant woman is unvaccinated. Rates of stillbirth, abortion, preterm delivery, and neonatal demise rise significantly in pregnancies complicated by this infection. The smallpox vaccine is made with live virus. Thus, pregnancy should be delayed for 4 weeks after vaccination.

Anthrax

Bacillus anthracis is a gram-positive, spore-forming, aerobic bacterium. It can cause three main types of clinical anthrax: inhalational, cutaneous, and gastrointestinal (Centers for Disease Control and Prevention, 2020b). Anthrax meningitis may accompany any of the clinical anthrax forms and is fatal in most cases. When inhaled, anthrax spores are deposited in the alveoli. They are engulfed by macrophages and germinate in mediastinal lymph nodes. The incubational period is usually less than 1 week but may be as long as 2 months. Within 1 to 5 days of symptom onset, the second stage is heralded by the abrupt onset of severe respiratory distress and high fevers. Mediastinitis and hemorrhagic thoracic lymphadenitis are common. Chest radiographs show a widened mediastinum. Case-fatality rates with inhalational anthrax are high, even with aggressive antibiotic and supportive therapy.

Other Bioterrorism Agents

Other category A bioterrorism agents include *Francisella tularensis*—tularemia, *Clostridium botulinum*—botulism, *Yersinia pestis*—plague, and Ebola, Marburg, Lassa, or Machupo viruses—hemorrhagic fever. The guidelines for these biological agents are evolving and are detailed at the CDC Bioterrorism website: emergency.cdc.gov/bioterrorism.

CHAPTER 68

Sexually Transmitted Infections

Sexually transmitted infections (STIs) include syphilis, gonorrhea, chlamydial and trichomonal infections, and infections caused by human immunodeficiency virus (HIV), herpes simplex virus (HSV), human papillomavirus (HPV), and hepatitis B and C viruses. In describing their pathogenesis, *horizontal transmission* is transfer to a contemporary. Instead, *vertical transmission* refers to passage of an infectious agent from the mother to her fetus through the placenta, during labor or delivery, or by breastfeeding. Many STIs can harm the mother or fetus. Thus, these are sought through both asymptomatic screening and symptomatic diagnostic testing and then treated. For this, the Centers for Disease Control and Prevention (CDC) provides guidelines, which are described throughout this chapter.

For STI screening and diagnosis, *serological testing* is recommended in some cases and identifies antibodies formed by the patient against the pathogen. In others, *direct detection* of an infectious agent by culture or by a nucleic acid amplification test (NAAT) of body fluids or lesions is suitable. NAATs include any molecular method used to detect the presence of DNA or RNA of a pathogen. NAATs may be polymerase chain reaction (PCR) tests (most common), transcription-mediated amplification (TMA) tests, or others. NAATs may be qualitative (detecting presence or absence only) or quantitative depending on the specific test. The terms NAAT and PCR may be used interchangeably in some cases when appropriate.

If one STI is identified, patients are offered screening for all STIs, because these infections are commonly comorbid. Treatment of most STIs is associated with improved pregnancy outcome and prevention of perinatal morbidity. Logically, education, screening, treatment, and prevention are essential components of prenatal care.

SYPHILIS

This infection remains a major threat for both mother and fetus. Since 2001, the combined rate of primary and secondary syphilis has risen almost yearly, and among women in 2019, the rate was 4 cases per 100,000 persons (Centers for Disease Control and Prevention, 2021b). For congenital syphilis, the rate in 2019 was 48 cases per 100,000 live births. This is a nearly 300 percent rise since 2015. Of risks, higher congenital syphilis rates are linked to inadequate prenatal care, substance use during pregnancy, African American race, and lack of screening and treatment (Smullin, 2021). The CDC also includes sex work, multiple or new sexual partners, incarceration, or homelessness (Workowski, 2021). Syphilis remains a significant global health problem (Korenromp, 2019).

Pathogenesis

Syphilis is caused by the spirochetal bacterium *Treponema pallidum.* With horizontal transmission, minute abrasions on the vaginal mucosa provide entry, and cervical eversion, hyperemia, and friability raise this risk. Spirochetes replicate and

disseminate through lymphatic channels and then hematogenously if untreated.

During vertical transmission, spirochetes readily cross the placenta. This is the most common route, but neonatal infection may result from contact with spirochetes from lesions at delivery or across the placental membranes. Fetal infection develops in >50 percent of untreated early maternal syphilis cases and in up to 10 percent of late latent disease (Fiumara, 1975; Hollier, 2001).

Clinical Manifestations

Maternal Syphilis and Definitions

This is staged according to clinical features and disease duration.

- *Primary syphilis* is diagnosed by its characteristic chancre, which develops at the inoculation site. Typically, a solitary, painless lesion has a raised, firm border and a red, smooth ulcerated base without significant pus (Fig. 68-1). Nonsuppurative lymphadenopathy may develop. A chancre usually resolves spontaneously in 2 to 8 weeks, even if untreated. Multiple lesions, if found, are predominantly in women with HIV co-infection.
- *Secondary syphilis* stems from spirochete dissemination to multiple organ systems. Manifestations develop 4 to 10 weeks after the chancre appears and include dermatological abnormalities in up to 90 percent. A diffuse macular rash, plantar and palmar circular lesions, patchy alopecia, and mucous patches may be seen (Fig. 68-2). *Condylomata lata* are flesh-colored flat nodules found on the perineum and perianus. Mucosal lesions teem with spirochetes and are highly infectious. Women may have constitutional symptoms such as fever, headache, and myalgias. Hepatitis, nephropathy, ocular changes, anterior uveitis, and periostitis are less common findings. Manifestations of secondary syphilis resolve without treatment after 1 to 6 months, despite incomplete clearance of organisms by the immune system.
- With *latent syphilis*, clinical manifestations of primary or secondary syphilis either have resolved or were never recognized, but infection persists and is identified by serological testing. *Early latent syphilis* is subclinical disease acquired within the preceding 12 months. Timing of infection is determined by laboratory seroconversion results, clearly described symptoms consistent with primary or secondary syphilis within the prior 12 months, or exposure to a sexual partner in the previous 12 months with primary, secondary, or early latent syphilis. If the duration of infection is either unclear or beyond 12 months, the term is *latent syphilis, unknown duration or late*.
- *Tertiary syphilis* is a slowly progressive disease that affects any organ system but is rarely seen in reproductive-aged women.

FIGURE 68-1 Primary syphilis. Chancres show a raised, firm border and smooth base and may be singular or multiple, as seen here. Arrows point to two reciprocal or "kissing" lesions, which develop as infection on one side spreads to the other when tissues are apposed. (Reproduced with permission from Dr. Allison J. Tracy, MD.)

Early-stage syphilis includes primary, secondary, and early latent syphilis. These are associated with high spirochete loads, and partner transmission rates range from 30 to 60 percent (Garnett, 1997; Singh, 1999). *Late-stage syphilis* includes latent syphilis, unknown duration or late and tertiary syphilis. In these, transmission rates decline because of smaller inoculum sizes.

Congenital Syphilis

Without screening and treatment, approximately 70 percent of infected women will have an adverse pregnancy outcome

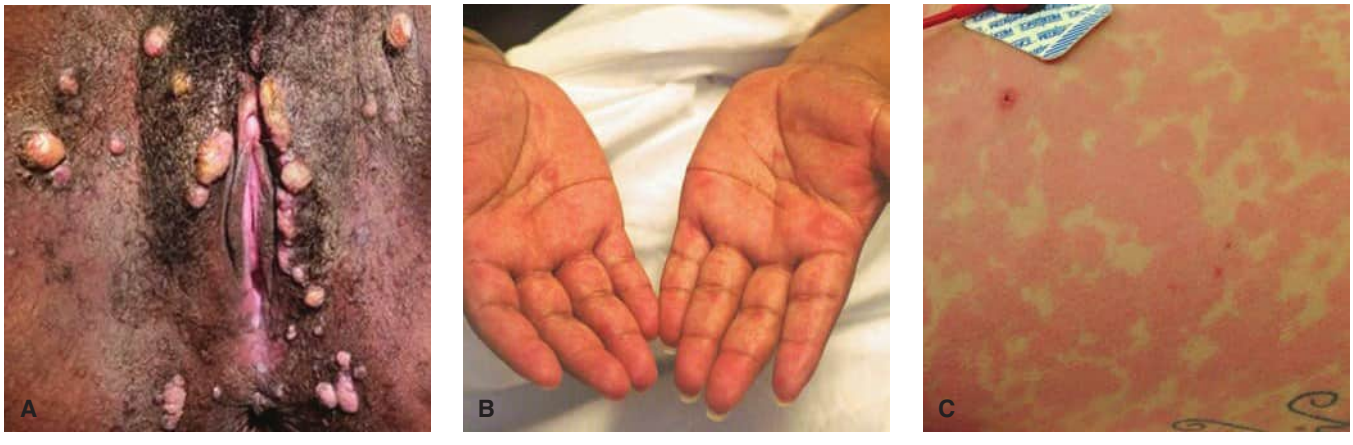

FIGURE 68-2 Secondary syphilis. **A.** Condyloma lata. (Reproduced with permission from Dr. Ralynn Brann.) **B.** Target lesions on the palms. **C.** Diffuse maculopapular rash.

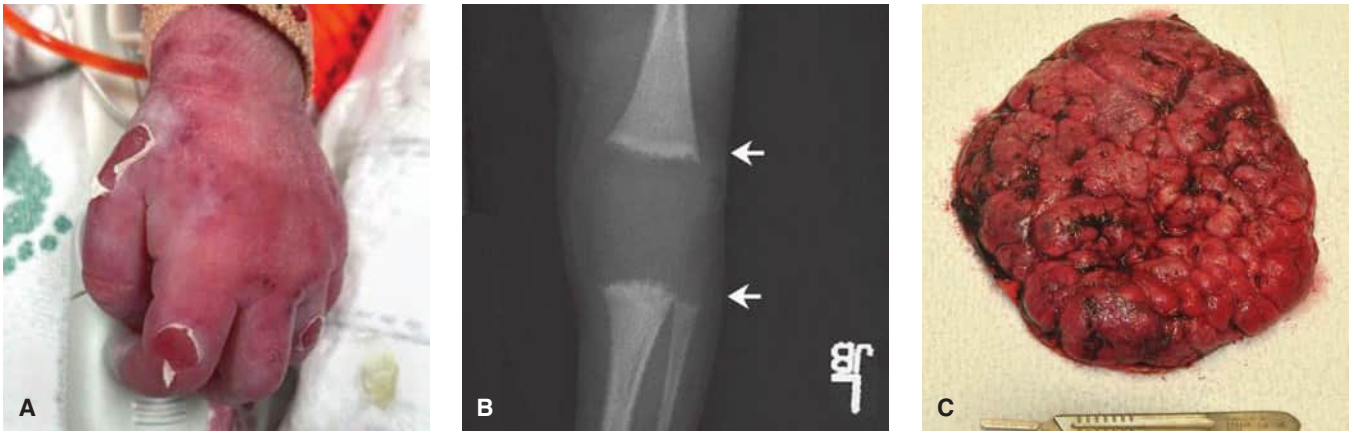

FIGURE 68-3 Congenital syphilis. **A.** A desquamating skin rash known as *pemphigus syphiliticus* may be seen. **B.** Neonatal lower-extremity long-bone radiographs show a "moth-eaten" appearance (*arrows*). **C.** Enlarged hydropic placenta of a syphilis-infected pregnancy.

(Hawkes, 2011). Maternal infection can lead to congenital infection, preterm labor, low birthweight, and fetal or neonatal death (Qin, 2014). Because of its immune incompetence prior to mid-pregnancy, the fetus is less likely to manifest the immunological inflammatory response characteristic of congenital infection before this time (Silverstein, 1962). However, congenital infection is still presumed in all cases, and thus treatment is imperative.

When vertical transmission occurs, severe congenital syphilis progresses along a continuum. Hepatic abnormalities are followed by anemia, thrombocytopenia, and then ascites and hydrops. Stillbirth remains a major complication (Centers for Disease Control and Prevention, 2021b). The newborn may have jaundice with petechiae or purpuric skin lesions, lymphadenopathy, rhinitis, pneumonia, myocarditis, nephrosis, or long-bone involvement (Fig. 68-3).

With syphilitic infection, the placenta becomes large and pale. Microscopically, villi lose their characteristic arborization, and blood vessels diminish or are obliterated as a result of endarteritis and stromal cell proliferation. Sheffield and colleagues (2002c) described these villi in more than 60 percent of placentas from women with untreated syphilis at delivery. Examination of the umbilical cord may reveal necrotizing funisitis, and spirochetes may be microscopically seen after immunohistochemical staining (Adhikari, 2020).

Diagnosis

In their 2018 guidance, the United States Preventive Services Task Force (USPSTF) recommends screening for syphilis in all pregnant women to prevent congenital infection. Testing is performed at the first prenatal visit. In populations with a high prevalence of syphilis or in persons with the risk factors noted earlier, serological testing is repeated at 28 weeks' gestation and again at delivery (Workowski, 2021).

Treponema pallidum cannot be cultured from clinical specimens. However, direct diagnosis of early-stage disease can be completed by dark-field microscopic examination, NAAT, or immunostaining of lesion exudate, tissue, or body fluid. These methods are not widely available and are less sensitive for blood specimens (Pillay, 2018). In practice, a diagnosis is made with serological testing coupled with clinical findings.

Two types of serological tests are employed to diagnose and screen, and sequential use of both reduces false-positive diagnoses. If the first is positive, the second type is then performed. This combination identifies infection but by itself does not determine disease stage. Instead, disease stage is assigned based on initial serological titer levels, patient history of potential exposures and prior treatment, and clinical-stage definitions, described earlier.

Traditionally, the first type is *nontreponemal testing,* and either the Venereal Disease Research Laboratory (VDRL) or the rapid plasma reagin (RPR) is selected. Both tests measure patient immunoglobulin M and G (IgM and IgG) antibodies formed against cardiolipin that is released from damaged host cells and possibly also from treponemes. Notably, these same antibodies can also be produced in response to other acute events that include recent vaccination, febrile illness, and pregnancy itself. They can be produced in response to chronic conditions such as intravenous (IV) drug abuse, systemic lupus erythematosus, aging, leprosy, or cancer. As such, these all serve as potential sources of false-positive results (Larsen, 1995). Conversely, early infection may be characterized by very high levels of antibody or antigen, which prevent immune complex formation and lead to false-negative test results. This is the prozone effect. Alternatively, seroconversion occurs at around the third week of infection but can take up to 6 weeks (Peeling, 2004). Thus, women with very early primary syphilis can have initially false-negative serological test results.

With positive nontreponemal test results, findings are quantified and expressed as titers. Because titers reflect disease activity, they rise during early syphilis and often exceed levels of 1:32 in secondary syphilis. A nontreponemal titer is usually measured on the day of treatment initiation. Subsequent titer declines are considered relative to this day-of-treatment titer.

The second type of serological test is used to confirm the presence of *T pallidum*–specific antibodies. These tests include fluorescent treponemal-antibody absorption tests (FTA-ABS), *T pallidum* passive particle agglutination (TP-PA) tests, and various immunoassays (Association of Public Health Laboratories, 2020). *Of note, these treponemal-specific tests generally remain positive throughout life, even after treatment.* Antibodies may be detected by treponemal assays up to a few weeks earlier than those detected by nontreponemal tests (Levett, 2015).

TABLE 68-1. Interpretation of Serologic Tests Using Reverse Sequence Syphilis Screening

Treponemal Test	VDRL or RPR	TP-PA	Possible Interpretations
Nonreactive[a]			1. Absence of syphilis 2. Very early syphilis before seroconversion
Reactive[b]	Nonreactive	Reactive	1. Prior treated syphilis[c]
		Reactive	2. Untreated syphilis[c]
		Nonreactive	3. False-positive treponemal test[d]
Reactive	Reactive		1. Active syphilis[c] 2. Recently treated syphilis with nontreponemal titers that have not yet become nonreactive[c] 3. Treated syphilis with persistent titers (serofast)[e]
Nonreactive[a]	Reactive		1. False-positive nontreponemal test

[a]No further testing performed if the initial treponemal test is negative and if there is no clinical suspicion for early syphilis.
[b]Verified using a second, different treponemal test (TP-PA) if the nontreponemal test is nonreactive.
[c]If prior treatment received, verify treatment adequacy for clinical stage and assess for reexposure. If inadequate, unverified, or no treatment received, perform full clinical staging evaluation and begin treatment course.
[d]May be seen in pregnancy or among immigrants with previous exposure to endemic treponematoses.
[e]Successful treatment is usually considered verification of adequate treatment with a fourfold decline in titers (e.g., from 1:32 to 1:8).
RPR = rapid plasma reagin; TP-PA = *T pallidum* particle agglutination assay; VDRL = Venereal Disease Research Laboratory.
From Centers for Disease Control and Prevention, 2011.

Traditionally, nontreponemal tests are used first for screening, and results are then confirmed by a treponemal-specific test. In a newer *reverse sequence* strategy, screening begins *first* with a treponemal-specific test. Each of the serological tests has limitations, including false-positive and -negative results. Management of discordant finding with this latter sequence is shown in Table 68-1. Notably, both approaches are suitable if a screening, follow-up, and treatment program is in place.

In contrast to these laboratory tests, rapid "point-of-care" (POC) syphilis screening of blood or serum samples is available. Most tests are treponemal-specific, and positive POC results can then be confirmed by laboratory-based tests. In hard-to-reach populations, immediate treatment of women with positive POC results is associated with lower rates of stillbirth, neonatal death, and congenital syphilis (Brandenburger, 2021). This practice, however, risks overtreating previously cured women who still have residual persistent treponemal antibodies. This limitation may be overcome by newer POC dual tests, which simultaneously assess nontreponemal and treponemal antibodies (Satyaputra, 2021).

Following maternal diagnosis, sonographic evaluation is performed for fetuses >20 weeks' gestation to search for signs of congenital syphilis. Rac and associates (2014) noted that 31 percent of infected women diagnosed at ≥18 weeks' gestation had fetuses with abnormal sonographic findings. Hepatomegaly, placental thickening, hydramnios, ascites, hydrops fetalis, and elevated middle cerebral artery Doppler velocimetry measurements suggest fetal infection. Before 20 weeks, treatment is highly successful, and abnormal sonographic findings are rare (Nathan, 1997).

With maternal infection and with a fetus of viable age that shows sonographic findings, antepartum fetal heart rate (FHR) monitoring prior to antibiotic treatment is recommended. If the FHR tracing is reassuring, antibiotic therapy can proceed. In contrast, spontaneous late decelerations or a nonreactive FHR tracing likely reflects an extremely ill fetus that may poorly tolerate a Jarisch-Herxheimer reaction, described subsequently. In this extreme case, consultation with a neonatologist regarding a plan of delaying treatment, pursuing delivery, and then treating in the nursery is a consideration (Wendel, 2002).

After antibiotic treatment, further sonographic surveillance or antenatal testing of fetal well-being is determined in consultation with specialists. Following adequate treatment, sonographic signs of congenital infection resolve over weeks to months, and delivery is reserved for usual obstetrical indications (Rac, 2014). In fetuses *without* initial signs of congenital syphilis, subsequent sonographic evaluations are reserved for other fetal indications.

Treatment

Syphilis therapy during pregnancy aims to eradicate maternal infection and to prevent or treat congenital syphilis. Parenteral penicillin G benzathine remains the preferred treatment for all stages of syphilis during pregnancy (Table 68-2). A second dose of benzathine penicillin G may be given 1 week after the initial dose in patients with early-stage syphilis or sonographic signs of congenital infection. This aims to reduce the risk of fetal treatment failure and is our current practice at Parkland Hospital. High maternal serological titers, preterm delivery, and delivery shortly after antepartum therapy are all risks for failure of maternal treatment to prevent neonatal infection (Sheffield, 2002b). Women should abstain from sexual contact for 7 days, until all skin/mucous membrane lesions heal, and until sexual partners are treated.

TABLE 68-2. Recommended Treatment for Pregnant Women with Syphilis

Category	Treatment
Early syphilis[a]	Benzathine penicillin G (Bicillin L-A)[b], 2.4 million units as a single intramuscular injection; some recommend a second dose 1 week later to help prevent congenital syphilis
>1-yr duration[c]	Benzathine penicillin G (Bicillin L-A)[b], 2.4 million units intramuscularly weekly for 3 doses[d]

[a]Primary, secondary, and early latent syphilis of less than 1-year duration.
[b]Bicillin C-R is not a suitable option.
[c]Latent syphilis of unknown or more than 1-year duration; tertiary syphilis. Missed doses are not acceptable for pregnant women, and those who miss any dose of therapy must repeat the full course of therapy.
[d]Optimal treatment interval is 7 days. If >9 days pass between doses, the entire treatment course is repeated.
Data from Workowski, 2021.

There are no proven alternatives to penicillin therapy during pregnancy. Some data support a 1-g daily IV dose of ceftriaxone for 10 days (Cao, 2017; Liang, 2016). Tetracyclines are effective but not recommended during pregnancy, because of the risk for offspring teeth discoloration.

Following treatment of syphilis before 24 weeks' gestation, nontreponemal tests are repeated in either the third trimester or no sooner than 8 weeks after treatment unless reinfection is suspected (Workowski, 2021). Following treatment after 24 weeks, nontreponemal titers may be repeated in the third trimester in some cases and are repeated at delivery. Adequate serological response to treatment is suggested by a fourfold decline in nontreponemal titer and resolution of any clinical symptoms. A fourfold decline in titer is more likely to occur following treatment of early-stage syphilis, which typically has high nontreponemal titers. Absence of a fourfold decline does not itself determine treatment failure, particularly when the initial nontreponemal titer is <1:8. Titers are best interpreted in conjunction with clinical history and by those experienced with treatment of syphilis in pregnancy. Because VDRL titers do not correspond directly to RPR titers, consistent use of the same test for surveillance is recommended.

Some successfully treated patients may still exhibit persistently low-level positive titers, which are referred to as "serofast." This state is more likely in older individuals, those with lower initial nontreponemal antibody titers, and those with later stages of syphilis (Seña, 2015).

In some instances, a woman may present without symptoms but describes recent sexual contact with a person who has been diagnosed with syphilis. She should be evaluated clinically and serologically. If their sexual contact occurred within the preceding 90 days, the gravida is treated presumptively for early syphilis, even if serological test results are negative. This accounts for early infection but before seroconversion. If contact was more than 90 days ago, treatment is based on serological results.

Penicillin Reactions

Women with a history of penicillin allergy should have either an oral stepwise penicillin-dose challenge or skin testing performed to confirm the risk of IgE-mediated anaphylaxis. If confirmed, penicillin desensitization is recommended and followed by benzathine penicillin G treatment (Table 68-3) (Wendel, 1985).

Distinct from allergy, the *Jarisch-Herxheimer reaction* can develop following penicillin treatment in most women with primary syphilis and approximately half with secondary infection. Uterine contractions, mild maternal temperature elevation, decreased fetal movement, and FHR decelerations are findings. Treatment is supportive with antipyretics as needed, hydration, and oxygen supplementation (Klein, 1990). In a study of 50 gravidas who received benzathine penicillin G for syphilis, the incidence of Jarisch-Herxheimer reactions was 40 percent (Myles, 1998). Of the 31 women monitored electronically, 42 percent developed regular uterine contractions, and 39 percent developed variable decelerations. All contractions resolved within 24 hours. Thus, for fetuses of viable gestational age,

TABLE 68-3. Penicillin Allergy—Oral Desensitization Protocol for Patients with a Positive Skin Test

Penicillin V Suspension Dose[a]	Amount[b] (units/mL)	mL	Units	Cumulative Dose (units)
1	1000	0.1	100	100
2	1000	0.2	200	300
3	1000	0.4	400	700
4	1000	0.8	800	1500
5	1000	1.6	1600	3100
6	1000	3.2	3200	6300
7	1000	6.4	6400	12,700
8	10,000	1.2	12,000	24,700
9	10,000	2.4	24,000	48,700
10	10,000	4.8	48,000	96,700
11	80,000	1.0	80,000	176,700
12	80,000	2.0	160,000	336,700
13	80,000	4.0	320,000	656,700
14	80,000	8.0	640,000	1,296,700

[a]Interval between doses: 15 minutes. Elapsed time: 3 hours and 45 minutes. Cumulative dose: 1.3 million units. Observation period: 30 minutes before parenteral administration of penicillin.
[b]The specific amount of drug was diluted in approximately 30 mL of water and administered orally.

consideration is given to administering the first dose of antibiotic in labor and delivery to permit continuous fetal monitoring for at least 24 hours when the fetus has sonographic signs of syphilis (Adhikari, 2020; Wendel, 2002). With or without sonographic signs of fetal infection, patients are counseled on symptoms of the Jarisch-Herxheimer reaction prior to syphilis treatment and are encouraged to seek evaluation if they develop.

GONORRHEA

Infection Rates and Effects

Of reportable bacterial STIs, those caused by *Neisseria gonorrhoeae* are the second most common. The incidence in women in the United States has continued to rise since 2015, and the highest rates are in those aged 15 to 24 years (Centers for Disease Control and Prevention, 2021b). Among women giving birth in 2018, the rate was 310 cases per 100,000 live births (Gregory, 2020). In most gravidas, infection is limited to the cervix, urethra, and periurethral and greater vestibular (Bartholin) glands. Acute salpingitis is rare in pregnancy. However, pregnant women account for a disproportionate number of disseminated gonococcal infections (Bleich, 2012).

Gonococcal infection can have adverse effects in any trimester. In affected women, associated rates of preterm delivery, preterm prelabor ruptured membranes (PPROM), low birthweight, and perinatal mortality are slightly higher than in those without infection (Vallely, 2021). Miscarriage rates are not increased. However, untreated gonococcal cervicitis is associated with septic abortion and with uterine infection after surgical abortion (Burkman, 1976) (Chap. 11, p. 203).

Vertical transmission of gonorrhea mainly occurs through fetal contact with cervical infection during birth. The predominant sequela is *gonococcal ophthalmia neonatorum*, which can lead to corneal scarring, ocular perforation, and blindness. Transmission rates are high and approximate 40 percent (Laga, 1986). Outlined in Chapter 32 (p. 593), ocular prophylaxis is provided to all newborns (U.S. Preventive Services Task Force, 2019a).

Screening and Treatment

Pregnant women who live in high-prevalence areas or who are at risk for gonorrhea should undergo first-trimester screening. Risk factors include age ≤25 years, prior or current STI, sex work, a new or nonmonogamous partner, a partner with an STI, multiple sexual partners, and inconsistent condom use if not monogamous (Workowski, 2021). Gonococcal infection is a marker for concomitant chlamydial infection. Thus, if chlamydial testing is unavailable, presumptive chlamydial therapy is given to women treated for gonorrhea.

Screening for gonorrhea in women is by culture or NAAT. NAATs have replaced culture in most laboratories, and kits are available for specific collection from the vagina, endocervix, or urine. Of these, vaginal or cervical samples are preferred, as urine collection may detect up to 10 percent fewer infections (Papp, 2014). If used, the initial urine stream, not midstream, is collected. In women with vaginal symptoms and who practice anal intercourse, rectal screening can be considered. One study of nonpregnant women at urban STI clinics found that approximately 20 percent of rectal chlamydia and gonorrhea infections would be missed if only cervical, vaginal, or urine samples were obtained (Llata, 2018). NAATs are also suitable for diagnosis of rectal or pharyngeal disease (Food and Drug Administration, 2019).

An ultrarapid NAAT for gonorrhea and chlamydia has been approved by the Food and Drug Administration (FDA) for point-of-care use. It performs similarly to laboratory-based testing, and results are available in approximately 30 minutes (Food and Drug Administration, 2021; Van Der Pol, 2020). This test has not been rigorously studied in pregnant women but may reduce barriers to prompt treatment in patients with limited access to care.

Gonorrhea treatment continues to evolve due to the ability of *N gonorrhoeae* to develop antimicrobial resistance (Table 68-4) (St Cyr, 2020). In gravidas, if chlamydia has not been excluded, a 1-g oral dose of azithromycin is added. Patients abstain from intercourse for 7 days after they and their sexual partner(s) have completed treatment.

For those with pharyngeal infection, non-ceftriaxone-based regimens have higher failure rates. Thus, those with contraindications to ceftriaxone merit infectious disease specialist consultation. With pharyngeal infection, a test-of-cure 1 to 2 weeks after treatment is recommend. This is unnecessary after treatment of urogenital or rectal gonorrhea.

To exclude reinfection, repeat testing is recommended 3 months after treatment of any gonorrhea infection. For any

TABLE 68-4. Treatment of Gonorrhea in Pregnancy[a,b]

Regimen	Drug and Dosage
Preferred	Weight <150 kg (<300 lb): ceftriaxone, single 500-mg IM injection[c] Weight ≥150 kg (≥300 lb): ceftriaxone, two simultaneous 500-mg IM injections[c]
Alternative	Cefixime, 800-mg single oral dose Gentamicin, single 240-mg IM dose *plus* azithromycin, 2-g single oral dose

[a]If *Chlamydia trachomatis* co-infection not excluded, then a 1-g oral azithromycin dose is added to regimens not already including azithromycin.
[b]Retesting is recommended at 3 months to exclude reinfection.
[c]1 mL of 1% lidocaine may be added to reduce injection site pain.
IM = intramuscular.
Data from St Cyr, 2020.

woman treated for gonorrhea in the first trimester and for any uninfected woman who is at high risk for gonococcal infection, testing is repeated in the third trimester (American Academy of Pediatrics, 2017; Workowski, 2021).

Sexual contacts are treated. Expedited therapy, discussed with chlamydial infection, is a less-desirable option due to the now-preferred injectable regimen. If elected, a single, oral, 800-mg dose of cefixime is provided. If chlamydia is not excluded, oral doxycycline, 100 mg twice daily for 7 days, is added.

Disseminated Gonococcal Infections

Gonococcal bacteremia may cause disseminated infections that manifest as petechial or pustular skin lesions, arthralgias, or septic arthritis. Antimicrobial susceptibility testing is requested for isolates cultured from infection sites. For treatment, ceftriaxone, 1 g IV or intramuscularly, is given every 24 hours and continued for 24 to 48 hours after clinical improvement (Workowski, 2021). An oral agent that is selected based on susceptibility testing is then provided to complete 1 week of therapy. Prompt recognition and antimicrobial treatment will usually yield favorable outcomes in pregnancy (Bleich, 2012). Meningitis and endocarditis are rare in pregnancy, but they may be fatal. For gonococcal *endocarditis*, ceftriaxone 1 to 2 g IV every 12 hours should be continued for at least 4 weeks, and for *meningitis*, 10 to 14 days. In all these cases, a single, 1-g, oral dose of azithromycin is provided to treat potential chlamydial co-infection (Workowski, 2021).

CHLAMYDIAL INFECTION

Infection Rates and Effects

Chlamydia trachomatis is an obligate intracellular bacterium that attaches to columnar or transitional-cell epithelium to cause urogenital infection. It is the most common reportable STI in the United States. The chlamydial infection rate was 694 cases per 100,000 women in 2019, and the highest rate is in those aged 15 to 24 years (Centers for Disease Control and Prevention, 2021b). Among women giving birth in 2018, the rate was 1844 cases per 100,000 live births (Gregory, 2020). Most infected pregnant women are asymptomatic, but a third have urethral syndrome, urethritis, or greater vestibular (Bartholin) gland infection (Peipert, 2003). Mucopurulent cervicitis may result from chlamydial or gonococcal infection or both. Uncommon manifestations during pregnancy are endometritis, salpingitis, reactive arthritis, and Reiter syndrome.

The role of chlamydial infection in pregnancy complications remains controversial. It is disputed whether untreated cervical infection raises rates of preterm delivery, PPROM, low birthweight, or perinatal mortality (Andrews, 2000; Reekie, 2018; Silva, 2011). Chlamydial infection is not associated with a greater risk of chorioamnionitis or with peripartum pelvic infection (Berman, 1987; Gibbs, 1987). However, delayed postpartum uterine infection has been described by Hoyme and associates (1986). The syndrome, which develops 2 to 3 weeks postpartum, is distinct from early postpartum metritis. It is characterized by vaginal bleeding or discharge, low-grade fever, and uterine tenderness.

Infection at delivery poses a higher risk to the newborn than to the mother. Vertical transmission leads to infection in 8 to 44 percent of neonates delivered vaginally from affected women (Rosenman, 2003). Of neonatal infections, conjunctivitis is the most common (Chap. 32, p. 593). Perinatal transmission to newborns can also cause pneumonia.

Screening and Treatment

Currently, the USPSTF and the American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2017) recommend chlamydia screening for all women at the first prenatal visit (LeFevre, 2014). The College further suggests testing in the third trimester for those treated in the first trimester, all women aged ≤25 years, and those aged >25 years with behavioral factors, which mirror those for gonorrhea. Dionne-Odom and associates (2020) reported a reinfection rate of 10 percent in pregnant women successfully treated before delivery.

Diagnosis is made predominantly by NAAT rather than culture. Of samples for NAAT, vaginal or cervical samples are preferred, because urine collection may detect up to 10 percent fewer infections (Papp, 2014; Wiesenfeld, 2017). However, Roberts and associates (2011) evaluated NAAT of urine specimens compared with cervical secretions in more than 2000 pregnant women and found them to be equivalent. As with gonorrhea, the first portion of the urine stream is collected.

Currently recommended treatment regimens for chlamydial infections are shown in Table 68-5. Azithromycin is first-line treatment in pregnancy. The fluoroquinolones and doxycycline are usually avoided in pregnancy, and erythromycin estolate is contraindicated because of drug-related hepatotoxicity.

A test of cure is repeated 4 weeks after therapy completion in pregnancy. Earlier NAAT may resample dead but treated organisms (Lazenby, 2017). A positive result can reflect a reinfection, a false-positive case from dead organisms, or treatment failure or noncompliance. Fortunately, drug resistance is rare for *C trachomatis* (Deguchi, 2018). Our practice is to re-treat women with positive test-of-cure results. Additionally, repeat screening 3 months after treatment is recommended to exclude reinfection (Workowski, 2021).

Expedited Partner Therapy

To prevent STI transmission, guidelines for expedited partner therapy (EPT) have been created by the Centers for Disease Control and Prevention (2006a) and are endorsed by the American College of Obstetricians and Gynecologists (2020a).

TABLE 68-5. Oral Treatment of *Chlamydia trachomatis* Infection in Pregnancy[a]

Regimen	Drug and Dosage
Preferred	Azithromycin, 1 g as a single dose
Alternative	Amoxicillin, 500 mg three times daily for 7 d

[a]Test of cure is recommended at 1 month. Retesting is performed at 3 months to exclude reinfection.
Data from Workowski, 2021.

With EPT, treatment is provided to persons who were sexual contacts of the patient within the prior 60 days. Partner therapy may be a prescription slip for the partner, direct medication administration to the partner and patient simultaneously, or a medication packet delivered to the partner(s) by the patient. Ideally, EPT does not replace traditional partner referral to allow their medical assessment, counseling, and screening for other STIs.

EPT is acceptable for treatment of sexual contacts with chlamydial infection. Because of new guidelines that recommend injectable ceftriaxone alone, EPT for gonorrhea is less desirable unless the partner(s) will be unable or unwilling to seek treatment (Centers for Disease Control and Prevention, 2021a). Fewer data are available to assess this strategy for trichomoniasis (Kissinger, 2006; Schwebke, 2010). EPT is not recommended for syphilis.

EPT is legally permissible or potentially allowable in all states. Links to specific state laws are found at: www.cdc.gov/std/ept/legal/default.htm. Notably, the risk of litigation following an adverse outcome may be elevated when a practice has uncertain legal status or is outside formally accepted community practice standards (Centers for Disease Control and Prevention, 2006a) Medication-related adverse reactions among treated partners is rare (Jamison, 2019).

The goal of EPT in pregnancy is to lower reinfection rates and adverse maternal and neonatal effects. A recent study at Parkland Hospital showed that EPT did not lower the chlamydia reinfection rate prior to delivery (Zofkie, 2021). Partner compliance, cost, and education may be factors (McCool-Myers, 2020; Slutsker, 2020).

HERPES SIMPLEX VIRUS

Adult Disease

Orogenital HSV infection manifests as shallow ulcers on affected mucosa. Infection stems from either of two different HSV viruses that are distinguished based on immunological differences. Yet, the two viruses have significant DNA homology, and thus prior infection with one type attenuates a primary infection with the other. Type 2 HSV is recovered almost exclusively from the genital tract and is usually transmitted sexually. Type 1 is responsible for most nongenital infections and typically is acquired in childhood. However, more than half of the new cases of genital herpes in adolescents and young adults are now caused by HSV-1 infection (Bernstein, 2013). This rise in the prevalence of HSV-1 genital disease may stem from an increase in rates of oral-genital sexual practices. Another explanation is that HSV-1 acquisition has declined in childhood as a result of improved living conditions and hygiene (Chemaitelly, 2019). Without prior exposure, young people without HSV-1 antibodies are rendered susceptible to *genital* acquisition of HSV-1 or -2.

Genital herpes simplex virus affects an estimated 19 million adolescents and adults in the United States (Spicknall, 2021). In pregnant women, the HSV-2 seroprevalence was 21 percent, and for HSV-1, it was 59 percent from 2007 to 2014. However, from 1999 to 2014, pregnant women with fewer sex partners were increasingly seronegative for both virus types (Patton, 2018). Seronegative pregnant women have a 4 to 5 percent risk to acquire either serotype during pregnancy (Brown, 1997; Kulhanjian, 1992). For those who are already HSV-1 seropositive, acquisition risk for HSV-2 approximates 2 percent (Brown, 1997).

Once transmitted by contact, viruses replicate at the entry site. Following mucocutaneous infection, the virus moves retrograde along sensory nerves. It remains latent in cranial nerves or dorsal spinal ganglia, but recurrences are common. HSV infections may be categorized into three groups.

First-episode primary infection describes the case in which HSV-1 or 2 is isolated from a lesion in the absence of HSV-1 or -2 serological antibodies. The typical incubation period of 6 to 8 days may be followed by a papular eruption with itching or tingling that then becomes painful and vesicular. Multiple vulvar and perineal lesions may or may not coalesce but then ulcerate (Fig. 68-4). Associated inguinal adenopathy can be severe. Many women do not present with typical lesions, and abraded or knife-cut lesions instead may be found. Cervical involvement is common, although it may be unapparent clinically. Transient systemic influenza-like symptoms or isolated high fevers with or without painful lesions are frequent and attributed to viremia. Uncommonly, women require hospitalization for febrile syndrome or for pain control of widespread ulceration. Hepatitis, encephalitis, or pneumonia infrequently develop, and disseminated disease is rare. After 2 to 4 weeks, all signs and symptoms of infection disappear. In contrast to these classic symptoms, the percentage of asymptomatic primary HSV-2 genital infections may reach 90 percent (Fanfair, 2013).

First-episode nonprimary infection is diagnosed when one HSV type is isolated from a lesion in a woman who has only antibodies to the other HSV serotype. For example, prior childhood HSV-1 infection likely provides cross-reacting antibodies to blunt the effects of new HSV-2 acquisition. Compared with primary infection, nonprimary infections produce fewer systemic manifestations or lesions, less pain, and briefer duration of lesions and viral shedding.

FIGURE 68-4 First-episode primary genital herpes simplex virus infection. As shown by the arrows, lesions may be vesicular, may be crusted, or may be shallow ulcers.

Recurrent disease is characterized by isolation of HSV-1 or -2 from the genital tract in women who carry antibodies to the same serotype. During the latency period, in which viral particles reside in nerve ganglia, reactivation is common and mediated through poorly understood stimuli. In general, lesions are fewer in number, are less tender, and shed virus for a shorter period than those of primary infection. Typically, they recur at the same sites. Recurrences are most frequent in the first year after initial infection, and rates slowly decline subsequently (Benedetti, 1999). Gravidas with a known prior history of genital HSV often experience recurrences (Sheffield, 2006).

Asymptomatic viral shedding is defined by the absence of clinical findings. Most infected women shed virus intermittently over time, and most HSV transmission to a partner occurs during these periods of asymptomatic viral shedding.

Vertical Transmission

HSV poses a higher risk to the newborn than to the mother. Thus, strategies aim to curb rates of vertical transmission, which may occur by three routes: (1) peripartum in 85 percent, (2) postnatal in 10 percent, or (3) intrauterine in 5 percent (James, 2015). Evidence does not suggest an obvious link between HSV infection and miscarriage (Zhou, 2015).

Peripartum transmission is by far the more frequent route of infection, and the fetus is exposed to virus shed from the lower genital tract. HSV-1 or -2 invades the uterus following membrane rupture or is transmitted by contact at delivery. The newborn is mainly infected, but rare cases of maternal endometritis have been described (Hollier, 1997; McGill, 2012). Of neonatal manifestations, infection may localize to the skin, eye, or mouth—*SEM disease*—in approximately 40 percent of cases. Instead, central nervous system (CNS) disease with encephalitis is seen in 30 percent. Last, disseminated disease that involves multiple major organs is found in 32 percent. Localized infection is usually associated with a good outcome. Conversely, even with acyclovir treatment, disseminated infection has a mortality rate of nearly 30 percent (Corey, 2009; Kimberlin, 2011). Of disseminated or cerebral infection survivors, serious developmental and CNS morbidity is seen in 20 to 50 percent.

In the United States, the neonatal infection rate ranges from 1 to 5 cases in 10,000 births (Donda, 2019; Mahant, 2019). Most infected newborns are born to mothers with no reported history of HSV infection (Gardella, 2010). The risk of neonatal infection correlates with the presence of HSV in the genital tract, HSV type, invasive obstetrical procedures, and stage of maternal infection (Brown, 2005, 2007). Neonates born to women who acquire genital HSV near the time of delivery have a 30- to 50-percent risk of infection. This is attributed to higher viral loads and the lack of transplacental protective antibodies (Brown, 1997, 2000). With recurrent HSV, the neonatal infection rate is <1 percent (Pasternak, 2010; Prober, 1987).

Postpartum transmission is uncommon and passed to the newborn by contact with an infected mother, family member, or health-care worker. The clinical presentation mirrors that with peripartum transmission.

In-utero transmission of HSV-1 or HSV-2 is rare and is part of the TORCH (toxoplasmosis, other, rubella, cytomegalovirus, herpes virus) group of infections. Intrauterine HSV infection classically leads to disease involving the skin (blisters, scarring), the CNS (hydranencephaly, microcephaly, intracranial calcification), or the eyes (chorioretinitis, microphthalmia). Bone and viscera can be involved (Marquez, 2011). Congenital infection with HSV or another TORCH infection is considered in a fetus with early or severe growth restriction, microcephaly, intracranial anomalies or calcifications, or hepatomegaly. If sonographic findings are identified, amniocentesis is recommended, and maternal HSV serological testing is done. Analysis of amnionic fluid for HSV-1 and HSV-2 serotypes is by NAAT (PCR) and culture (Curtin, 2013).

Diagnosis

The American College of Obstetricians and Gynecologists (2020d) and USPSTF (2016) recommend against routine serological HSV screening in asymptomatic gravidas. However, for a woman with a reported history of genital or oral lesions, a serological HSV diagnosis is sought. For women with either suspicious ulcers or sonographic findings suggestive of congenital infection, direct virological testing, described next, is performed along with serological testing for HSV. Testing for syphilis and other STIs is also considered for women with genital ulcers.

Direct virological tests, which are either PCR or culture, are performed on a specimen from a mucocutaneous lesion or from amniocentesis. For mucocutaneous lesions, PCR assays are more sensitive, the results generally are available in 1 to 2 days, and specimen handling is easier. The sensitivity of culture for detecting HSV is relatively low as vesicular lesions begin to ulcerate and then crust. Also, results sometimes are not available for 7 to 14 days (Strick, 2006). Regardless of the test performed, HSV viral types should be differentiated (LeGoff, 2014). Importantly, a negative culture or PCR result does not exclude infection. In contrast, false-positive results are rare. For amnionic fluid assessment, both culture and PCR are recommended (Curtin, 2013).

Serological assays detect antibodies produced against the specific HSV glycoproteins, G1 and G2. These proteins evoke type-specific antibody responses to HSV-1 and HSV-2 infection, respectively, and they reliably differentiate the two serotypes. Antibody detection confirms clinical infection and may reflect a carrier state in an asymptomatic patient. IgG antibodies develop 1 to 2 weeks after a primary infection and then persist. Serological testing may be falsely negative in the case of early infection but may also establish a nonprimary infection. For this reason, direct detection of the virus in a lesion with concomitant type-specific serological testing is helpful for clinical interpretation and counseling. Sensitivity and specificity of glycoprotein-based IgG tests approach 90 to 100 percent (Wald, 2002). IgM antibody detection is not a useful test, and antibodies may be detected with recurrent episodes.

Management

In nonpregnant patients, antiviral therapy with acyclovir, valacyclovir, or famciclovir is used to treat first-episode orogenital

TABLE 68-6. Oral Antiviral Medications for Herpesvirus Infection in Pregnancy[a]

Indication	Pregnancy Recommendation
Primary or first episode infection	Acyclovir, 400 mg three times daily for 7–10 d ***or*** Valacyclovir, 1 g twice daily for 7–10 d
Symptomatic recurrent infection (episodic therapy)	Acyclovir, 800 mg twice daily for 5 d ***or*** Acyclovir, 800 mg three times daily for 2 d ***or*** Valacyclovir, 500 mg twice daily for 3 d ***or*** Valacyclovir, 1 g once daily for 5 d
Daily suppression	Acyclovir, 400 mg three times daily from 36 weeks until delivery ***or*** Valacyclovir, 500 mg twice daily from 36 weeks until delivery

[a]Famciclovir not preferred during pregnancy due to fewer safety data.
Data from Workowski, 2021.

herpes. Oral or parenteral preparations attenuate clinical infection and viral shedding duration. Chronic suppressive therapy also is an option to limit recurrences and to reduce heterosexual transmission (Corey, 2004).

In pregnant women, acyclovir and valacyclovir are safe (Briggs, 2022; Stone, 2004). Data are limited regarding fetal effects with famciclovir.

For a primary outbreak during pregnancy, women may be given antiviral therapy to attenuate and decrease the duration of symptoms and viral shedding (Table 68-6). Women with HIV co-infection may require a longer duration of treatment. Those with severe or disseminated HSV are given IV acyclovir, 5 to 10 mg/kg every 8 hours for 2 to 7 days until clinically improved. This is followed by oral antiviral drugs to complete at least 10 days of total therapy (Workowski, 2021). For intense discomfort, oral analgesics and topical lidocaine ointment may provide some relief. Comorbid urinary retention is rare but can be treated briefly with an indwelling bladder catheter.

For recurrent HSV infections during pregnancy, antiviral treatment is provided mainly for symptom relief (see Table 68-6). Although uncommon, acyclovir resistance has been reported, predominantly in immunocompromised patients (Piret, 2016).

Of precautions during pregnancy, amniocentesis, percutaneous cord blood sampling, or transabdominal chorionic villus sampling may be performed even with active genital lesions. Transcervical procedures may best be delayed until lesions have resolved (American College of Obstetricians and Gynecologists, 2020d).

■ Peripartum Shedding Prophylaxis

To diminish vertical transmission risks, cesarean delivery is indicated for women with active genital lesions or prodromal symptoms. Several studies have shown that acyclovir or valacyclovir suppression initiated at 36 weeks' gestation for gravidas with recurrences during pregnancy lowers the number of HSV outbreaks at term. The goal is to decrease the need for cesarean delivery (Hollier, 2008). This suppressive therapy will also decrease viral shedding (Scott, 2002; Sheffield, 2006; Watts, 2003). One systematic review evaluated acyclovir prophylaxis given from 36 weeks to delivery to women with HSV recurrence during pregnancy. Sheffield and colleagues (2003) found that suppressive therapy was associated with significantly lower rates of clinical HSV recurrence, cesarean delivery for HSV recurrences, total HSV detection, and asymptomatic shedding. Subsequent studies using valacyclovir suppression showed similar results (Andrews, 2006; Sheffield, 2006). Because of these studies, the American College of Obstetricians and Gynecologists (2020d) recommends viral suppressive therapy to begin at ≥36 weeks' gestation for women with a clinical history of genital herpes. Suppression continues until delivery. Notably, despite maternal antiviral suppression, several cases of atypical neonatal herpes infection have been reported (Pinninti, 2012).

On presentation for delivery, a woman with a history of HSV should be questioned regarding current prodromal symptoms. A careful examination of the vulva, vagina, and cervix is performed for all, and women without genital lesions may proceed with labor and delivery. Usual obstetrical management, including invasive fetal monitoring, is supported in the absence of active lesions or prodromal symptoms (American College of Obstetricians and Gynecologists, 2020d).

Suspicious lesions should be swabbed for culture or NAAT evaluation. Cesarean delivery is indicated for women with suspicious genital lesions or prodromal symptoms. Moreover, for women with a clinical recurrence at delivery, there is no absolute duration of membrane rupture beyond which the fetus would not benefit from cesarean delivery (American College of Obstetricians and Gynecologists, 2020e).

Cesarean delivery is not recommended for women with a history of HSV infection but no active genital disease at the time of delivery. Moreover, an active lesion in a nongenital area can be covered by an occlusive dressing, and vaginal delivery is allowed.

With PPROM, no evidence suggests that external lesions cause ascending fetal infection. However, antiviral treatment during expectant care is recommended. Major and associates (2003) described expectant management in 29 such women at gestational ages <31 weeks. No cases of neonatal HSV developed, and the maximum infection risk was calculated to be 10 percent.

Women with active HSV lesions may breastfeed if the breast skin has no lesions. Strict hand washing is essential. Valacyclovir and acyclovir may be used for symptomatic maternal lesions during breastfeeding, as drug concentrations in breast milk are low (Sheffield, 2002a).

HUMAN PAPILLOMAVIRUS

Maternal Infection and Prevention

This is a common STI, and numerous serotypes infect the lower genital tract. In the United States from 2005 to 2006, the overall HPV prevalence was 40 percent in females aged 14 to 59 years (Liu, 2016). Prevalence is highest in younger women, and some of this seroprevalence now reflects HPV vaccination in this age group (Brouwer, 2015). Reproductive-aged women often become infected within a few years of sexual activity onset, and most infections are asymptomatic and transient. High-risk types are those with the most oncogenic potential. Of these, HPV types 16 and 18 are often associated with lower reproductive tract dysplasia (Chap. 66, p. 1165). Mucocutaneous genital warts termed *condyloma acuminata* are usually caused by types 6 and 11.

The clear link between HPV infection and cervical neoplasia led to development of vaccines that reduce cervical cancer risk (Lei, 2020). Although three vaccines are licensed, only one vaccine is currently available in the United States. Gardasil 9 is a nonavalent HPV vaccine against serotypes 6, 11, 16, 18, 31, 35, 45, 52, and 58. This vaccine is not recommended for gravidas. However, inadvertent exposures do occur, and no adverse pregnancy outcomes are associated (Kharbanda, 2021; Moreira, 2016; Scheller, 2017). If a woman is found to be pregnant after starting the vaccination series, remaining doses are delayed and given after delivery. Women who are breastfeeding may be vaccinated. Gardasil is licensed for females aged 9 to 45 years, and the target age is 11 to 12 years. It is recommended for those aged 9 to 26 years. It is suitable for those aged 27 to 45 years, after shared decision-making regarding age-related benefits and risks (American College of Obstetricians and Gynecologists, 2020b). The three-dose series is given on a schedule of 0, 2, and 6 months for those aged older than 15 (Table 10-7, p. 189). A two-dose regimen is used for younger individuals.

Condyloma Acuminata Treatment

Genital warts frequently grow in number and size with pregnancy. They commonly undergo apoptosis and resolution postpartum. Rarely, lesions may fill the vagina or cover the perineum and make vaginal delivery or episiotomy difficult. Genital wart eradication during pregnancy is usually unnecessary unless they are symptomatic. Therapy is directed toward debulking symptomatic warts yet minimizing treatment toxicity to the mother and fetus.

Trichloroacetic or *bichloracetic acid* in an 80- to 90-percent solution applied topically weekly is an effective regimen for external warts. Some prefer *cryotherapy, laser ablation*, or *surgical excision*. Agents that have limited safety data and thus are not recommended in pregnancy include podophyllin resin, podofilox solution or gel, imiquimod cream, and sinecatechins.

Neonatal Infection

Vertical transmission rates of HPV to the newborn are minimal. Juvenile-onset recurrent respiratory papillomatosis (JoRRP) is a rare, benign neoplasm of the larynx. It can cause hoarseness and respiratory distress in children and is most often caused by HPV 6 or 11. Risks for infection are maternal genital HPV infection and longer labors (Niyibizi, 2014). Although many newborns are likely exposed to HPV, few develop JoRRP (Smith, 2004). The incidence in 2013 in the United States was 5 cases in 10,000 births, and dropping rates are attributed to HPV vaccination (Meites, 2021). The benefit of cesarean delivery for prevention is unknown, and it is not recommended to avert HPV transmission.

VAGINITIS

Pregnant women frequently develop increased vaginal discharge. This may be a physiological discharge, described in Chapter 4 (p. 54), but should be differentiated from symptomatic vaginitis, which is also common in pregnancy. Fortunately, normal vaginal flora serve to prevent vaginitis. To better understand this, normal vaginal microflora composition and function are currently being studied in the Vaginal Human Microbiome Project (Huang, 2014).

Bacterial Vaginosis

Diagnosis

Bacterial vaginosis (BV) is a maldistribution of normal vaginal flora. With BV, numbers of lactobacilli are decreased, and anaerobic bacterial species are overrepresented. These anaerobes include *Gardnerella*, *Prevotella*, *Mobiluncus*, and *Bacteroides* species; *Atopobium vaginae*; and BV-associated bacteria, provisionally named BVAB1, BVAB2, and BVAB3. These last three are relatively newly recognized bacteria (Fredricks, 2005).

Ribosomal RNA gene-sequencing techniques have identified composite communities of vaginal flora, also called the *vaginal microbiota*. Five types of these composite communities exist and are referred to as *community state types (CSTs)*. A woman can be categorized to one of these five CSTs based on her vaginal microbiota composition (Ravel, 2011). Researchers have begun to quantify the risk of BV associated with these CST groups. Specifically, CSTs I, II, III, and V are rich in lactobacilli. CST IV is a heterogeneous microbiota of strict anaerobes and is associated with BV. CSTs vary racially, and CST IV is the most common in asymptomatic, healthy black women (Fettweis, 2014). Pregnancy-related changes in vaginal microbiota also are being defined and may hold keys to adverse BV-related pregnancy outcomes, discussed subsequently (Romero, 2014).

Of childbearing-aged women in the United States, nearly 30 percent have BV. In black women, the prevalence approximates 50 percent (Allsworth, 2007). Most women are asymptomatic. In those with symptoms, a foul, thin vaginal discharge is a typical complaint. Associated risk factors are douching, multiple partners, smoking, and altered host immunity (Desseauve, 2012; Koumans, 2007; Murphy, 2016).

For clinical diagnosis of BV, three of the four following *Amsel criteria* are present: (1) vaginal pH >4.5; (2) a thin, milky, noninflammatory vaginal discharge; (3) >20 percent clue cells seen microscopically; and (4) a fishy odor after addition of 10-percent potassium hydroxide to a vaginal secretion sample (Amsel, 1983). The last is described as a positive "whiff test" result. Likewise, alkalinity of seminal fluid and blood are responsible for complaints of foul odor after intercourse and with menses in affected women. Initially, a vaginal fluid sample is mixed with saline on a glass slide for microscopic evaluation, and this is often called a wet preparation or "wet prep." Clue cells are vaginal epithelial cells containing many attached bacteria, which create a poorly defined stippled cellular border (Fig. 68-5). Microscopically, leukocyte numbers are not increased. The higher vaginal pH stems from the diminished acid production due to a diminished lactobacilli population. Notably, *Trichomonas vaginalis* infection also is associated with anaerobic overgrowth and elaborated amines. Thus, women diagnosed with BV should have no microscopic evidence of trichomoniasis.

The *Nugent score*, used primarily in research rather than clinical practice, is a system employed for diagnosing BV (Nugent, 1991). During microscopic examination of a gram-stained vaginal discharge smear, scores are calculated by assessing bacteria staining and morphology.

NAATs to detect the bacterial types found in women with BV have suitable accuracy and may be used for symptomatic women (Coleman, 2018). However, these tests assess for bacteria that may also be part of normal flora in asymptomatic women. Moreover, compared with traditional methods, molecular tests have yet to show superior health outcomes but do add substantial cost.

Treatment

Adverse pregnancy-related health outcomes associated with BV are preterm birth, PPROM, and postpartum endometritis (Hillier, 1995; Watts, 1990). It also increases susceptibility to STIs, including HIV (Atashili, 2008; Brotman, 2010). For women at low risk for preterm birth, however, treatment of BV does not reduce preterm birth rates (Brocklehurst, 2013; Carey, 2000). The American College of Obstetricians and Gynecologists (2021) and USPSTF (2020) do not recommend routine BV screening of asymptomatic gravidas at low risk for preterm delivery. For women with prior preterm birth, evidence of screening and treatment benefits are conflicting (Kahwati, 2020). At Parkland Hospital, we do not routinely screen for BV among women with prior preterm birth.

Treatment is reserved for symptomatic women (Table 68-7). Agents not listed are best avoided due to insufficient data regarding their use in pregnancy (Workowski, 2021). It is still debated whether BV is a sexually transmitted infection, and treatment of a male partner does not lower recurrence rates (Amaya-Guio, 2016; Schwebke, 2021).

Trichomoniasis

Diagnosis

Vaginitis caused by *Trichomonas vaginalis* is common, and its prevalence in the United States approximates 2 percent in women (Patel, 2018). The prevalence is higher in those older than 30 years compared with younger women. Risks include black race, douching, and greater number of lifetime sexual partners (Sutton, 2007). Among women, frequent sites of infection include the urethra, endocervix, and vagina. Those with symptomatic vaginitis often have a purulent discharge, pruritus, vulvovaginal erythema, and colpitis macularis. The last is often termed a "strawberry cervix" and displays a patchy, maculoerythematous ectocervix.

Trichomonads are flagellated, pear-shaped, motile organisms that are somewhat larger than leukocytes. These parasites can readily be seen microscopically moving briskly in wet

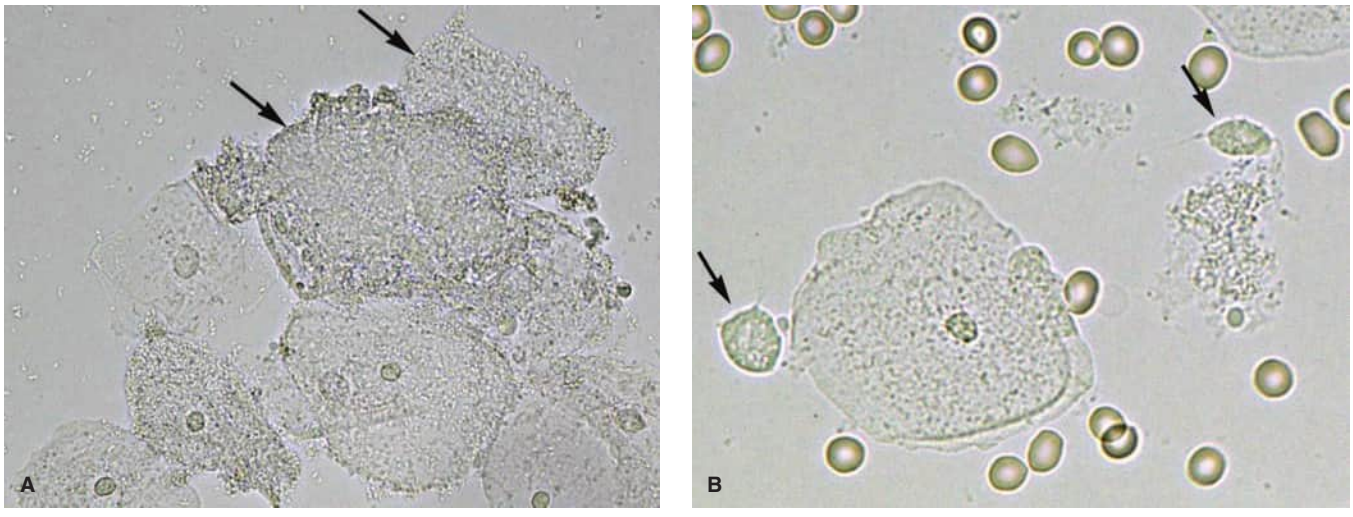

FIGURE 68-5 A. Bacterial vaginosis. Microscopy reveals several squamous cells heavily studded with bacteria. Clue cells are covered to the extent that cell borders are blurred and nuclei are not visible (*arrows*). **B.** Trichomonads (*arrows*).

TABLE 68-7. Treatment of Bacterial Vaginosis in Pregnancy[a]

Regimen	Drug and Dosage
Preferred	Metronidazole, 500 mg orally twice daily for 7 d ***or*** Metronidazole 0.75-percent gel, one applicator intravaginally, daily for 5 d
Alternative	Clindamycin, 300 mg orally twice daily for 7 d ***or*** Clindamycin ovules, 100 mg intravaginally nightly for 3 d

[a]Other agents not listed here are ideally avoided due to insufficient pregnancy data.
Data from Workowski, 2021.

preparation. Prompt inspection of vaginal secretions is advantageous because trichomonads slow with cooling. At times, *T vaginalis* may be found incidentally on a Pap test slide. Both of these microscopic approaches have low diagnostic sensitivity that approximates 60 percent (Krieger, 1988; Wiese, 2000). Pap tests can also yield false-positive results. Thus, Pap test trichomonad findings warrant confirmation with either a wet prep or NAAT.

Of other direct detection methods, culture is expensive, lengthy, and only 75 to 95 percent sensitive (Association of Public Health Laboratories, 2016; Huppert, 2007). Laboratory NAAT-based evaluation of a vaginal, endocervical, or urine sample is available, is completed in minutes to hours, and offers superior sensitivity of 95 to 100 percent (Van Der Pol, 2016). Although more costly than wet-preparation microscopy, a NAAT may be a useful, second-line diagnostic test for microscopy-negative samples. An optimal approach in pregnancy has not been established. Rapid POC testing is also available but may sacrifice sensitivity for speed. The OSOM Trichomonas Rapid Test provides results in 10 minutes, is suitable for office use, and has sensitivities of 88 to 98 percent (Herbst de Cortina, 2016).

Treatment

Treatment is reserved for symptomatic women (Table 68-8). Previously, a one-time, 2-g dose of oral metronidazole was used to eradicate *T vaginalis*. In nonpregnant women, a large randomized trial compared this traditional therapy against metronidazole, 500 mg orally twice daily for 7 days. The longer course provided improved efficacy (Kissinger, 2018). New guidelines from the American College of Obstetricians and Gynecologists (2020g) now recommend this change in nonpregnant women. The CDC recognizes this regimen for pregnancy.

Reinfection rates among women treated for trichomoniasis are high (Kim, 2020). Thus, retesting for *T vaginalis* is recommended for all sexually active women within 3 months following initial therapy (Workowski, 2021). Some authors recommend retesting 3 weeks after treatment in pregnancy (Lazenby, 2019).

TABLE 68-8. Oral Treatment of Trichomoniasis in Pregnancy[a,b]

Regimen	Drug and Dosage
Preferred	Metronidazole, 500 mg orally twice daily for 7 d

[a]Retesting is encouraged at 3 months to exclude reinfection.
[b]Tinidazole is not recommended in pregnancy.
Data from Workowski, 2021.

Metronidazole is not teratogenic or fetotoxic, and it may be used in all pregnancy stages (Briggs, 2022; Czeizel, 1998; Workowski, 2021). The manufacturer recommends against its use during the first trimester (Pfizer, 2021). Fewer data are available for tinidazole, and thus metronidazole is preferred. For allergic patients, metronidazole desensitization is effective (Helms, 2008). With breastfeeding, the longer, lower-dose metronidazole regimen is not associated with adverse infant outcomes (LactMed, 2021).

Perinatal transmission of trichomoniasis by direct contact in the birth canal is rare but may lead to neonatal respiratory or genital infection (Bruins, 2013; Trintis, 2010). Some studies have linked trichomonal infection with preterm birth (Van Gerwen, 2021). A few other studies implicate this infection with PPROM and small-for-gestational age newborns (Silver, 2014). However, treatment in two randomized studies did not lower preterm birth rates (Klebanoff, 2001; Stringer, 2010).

In sum, treating symptomatic women is reasonable. For most asymptomatic women during pregnancy, screening is not done. However, screening at the first prenatal visit and prompt treatment are encouraged for gravidas with comorbid HIV infection. In this group, *T vaginalis* infection may be a risk factor for vertical HIV transmission (Gumbo, 2010).

Candidiasis

Candida albicans or other candidal species can be identified by culture from the vagina during pregnancy in approximately 20 percent of women. A link between candidiasis and preterm birth is not robust (Cotch, 1998; Roberts, 2015). Thus, asymptomatic colonization requires no treatment. The organism, however, can create a profuse, irritating discharge.

For symptoms, effective treatment is listed in Table 68-9. In pregnancy, the CDC recommends 7-day regimens and suggests topical rather than oral azoles (Workowski, 2021). In some women, infection is likely to recur and require repeat treatment. In these cases, symptomatic infection usually subsides after pregnancy (Sobel, 2007). Although not preferred treatment, a single, 150-mg oral fluconazole dose is generally not considered teratogenic. Data showing a small association with cardiac anomalies are conflicting, but more recent evidence is

TABLE 68-9. Daily, Intravaginal Agents in 7-Day Regimens for Vulvovaginal Candidiasis Treatment in Pregnancy

Brand Name	Formulation
Clotrimazole	
Clotrimazole	1% cream, 1 applicator
Miconazole

reassuring (Mølgaard-Nielsen, 2013; Zhu, 2020). In 2019, the FDA noted that reviewed data do not provide conclusive evidence for an increased miscarriage or stillbirth risk.

HUMAN IMMUNODEFICIENCY VIRUS

Pathogenesis

For *human immunodeficiency viruses*, which are *HIV-1* and *HIV-2,* sexual intercourse is the main mode of transmission. The virus can be passed by blood, and infected mothers may infect their fetuses during labor and delivery or by breast milk. The primary determinant of transmission is the maternal plasma viral load.

For sexual transmission, the viral HIV envelope binds to mucosal dendritic cells. These cells then present the viral particle to specific T lymphocytes. These lymphocytes are defined phenotypically by their *cluster of differentiation 4 (CD4)* glycoprotein surface antigens. The CD4 site serves as a receptor for the virus. Once infected, CD4 T lymphocytes are gradually depleted, which creates an immunodeficiency that is characterized by low serum CD4 counts. In some infected with HIV, *acquired immunodeficiency syndrome (AIDS)* reflects profound immunodeficiency that gives rise to various opportunistic infections and neoplasms.

The incubation period from exposure to clinical disease averages 3 to 6 weeks. Acute HIV infection is similar to many other viral syndromes and usually lasts less than 10 days. Common symptoms, if any, include fever, fatigue, rash, headache, lymphadenopathy, pharyngitis, myalgias, nausea, and diarrhea. After symptoms abate, the level of viremia usually declines to a set point, and patients with the highest viral burden at this time progress more rapidly to AIDS and death. According to the CDC, AIDS is defined by a CD4 T-cell count <200 cells/μL, by CD4 T cells constituting <14 percent of all lymphocytes, or by one of several AIDS-defining illnesses (Selik, 2014). Route of infection, viral strain's pathogenicity, initial viral inoculum, and the host's immunological status all affect progression.

Prenatal HIV Screening

In the United States, approximately 5000 women with HIV give birth annually (Nesheim, 2018). However, the estimated number of perinatally acquired HIV cases has dropped, and the rate was 0.9 per 100,000 live births in 2018 (Centers for Disease Control and Prevention, 2020a). The decline predominantly stems from prenatal HIV testing and antiretroviral therapy (ART) for the woman and then her neonate.

The CDC (2006b) and the American College of Obstetricians and Gynecologists (2020f) recommend prenatal HIV screening using an *opt-out approach*. With this, HIV testing is routinely included in antenatal testing, but this testing may be declined. Women are given information regarding HIV but are not required to sign a specific consent. This opt-out strategy has raised HIV testing rates and is permitted in every United States jurisdiction (Centers for Disease Control and Prevention, 2020b).

Repeat screening during the third trimester, preferably before 36 weeks' gestation, is *considered* for all pregnant women. Retesting is *recommended* in areas where HIV rates exceed 1 case per 1000 pregnant women screened or for those with risk factors. These include incarceration, injection drug use, prostitution, a suspected or known HIV-infected sexual partner, a new or multiple sexual partners, or diagnosis of another STI (American College of Obstetricians and Gynecologists, 2020f).

The initial laboratory screening test for HIV is an antigen/antibody combination immunoassay that detects antibodies against HIV-1 and HIV-2 and detects HIV-1 p24 antigen (Centers for Disease Control and Prevention, 2018a). No further testing is required for specimens that yield negative results on the initial immunoassay unless a known recent exposure to HIV has occurred. Antibody can be detected in most patients within 1 month of infection, and thus a test for antibodies alone may not exclude early infection. Instead, for acute primary HIV infection, identification of viral p24 core antigen or viral RNA is necessary.

Specimens with a "reactive" (that is, a positive) antigen/antibody combination immunoassay result should be tested with an antibody immunoassay that differentiates HIV-1 antibodies from HIV-2 antibodies (Fig. 68-6). The HIV-1/HIV-2 antibody differentiation immunoassay provides results that are reported as positive or negative for HIV-1 antibodies, for HIV-2 antibodies, or for HIV antibodies, undifferentiated. If these two serial immunoassays (the initial screen and the differentiation assay) are discordant, an HIV-1 NAAT—qualitative or quantitative HIV RNA test—is performed (Centers for Disease Control and Prevention, 2018a).

At delivery, women with undocumented HIV status should have a fourth-generation HIV antigen/antibody combination screening test performed on a blood sample. A negative screening test result does not need confirmation. However, in cases of recent HIV exposure, consideration is given to peripartum interventions to reduce perinatal transmission despite negative HIV testing. Repeat interval testing is recommended to exclude very early infection not identified with the initial screen. With a positive fourth-generation HIV testing result, peripartum and neonatal interventions to reduce perinatal transmission are initiated. These include intravenous zidovudine infusion during labor and avoidance of breastfeeding, although breast

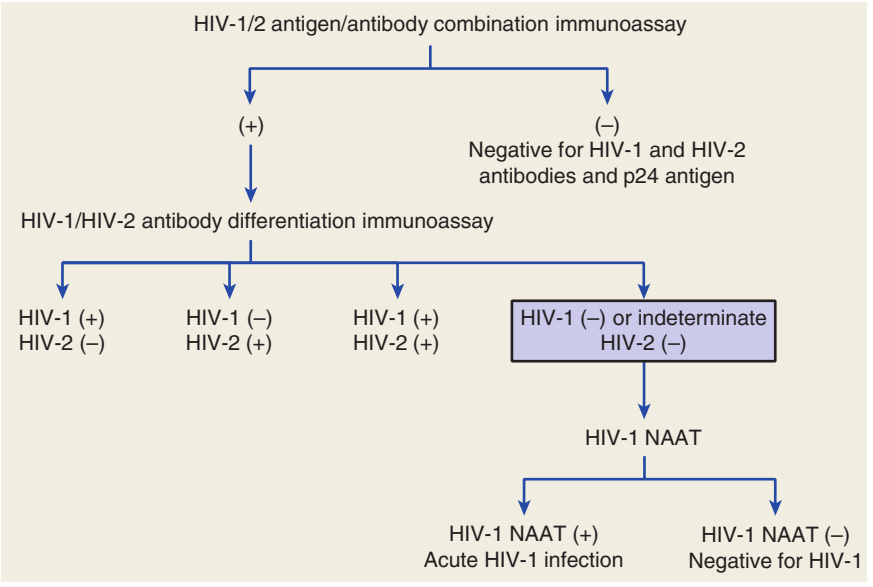

FIGURE 68-6 Algorithm for HIV testing. For specimens that are reactive on the initial antigen/antibody combination immunoassay and nonreactive or indeterminate on the HIV-1/HIV-2 antibody differentiation immunoassay, a nucleic acid amplification test (NAAT) is performed. Following a nonreactive HIV-1/HIV-2 antibody differentiation immunoassay, a positive HIV-1 NAAT indicates laboratory evidence for acute HIV-1 infection. A positive HIV-1 NAAT result following indeterminate HIV-1/HIV-2 antibody differentiation immunoassay indicates the presence of HIV-1 infection confirmed by HIV-1 NAAT. A negative HIV-1 NAAT result following nonreactive or indeterminate HIV-1/HIV-2 antibody differentiation immunoassay indicates a false-positive result on the initial antigen/antibody combination immunoassay. (Reproduced with permission from Centers for Disease Control and Prevention, 2018a.)

milk may be stored until confirmatory test results are available (Panel on Treatment of Pregnant Women with HIV Infection and Prevention of Perinatal Transmission, 2021). Interventions are continued until the results of an antibody differentiation assay—and qualitative or quantitative RNA test if indicated—is known. Interventions can be discontinued if confirmatory testing is negative. To confirm a positive result from any initial HIV test, the laboratory testing algorithm in Figure 68-6 is used and begins with the antigen/antibody combination immunoassay.

Vertical Transmission

Viral burden and neonatal infection rates are directly related. In one cohort, neonatal infection was 1 percent with <400 copies/mL, and it was 23 percent when maternal viral RNA levels were >30,000 copies/mL (Cooper, 2002). Among 2615 neonates born to mothers taking ART before conception and during pregnancy, no cases of vertical transmission occurred when maternal viral loads were <50 copies/mL at delivery (Mandelbrot, 2015). Transmission of HIV infection, however, has been observed at all HIV RNA levels, including those that were nondetectable by current assays. Transplacental HIV transmission can occur early, and the virus has even been identified in specimens from elective abortion (Lewis, 1990). Kourtis and colleagues (2001) estimated that 20 percent of vertical transmission occurs before 36 weeks' gestation, 50 percent in the days before delivery, and 30 percent intrapartum. Transmission rates for breastfeeding may be as high as 30 to 40 percent and are associated with increasing HIV viral burden (Kourtis, 2006, 2007; Slyker, 2012). In nonpregnant individuals, concomitant STIs and horizontal HIV transmission are linked. Evidence also supports that vertical transmission rates may be increased by comorbid STIs (Schulte, 2001; Watts, 2012).

Antepartum Care

Pregnant women with HIV infection need special attention and are seen in consultation by physicians with special interest in this field. An additional resource is the National Perinatal HIV Hotline (1–888–448–8765), which provides free antepartum, intrapartum, or postpartum consultation to providers. At Parkland Hospital, a pregnant woman with HIV infection is initially assessed with the following:

- Standard prenatal laboratory surveys that include serum creatinine, complete blood count, and bacteriuria screening
- Plasma HIV RNA quantification, which establishes the "viral load" value, and antiretroviral resistance testing if the viral load is at least 500 to 1000 copies/mL
- CD4 T-cell count
- Screening for chlamydial infection, gonorrhea, syphilis, and trichomoniasis, if not previously performed with new HIV diagnosis
- Serum hepatic aminotransferase levels
- HSV-1 and -2, cytomegalovirus, toxoplasmosis, and hepatitis B and C serological screening
- Baseline chest radiograph
- Tuberculosis testing with purified protein derivative (PPD) skin testing or with interferon-gamma release assay
- Evaluation of need for pneumococcal, hepatitis A, hepatitis B, Tdap, COVID-19, and influenza vaccines
- Sonographic evaluation to establish gestational age.

During pregnancy, the risk of HIV transmission does not appear to be increased with amniocentesis or other invasive diagnostic procedures in women receiving effective ART that results in viral suppression (Floridia, 2017). For women not receiving ART, the risk rises approximately twofold (Mandelbrot, 1996). If amniocentesis is performed, efforts are taken to avoid passing through the placenta (Panel on Treatment of Pregnant Women with HIV Infection and Prevention of Perinatal Transmission, 2021).

Antiretroviral Therapy

In overview, the ideal strategy to suppress viral load and minimize vertical HIV transmission includes (1) preconceptional ART, (2) antepartum ART, (3) intrapartum continuation of the antepartum oral ART regimen plus IV zidovudine, and (4)

newborn ART prophylaxis. ART is recommended for all pregnant women with HIV infection, and it should be initiated as early in pregnancy as possible. Treatment reduces the risk of perinatal transmission regardless of CD4 T-cell count or HIV RNA level. Regimen adherence is emphasized to help prevent viral drug resistance. Gravidas are treated with at least three antiretroviral (ARV) agents.

The Panel on Treatment of Pregnant Women with HIV Infection and Prevention of Perinatal Transmission (2021) has issued guidelines for four different scenarios during pregnancy (Table 68-10). The following paragraphs summarize these recommendations.

First, women already taking ART at pregnancy onset are encouraged to continue their regimen if viral suppression is adequate and if the ARV is safe and tolerated. Didanosine, stavudine, and full-dose ritonavir, which differs from ritonavir-boosted agents, are exceptions due to pregnancy toxicity but not teratogenicity. The lopinavir/ritonavir combination is no longer recommended based on risks for preterm and small-for-gestational-age neonates.

Second, women who have never received antiretroviral therapy—*antiretroviral naïve*—are given ART regardless of trimester. In general, the starting regimen comprises two nucleoside reverse transcriptase inhibitors that are coupled into a single agent *plus* either a ritonavir-boosted protease inhibitor or an integrase inhibitor.

Third, women who have previously received antiretroviral therapy but are currently not taking medications should undergo HIV-resistance testing because prior ART use raises the risk of drug resistance. However, ART is initiated prior to receiving results of these drug-resistance tests. In this case, initial ART selection should factor results of any prior resistance testing, if available; prior ART regimen; and current ART pregnancy guidelines, that is, those for ART-naïve women. Drug-resistance testing may then modify the initial regimen.

TABLE 68-10. Recommendations for HIV Antiviral Drug Use During Pregnancy

Clinical Scenario	Recommendations
Taking ART and becomes pregnant	Continue current medication if viral suppression adequate and patient tolerating
ART naïve	Initiate ART: combine two NRTIs with either a ritonavir-boosted PI or an integrase inhibitor – Preferred NRTI dual combinations: abacavir/lamivudine, tenofovir disoproxil fumarate (TDF)/emtricitabine, or TDF/lamivudine. If abacavir is used, HLA-B*5701 testing is completed to identify potential hypersensitivity reaction – Preferred PI: atazanavir/ritonavir or darunavir/ritonavir – Preferred integrase inhibitor: dolutegravir or raltegravir. Dolutegravir should not be administered within 2 hr of prenatal vitamins, iron, or calcium
Prior ART use but not currently	Initiate ART, with regimen based on prior therapy history and resistance testing
No ART use and presents in labor	IV ZDV (see Intrapartum care below)
Antepartum care	See antepartum screening test list (p. 1220) Initiate ART as early as possible For those with HIV RNA levels >500–1000 copies/mL, order HIV antiretroviral drug-resistance testing but do not delay ART initiation while awaiting results Repeat HIV RNA levels 2–4 wks after initiating (or changing) ART drugs; monthly until RNA levels are undetectable; then at least every 3 mo; and finally at 34–36 weeks' gestation for delivery planning CD4+ count should be monitored at the initial visit and every 3–6 mo
Intrapartum care	If HIV RNA level >1000 copies/mL or is unknown, plan cesarean delivery at 38 weeks' gestation before labor or ROM If HIV RNA levels >1000 copies/mL or is unknown but labor or ROM has ensued, benefits of cesarean delivery are unclear and labor plans are individualized If HIV RNA level ≤1000 copies/mL, vaginal delivery is permitted; cesarean delivery is not routinely recommended Start IV ZDV unless the following criteria are met: taking a prescribed oral ART regimen, HIV RNA level <50 copies/mL at 34 to 36 weeks' gestation or 3–4 weeks before delivery. Dosing is a 2-mg/kg IV load over 1 hr, then 1 mg/kg/hr until delivery. IV ZDV should begin 3 hr before scheduled cesarean delivery Those taking oral antepartum ART should continue during labor with sips of water

ART = antiretroviral therapy; NRTI = nucleoside reverse transcriptase inhibitor; ROM = rupture of membranes; ZDV = zidovudine.
Adapted from the Panel on Treatment of Pregnant Women with HIV Infection and Prevention of Perinatal Transmission, 2021.

For these three categories of women taking antepartum ART, therapy surveillance is outlined in Table 68-10. Most patients with adequate viral response have at least a 1-log viral load decline within 1 to 4 weeks after starting therapy. Newer integrase inhibitors rapidly decrease viral loads and are useful for women presenting late to prenatal care (Lockman, 2021). For those who fail to achieve this degree of decline, regimen compliance is assessed, resistance studies are reviewed, and ART modification is considered.

During labor and delivery, an oral ART regimen is continued with sips of water. Additionally, IV zidovudine is administered to women during labor and before cesarean delivery. An exception to this addition is the patient who is strictly adherent to her prescribed oral ART regimen and who has an HIV RNA level that was previously documented to be <50 copies/mL at 34 to 36 weeks' gestation or at 3 to 4 weeks before delivery. At Parkland Hospital, we administer intrapartum IV zidovudine to all HIV-positive women, regardless of viral load. A 2-mg/kg loading dose is infused over 1 hour and is followed with zidovudine, 1 mg/kg/hr until delivery. Women with HIV undergoing a scheduled cesarean delivery are given IV zidovudine as a loading dose followed by 2 more hours of continuous maintenance therapy—a total of 3 hours of infused zidovudine prior to surgery.

The fourth group includes women who present in labor and who are taking no ART regimen. These women are given IV zidovudine intrapartum as just described.

Delivery Planning

In some cases, cesarean delivery lowers HIV prenatal transmission rates (International Perinatal HIV Group, 1999). The American College of Obstetricians and Gynecologists (2020c) suggests that scheduled cesarean delivery be discussed and recommended for HIV-infected women with HIV-1 RNA load >1000 copies/mL. Scheduled delivery is recommended at 38 weeks' gestation in these women to avoid spontaneous labor. Management of women with either HIV-1 RNA load >1000 copies/mL or unknown viral load who present in labor or with ruptured membranes is individualized. For these women, IV zidovudine is recommended as previously described. In the case of early labor, cesarean delivery is preferred to vaginal birth.

For women with HIV RNA load ≤1000 copies/mL, cesarean delivery to reduce the risk of vertical HIV transmission is not recommended and is unlikely to confer additional benefit to women already taking ART and achieving viral suppression (Briand, 2013; Jamieson, 2007). Vaginal delivery in this group is the goal, and awaiting spontaneous onset of labor is suitable. Labor is not induced to prevent perinatal HIV transmission.

During labor, artificial membrane rupture, fetal scalp electrode placement, episiotomy, and operative vaginal delivery are performed for standard obstetrical indications but are avoided if possible in women with detectable RNA viral load (Peters, 2016). Labor augmentation is used when needed to shorten the interval to delivery to help further lower the transmission risk. For the benefits described in Chapter 27 (p. 500), delayed cord clamping in preterm neonates is acceptable and may be considered for term newborns**.** Neuraxial analgesia is suitable. Postpartum hemorrhage is best managed with oxytocin and prostaglandin analogues. *Methylergonovine (Methergine) and other ergot alkaloids adversely interact with reverse transcriptase and protease inhibitors to cause severe vasoconstriction.*

Postpartum Care

Vertical transmission rates rise with breastfeeding, and it generally is not recommended for women with HIV infection in the United States, where formula is readily available (Committee on Pediatric AIDS, 2013). In nutritionally deprived countries, where infectious disease and malnutrition are primary causes of infant death, the World Health Organization (2016) recommends exclusive breastfeeding during the first 6 to 12 months.

The Panel on Treatment of Pregnant Women with HIV Infection and Prevention of Perinatal Transmission (2021) strongly recommends that ART regimens not be discontinued postpartum but continued lifelong for the advantages of viral suppression. Ideally, all those planning pregnancy should be receiving ART and have a viral load below detectable levels before conception. As one benefit, interpregnancy viral load suppression is associated with less vertical transmission in a subsequent pregnancy (French, 2014; Stewart, 2014). Reassuringly, for those seeking subsequent pregnancy, when ART is available, repeated pregnancy in a healthy woman with HIV has no significant effect on disease progression (Calvert, 2015). Transition postpartum to general HIV care is critical to maintain viral suppression (Swain, 2016).

Prevention

For adults without HIV infection but with risks for HIV acquisition, the USPSTF (2019b) recommends offering preexposure prophylaxis (PrEP) to decrease the risk of acquiring HIV. Risk factors for heterosexually active women without HIV infection are a partner with HIV, syphilis or gonorrhea within the past 6 months, and inconsistent condom use with a high-risk partner. The last is a partner with injection drug use or with multiple other sexual partners. Current guidance from the CDC (2018b) emphasizes the use of ART to achieve viral suppression in the infected partner and barrier use as primary methods of preventing horizontal transmission. However, PrEP for the HIV-negative partner is considered, including during pregnancy to reduce the risk of HIV acquisition and also vertical transmission. PrEP with tenofovir disoproxil fumarate (TDF)/emtricitabine taken orally daily is acceptable during pregnancy and is encouraged particularly if the HIV viral load of the infected partner is unknown or unsuppressed. Barrier methods are reinforced.

For conception in HIV-serodiscordant couples, assisted reproductive technologies are available. In lower-resource settings, acceptable approaches combine *safer conception methods*. These include combinations of treatment to achieve viral suppression for the HIV-seropositive partner, PrEP for the HIV-seronegative partner, STI screening and treatment, timed condomless sex during peak fertility days, and self-insemination, (American Society for Reproductive Medicine, 2021; Schwartz, 2019).

If pregnancy is undesired, contraception options are discussed (Chap. 38, p. 664). Counseling also includes education

for decreasing high-risk sexual behaviors to prevent HIV transmission or acquisition and to decrease other STI acquisition.

APPENDIX

APPENDIX I. Serum and Blood Constituents

HEMATOLOGY

	Nonpregnant Adult[a]	1st Trimester	2nd Trimester	3rd Trimester	References
Erythropoietin[b] (U/L)	4–27	12–25	8–67	14–222	8, 11, 58
Ferritin[b] (ng/mL)	10–150[d]	6–130	2–230	0–116	8, 11, 46, 52, 56, 58, 73, 82
Folate, red blood cell (ng/mL)	150–450	137–589	94–828	109–663	56, 57, 84
Folate, serum (ng/mL)	5.4–18.0	2.6–15.0	0.8–24.0	1.4–20.7	8, 53, 56, 57, 64, 69, 84
Haptoglobin (mg/mL)	25–250	130 ± 43	115 ± 50	135 ± 65	31
Hemoglobin[b] (g/dL)	12–15.8[d]	11.6–13.9	9.7–14.8	9.5–15.0	11, 56, 58, 69, 73
Hematocrit[b] (%)	35.4–44.4	31.0–41.0	30.0–39.0	28.0–40.0	7, 8, 11, 52, 56 69, 77
Iron, total binding capacity (TIBC)[b] (μg/dL)	251–406	278–403	Not reported	359–609	73
Iron, serum[b] (μg/dL)	41–141	72–143	44–178	30–193	11, 73
Mean corpuscular hemoglobin (MCH) (pg/cell)	27–32	30–32	30–33	29–32	52
Mean corpuscular volume (MCV) ($\times m^3$)	79–93	81–96	82–97	81–99	7, 52, 56, 69
Platelet ($\times 10^9$/L)	165–415	174–391	155–409	146–429	5, 7, 18, 52, 56
Mean platelet volume (MPV) (μm^3)	6.4–11.0	7.7–10.3	7.8–10.2	8.2–10.4	52
Red blood cell count (RBC) ($\times 10^6/mm^3$)	4.00–5.20[d]	3.42–4.55	2.81–4.49	2.71–4.43	7, 52, 56, 69
Red cell distribution width (RDW) (%)	<14.5	12.5–14.1	13.4–13.6	12.7–15.3	52
White blood cell count (WBC) ($\times 10^3/mm^3$)	3.5–9.1	5.7–13.6	5.6–14.8	5.9–16.9	7, 10, 52, 56, 69
Neutrophils ($\times 10^3/mm^3$)	1.4–4.6	3.6–10.1	3.8–12.3	3.9–13.1	5, 7, 10, 52
Lymphocytes ($\times 10^3/mm^3$)	0.7–4.6	1.1–3.6	0.9–3.9	1.0–3.6	5, 7, 10, 52
Monocytes ($\times 10^3/mm^3$)	0.1–0.7	0.1–1.1	0.1–1.1	0.1–1.4	7, 10, 52
Eosinophils ($\times 10^3/mm^3$)	0–0.6	0–0.6	0–0.6	0–0.6	7, 10
Basophils ($\times 10^3/mm^3$)	0–0.2	0–0.1	0–0.1	0–0.1	7, 10
Transferrin (mg/dL)	200–400[c]	254–344	220–441	288–530	46, 52
Transferrin, saturation without iron (%)	22–46[b]	Not reported	10–44	5–37	58
Transferrin, saturation with iron (%)	22–46[b]	Not reported	18–92	9–98	58

COAGULATION

	Nonpregnant Adult[a]	1st Trimester	2nd Trimester	3rd Trimester	References
Antithrombin III, functional (%)	70–130	89–114	78–126	82–116	17, 18, 47
D-Dimer (μg/mL)	0.22–0.74	0.05–0.95	0.32–1.29	0.13–1.7	18, 28, 29, 43, 47, 51, 62
Factor V (%)	50–150	75–95	72–96	60–88	49
Factor VII (%)	50–150	100–146	95–153	149–2110	18
Factor VIII (%)	50–150	90–210	97–312	143–353	18, 49
Factor IX (%)	50–150	103–172	154–217	164–235	18
Factor XI (%)	50–150	80–127	82–144	65–123	18
Factor XII (%)	50–150	78–124	90–151	129–194	18
Fibrinogen (mg/dL)	233–496	244–510	291–538	301–696	18, 28, 29, 47, 51, 52, 62
Fibronectin (mg/L)	290 ± 85	377 ± 309	315 ± 295	334 ± 257	33
Homocysteine (μmol/L)	4.4–10.8	3.34–11	2.0–26.9	3.2–21.4	53, 56, 57, 64, 84
International normalized ratio (INR)	0.9–1.04[g]	0.86–1.08	0.83–1.02	0.80–1.09	17, 51
Partial thromboplastin time, activated (aPTT) (sec)	26.3–39.4	23.0–38.9	22.9–38.1	22.6–35.0	17, 18, 51, 52
Prothrombin time (PT) (sec)	12.7–15.4	9.7–13.5	9.5–13.4	9.6–12.9	18, 51, 52
Protein C, functional (%)	70–130	78–121	83–133	67–135	17, 27, 49
Protein S, total (%)	70–140	39–105	27–101	33–101	18, 27, 49
Protein S, free (%)	70–140	34–133	19–113	20–65	27, 49
Protein S, functional activity (%)	65–140	57–95	42–68	16–42	49
Thrombin time (TT) (sec)	17.7 ± 2.8	16.1 ± 1.5	15.4 ± 2.7	16.5 ± 2.4	33
Thrombomodulin (ng/mL)	2.7 ± 3.1	4.3 ± 1.3	4.2 ± 1.2	3.6 ± 1.3	33
Tissue plasminogen activator (ng/mL)	1.6–13[h]	1.8–6.0	2.36–6.6	3.34–9.20	17, 18, 29
Tissue plasminogen activator inhibitor-1 (ng/mL)	4–43	16–33	36–55	67–92	18, 29
von Willebrand disease					
von Willebrand factor antigen (%)	75–125	62–318	90–247	84–422	47, 55, 85
ADAMTS-13, von Willebrand cleaving protease (%)	40–170[i]	40–160	22–135	38–105	47, 55

BLOOD CHEMICAL CONSTITUTENTS

	Nonpregnant Adult[a]	1st Trimester	2nd Trimester	3rd Trimester	References
Alanine aminotransferase (ALT) (U/L)	7–41	3–30	2–33	2–25	6, 46, 52, 82
Albumin (g/dL)	4.1–5.3[d]	3.1–5.1	2.6–4.5	2.3–4.2	3, 6, 30, 35, 46, 52, 84
Alkaline phosphatase (U/L)	33–96	17–88	25–126	38–229	3, 6, 46, 52, 82
Alpha-1 antitrypsin (mg/dL)	100–200	225–323	273–391	327–487	52
Alpha-fetoprotein (ng/mL)	—	—	~130–400	~130–590	48
Ammonia (μM)	31 ± 3.2	—	—	27.3 ± 1.6	39
Amylase (U/L)	20–96	24–83	16–73	15–81	40, 46, 52, 80
Anion gap (mmol/L)	7–16	13–17	12–16	12–16	52
Aspartate aminotransferase (AST) (U/L)	12–38	3–23	3–33	4–32	6, 46, 52, 82
Bicarbonate (mmol/L)	22–30	20–24	20–24	20–24	52
Bilirubin, total (mg/dL)	0.3–1.3	0.1–0.4	0.1–0.8	0.1–1.1	6, 46
Bilirubin, unconjugated (mg/dL)	0.2–0.9	0.1–0.5	0.1–0.4	0.1–0.5	6, 52
Bilirubin, conjugated (mg/dL)	0.1–0.4	0–0.1	0–0.1	0–0.1	6
Bile acids (μmol/L)	0.3–4.8[j]	0–4.9	0–9.1	0–11.3	6, 16
CA-125 (μg/mL)	7.2–27	2.2–268	12–25.1	16.8–43.8	4, 37, 79
Calcium, ionized (mg/dL)	4.5–5.3	4.5–5.1	4.4–5.0	4.4–5.3	30, 52, 59, 67
Calcium, total (mg/dL)	8.7–10.2	8.8–10.6	8.2–9.0	8.2–9.7	3, 35, 46, 52, 59, 67, 74
Ceruloplasmin (mg/dL)	25–63	30–49	40–53	43–78	52, 54
Chloride (mEq/L)	102–109	101–105	97–109	97–109	22, 46, 52
Creatinine (mg/dL)	0.5–0.9[d]	0.4–0.7	0.4–0.8	0.4–0.9	46, 52, 56
Gamma-glutamyl transpeptidase (GGT) (U/L)	9–58	2–23	4–22	3–26	6, 46, 52, 82
Lactate dehydrogenase (U/L)	115–221	78–433	80–447	82–524	35, 46, 52, 82
Lipase (U/L)	3–43	21–76	26–100	41–112	40
Magnesium (mg/dL)	1.5–2.3	1.6–2.2	1.5–2.2	1.1–2.2	3, 30, 35, 46, 52, 59, 74
Osmolality (mOsm/kg H_2O)	275–295	275–280	276–289	278–280	19, 74
Phosphate (mg/dL)	2.5–4.3	3.1–4.6	2.5–4.6	2.8–4.6	3, 30, 41, 46, 52
Potassium (mEq/L)	3.5–5.0	3.6–5.0	3.3–5.0	3.3–5.1	22, 30, 35, 46, 52, 74, 77
Prealbumin (mg/dL)	17–34	15–27	20–27	14–23	52
Protein, total (g/dL)	6.7–8.6	6.2–7.6	5.7–6.9	5.6–6.7	30, 35, 52
Sodium (mEq/L)	136–146	133–148	129–148	130–148	19, 30, 35, 46, 52, 74, 77
Urea nitrogen (mg/dL)	7–20	7–12	3–13	3–11	22, 46, 52
Uric acid (mg/dL)	2.5–5.6[d]	2.0–4.2	2.4–4.9	3.1–6.3	19, 46, 52

METABOLIC AND ENDOCRINE TESTS

	Nonpregnant Adult[a]	1st Trimester	2nd Trimester	3rd Trimester	References
Aldosterone (ng/dL)	2–9	6–104	9–104	15–101	23, 42, 81
Angiotensin-converting enzyme (ACE) (U/L)	9–67	1–38	1–36	1–39	22, 65
Cortisol (μg/dL)	0–25	7–19	10–42	12–50	52, 81
Hemoglobin A_{1C} (%)	4–6	4–6	4–6	4–7	59, 60, 70
Parathyroid hormone (pg/mL)	8–51	10–15	18–25	9–26	3
Parathyroid hormone-related protein (pmol/L)	<1.3[e]	0.7–0.9	1.8–2.2	2.5–2.8	3
Renin, plasma activity (ng/mL/hr)	0.3–9.0[e]	Not reported	7.5–54.0	5.9–58.8	22, 42
Thyroid stimulating hormone (TSH) (μIU/mL)	0.34–4.25	0.60–3.40	0.37–3.60	0.38–4.04	46, 52, 68
Thyroxine-binding globulin (mg/dL)	1.3–3.0	1.8–3.2	2.8–4.0	2.6–4.2	52
Thyroxine, free (fT_4) (ng/dL)	0.8–1.7	0.8–1.2	0.6–1.0	0.5–0.8	52, 68
Thyroxine, total (T_4) (μg/dL)	5.4–11.7	6.5–10.1	7.5–10.3	6.3–9.7	35, 52
Triiodothyronine, free (fT_3) (pg/mL)	2.4–4.2	4.1–4.4	4.0–4.2	Not reported	68
Triiodothyronine, total (T_3) (ng/dL)	77–135	97–149	117–169	123–162	52

VITAMINS AND MINERALS

	Nonpregnant Adult[a]	1st Trimester	2nd Trimester	3rd Trimester	References
Copper (μg/dL)	70–140	112–199	165–221	130–240	2, 36, 52
Selenium (μg/L)	63–160	116–146	75–145	71–133	2, 52
Vitamin A (retinol) (μg/dL)	20–100	32–47	35–44	29–42	52
Vitamin B_{12} (pg/mL)	279–966	118–438	130–656	99–526	56, 84
Vitamin C (ascorbic acid) (mg/dL)	0.4–1.0	Not reported	Not reported	0.9–1.3	75
Vitamin D, 1,25-dihydroxy (pg/mL)	25–45	20–65	72–160	60–119	3, 59
Vitamin D, 24,25-dihydroxy (ng/mL)	0.5–5.0[e]	1.2–1.8	1.1–1.5	0.7–0.9	71
Vitamin D, 25-hydroxy (ng/mL)	14–80	18–27	10–22	10–18	3, 71
Vitamin E (α-tocopherol) (μg/mL)	5–18	7–13	10–16	13–23	52
Zinc (μg/dL)	75–120	57–88	51–80	50–77	2, 52, 69

AUTOIMMUNE AND INFLAMMATORY MEDIATORS

	Nonpregnant Adult[a]	1st Trimester	2nd Trimester	3rd Trimester	References
C3 complement (mg/dL)	83–177	62–98	73–103	77–111	52
C4 complement (mg/dL)	16–47	18–36	18–34	22–32	52
C-reactive protein (CRP) (mg/L)	0.2–3.0	Not reported	0.4–20.3	0.4–8.1	34
Erythrocyte sedimentation rate (ESR) (mm/hr)	0–20[d]	4–57	7–47	13–70	83
IgA (mg/dL)	70–350	95–243	99–237	112–250	52
IgG (mg/dL)	700–1700	981–1267	813–1131	678–990	52
IgM (mg/dL)	50–300	78–232	74–218	85–269	52

SEX HORMONES

	Nonpregnant Adult[a]	1st Trimester	2nd Trimester	3rd Trimester	References
Dehydroepiandrosterone sulfate (DHEAS) (μmol/L)	1.3–6.8[e]	2.0–16.5	0.9–7.8	0.8–6.5	63
Estradiol (pg/mL)	<20–443[d,f]	188–2497	1278–7192	6137–3460	15, 63
Progesterone (ng/mL)	<1–20[d]	8–48		99–342	15, 63
Prolactin (ng/mL)	0–20[d]	36–213	110–330	137–372	3, 15, 45, 60
Sex hormone binding globulin (nmol/L)	18–114[d]	39–131	214–717	216–724	1, 63
Testosterone (ng/dL)	6–86[d]	25.7–211.4	34.3–242.9	62.9–308.6	63
17-Hydroxyprogesterone (nmol/L)	0.6–10.6[d,e]	5.2–28.5	5.2–28.5	15.5–84	63

LIPIDS

	Nonpregnant Adult[a]	1st Trimester	2nd Trimester	3rd Trimester	References
Cholesterol, total (mg/dL)	<200	141–210	176–299	219–349	9, 20, 38, 52
HDL-cholesterol (mg/dL)	40–60	40–78	52–87	48–87	9, 20, 38, 52, 66
LDL-cholesterol (mg/dL)	<100	60–153	77–184	101–224	9, 20, 38, 52, 66
VLDL-cholesterol (mg/dL)	6–40[e]	10–18	13–23	21–36	38
Triglycerides (mg/dL)	<150	40–159	75–382	131–453	9, 20, 38, 46, 52, 66
Apolipoprotein A-I (mg/dL)	119–240	111–150	142–253	145–262	20, 46, 60
Apolipoprotein B (mg/dL)	52–163	58–81	66–188	85–238	20, 46, 60

CARDIAC

	Nonpregnant Adult[a]	1st Trimester	2nd Trimester	3rd Trimester	References
Atrial natriuretic peptide (ANP) (pg/mL)	Not reported	Not reported	28.1–70.1	Not reported	12
B-type natriuretic peptide (BNP) (pg/mL)	22 ± 10	22 ± 10	32 ± 15	31 ± 21	14
Creatine kinase (U/L)	39–238[d]	27–83	25–75	13–101	50, 52
Creatine kinase-MB (U/L)	<6[k]	Not reported	Not reported	1.8–2.4	50
NT-pro-BNP (pg/mL)	50 ± 26	60 ± 45	60 ± 40	43 ± 34	14
Troponin I (ng/mL)	0–0.08	Not reported	Not reported	0–0.064 (intrapartum)	44, 76

BLOOD GAS

RENAL FUNCTION TESTS

	Nonpregnant Adult[a]	1st Trimester	2nd Trimester	3rd Trimester	References
Effective renal plasma flow (mL/min)	492–696[d,e]	696–985	612–1170	595–945	21, 24
Glomerular filtration rate (GFR) (mL/min)	106–132[d]	131–166	135–170	117–182	21, 24, 61
Filtration fraction (%)	16.9–24.7[l]	14.7–21.6	14.3–21.9	17.1–25.1	21, 24, 61
Osmolarity, urine (mOsm/kg)	500–800	326–975	278–1066	238–1034	72
24-hr albumin excretion (mg/24 hr)	<30	5–15	4–18	3–22	32, 72
24-hr calcium excretion (mmol/24 hr)	<7.5[e]	1.6–5.2	0.3–6.9	0.8–4.2	77
24-hr creatinine clearance (mL/min)	91–130	69–140	55–136	50–166	24, 77
24-hr creatinine excretion (mmol/24 hr)	8.8–14[e]	10.6–11.6	10.3–11.5	10.2–11.4	72
24-hr potassium excretion (mmol/24 hr)	25–100[e]	17–33	10–38	11–35	77
24-hr protein excretion (mg/24 hr)	<150	19–141	47–186	46–185	32
24-hr sodium excretion (mmol/24 hr)	100–260[e]	53–215	34–213	37–149	19, 77

[a]Unless otherwise specified, all normal reference values are from the seventeenth edition of *Harrison's Principles of Internal Medicine* (26).
[b]Range includes references with and without iron supplementation.
[c]Reference values are from *Laboratory Reference Handbook*, Pathology Department, Parkland Hospital, 2005.
[d]Normal reference range is specific range for females.
[e]Reference values are from the 15th edition of *Harrison's Principles of Internal Medicine* (13).
[f]Range is for premenopausal females and varies by menstrual cycle phase.
[g]Reference values are from Cerneca et al: Coagulation and fibrinolysis changes in normal pregnancy increased levels of procoagulants and reduced levels of inhibitors during pregnancy induce a hypercoagulable state, combined with a reactive fibrinolysis (17).
[h]Reference values are from Cerneca et al and Choi et al: Tissue plasminogen activator levels change with plasma fibrinogen concentrations during pregnancy (17, 18).
[i]Reference values are from Mannucci et al: Changes in health and disease of the metalloprotease that cleaves von Willebrand factor (55).
[j]Reference values are from Bacq et al: Liver function tests in normal pregnancy: a prospective study of 102 pregnant women and 102 matched controls (6).
[k]Reference values are from Leiserowitz et al: Creatine kinase and its MB isoenzyme in the third trimester and the peripartum period (50).
[l]Reference values are from Dunlop: Serial changes in renal haemodynamics during normal human pregnancy (21).

APPENDIX II. Maternal Echocardiographic Measurements

Left Ventricle	Pregnancy			Postpartum
	1st Trimester	2nd Trimester	3rd Trimester	
Geometry				
IVS_d (mm)	7.3 ± 1.0	7.4 ± 1.1	7.8 ± 1.2	7.1 ± 0.9
LVEDD (mm)	45–47.8	47–48.9	47–49.6	46–48.8
LVESD (mm)	28–30	29–30.1	30–30.8	28–30.6
PW_d	6.3 ± 0.7	6.6 ± 0.7	6.9 ± 1.0	6.1 ± 0.6
RWT	0.26–0.36	0.27–0.37	0.28–0.38	0.25–0.35
LV mass (g)	111–121	121–135	136–151	114–119
LV mass (g/m^2)	66 ± 13	70 ± 12	76 ± 16	67 ± 11
Systolic function				
FS (%)	37–38	76–78	80–85	67–69
SW thickening (%)	47 ± 17	53 ± 16	51 ± 15	54 ± 19
PW thickening (%)	66 ± 16	72 ± 16	74 ± 16	71 ± 14
VCFC (circ/sec)	1.15–0.3	1.18–0.16	1.18–0.12	1.18–0.12
ESS (g/cm^2)	59 ± 9	53 ± 11	52 ± 11	66 ± 12
Diastolic function				
Heart rate	75–76	76–78	80–85	67–69
Mitral E wave (m/sec)	0.85 ± 0.13	0.84 ± 0.16	0.77 ± 0.15	0.77 ± 0.11
Mitral A wave (m/sec)	0.5 ± 0.09	0.5 ± 0.1	0.55 ± 0.1	0.46 ± 0.1
Deceleration time (ms)	176 ± 44	188 ± 40	193 ± 33	201 ± 48
IVRT (ms)	90 ±19	79 ± 18	72 ± 16	69 ± 10
E wave duration (ms)	263 ± 50	276 ± 43	282 ± 37	288 ± 48
E and A wave duration (ms)	454 ± 121	412 ± 79	375 ± 63	523 ± 88

Values are ranges or means ± SD.
Circ = circumference; d = diastolic; ESS = end-systolic wall stress; FS = fractional shortening; IVRT = isovolumic relaxation time; IVS_d = interventricular septum–diastole; LV = left ventricle; LVEDD = left ventricular end-diastolic dimension; LVESD = left ventricular end-systolic dimension; PW = posterior wall; RWT = relative wall thickness; SW = septal wall; VCFC = rate-adjusted mean velocity of circumferential fiber thickening.
Data from Savu, 2012; Vitarelli, 2011.

APPENDIX III. Sonographic Measurements of the Embryo and Fetus

TABLE III-1. Mean Gestational Sac Diameter and Crown-Rump Length and Corresponding Menstrual Age

Menstrual Age (day)	Menstrual Age (wk)	Gestational Sac Size (mm)	Crown-Rump Length (cm)
30	4.3
