account for diminished activity at term. Figure 20-2 shows fetal movements during the last half of gestation in 127 pregnancies with normal outcomes. The mean number of weekly movements calculated from 12-hour daily recording periods rose from approximately 200 at 20 weeks' gestation to a maximum of 575 movements at 32 weeks. Weekly fetal movement counts then declined to an average of 282 at 40 weeks. Another study of nearly 300 gravidas found a similar movement pattern across gestational ages (Bradford, 2019b). More than 90 percent of these women reported stronger movements during the evening and nighttime.

Women perceive 16 to 45 percent of fetal movements detected by sonography (Brown, 2016). A higher body mass index does not decrease maternal perception of fetal movement (Bradford, 2019a; Sasson, 2016). It remains unclear if nulliparity or anterior placental location affect maternal impression of fetal activity (Brown, 2016; Sasson, 2016).

Clinical Application

Because women may perceive a decline in fetal movement in the days to weeks preceding stillbirth, maternal perception of fetal movement has been evaluated as a preventive aid (Heazell, 2008; Stacey, 2011). However, the optimal fetal-movement protocol remains undefined (Mangesi, 2015). Some methods rely on quantitative counts, such as 10 movements in 2 hours, whereas others rely on a mother's subjective impression. In one study, more than 68,000 pregnancies were randomly assigned between 28 and 32 weeks' gestation to an objective or subjective assessment group (Grant, 1989). Women in the objective arm were instructed to record the time needed to feel 10 movements each day. This required an average of 2.7 hours daily. Women in the subjective group were informally asked about movements during prenatal visits. Reports of decreased fetal motion were then evaluated with tests of fetal well-being. Antepartum death rates for normal singleton fetuses were similar in the two study groups, and most stillborn fetuses were dead by the time the mothers reported for medical attention. Rather than concluding that maternal perceptions were meaningless, the authors concluded that informal maternal impressions were as valid as formally recorded fetal movement counts.

Women's knowledge of these protocols also vary. In one survey of more than 400 gravidas, 85 percent noted receiving

instruction from their provider regarding normal fetal movement (Pollock, 2019). However, 60 percent described it as a subjective assessment, and 40 percent reported a quantitative method. In another study, more than two thirds of women could not explain fetal movement monitoring techniques (Berndl, 2013).

Although a long-standing pillar of maternal care, fetal movement surveillance may not be as predictive as thought. Nearly 6 to 7 percent of pregnancies are complicated by decreased fetal movement, but stillbirth rates are not increased in these cases (Harrington, 1998; Scala, 2015). In one study of more than 400,000 pregnancies complicated by decreased fetal movement, directed patient and staff education coupled with a prescriptive management plan did not reduce the stillbirth incidence (Norman, 2018). Aside from stillbirth, some data show that decreased fetal movement may help identify growth-restricted fetuses before birth (Saastad, 2011; Scala, 2015). In one of these studies, nearly 1100 pregnancies were assigned to subjective or objective assessment of fetal activity. The rate of 1-minute Apgar scores ≤3 was significantly reduced (0.4 versus 2.3 percent) when counting was used (Saastad, 2011).

Thus, although most pregnancies complicated by decreased fetal movement will result in normal outcomes, maternal perception of reduced fetal activity warrants further evaluation. No consensus guides a provider's response. Care is individualized and influenced by gestational age and pregnancy comorbidities. In low-risk pregnancies, documenting fetal heart tones and adequate amnionic fluid volume may be sufficient. For older fetuses, tests described in the upcoming sections are typically added. Our practice is a nonstress test and sonographic measurement of amnionic fluid volume.

Many women report excessive fetal movement in the third trimester. Its risk, if any, is poorly understood. Stacey and colleagues (2011) reported that a single episode of vigorous fetal activity is associated with a greater risk for fetal death. Similarly, others have described maternal perception of a single episode of excessive of fetal movement in the weeks prior to a stillbirth diagnosis (Heazell, 2017; Whitehead, 2020). More research is needed prior to recommending intervention.

FETAL BREATHING

Small inward and outward flow of tracheal fluid, indicating thoracic movement, was first identified in fetal sheep (Dawes, 1972). These chest wall movements differ from those following birth in that they are discontinuous. Another feature of fetal respiration is *paradoxical chest wall movement* (Fig. 20-3) (Johnson, 1988). In the newborn or adult, the opposite occurs. One interpretation of paradoxical respiratory motion might be coughing to clear amnionic fluid debris. Although the physiological basis for the breathing reflex is not completely understood, such exchange of amnionic fluid appears to be essential for normal lung development (Chap. 7, p. 130). Dawes (1974) identified two types of respiratory movements. The first are *gasps* or *sighs,* which occurred at a frequency of 1 to 4 per minute. The second, *irregular bursts of breathing,* occurred at rates up to 240 cycles per minute. These latter rapid respiratory movements were associated with rapid eye movement. Badalian

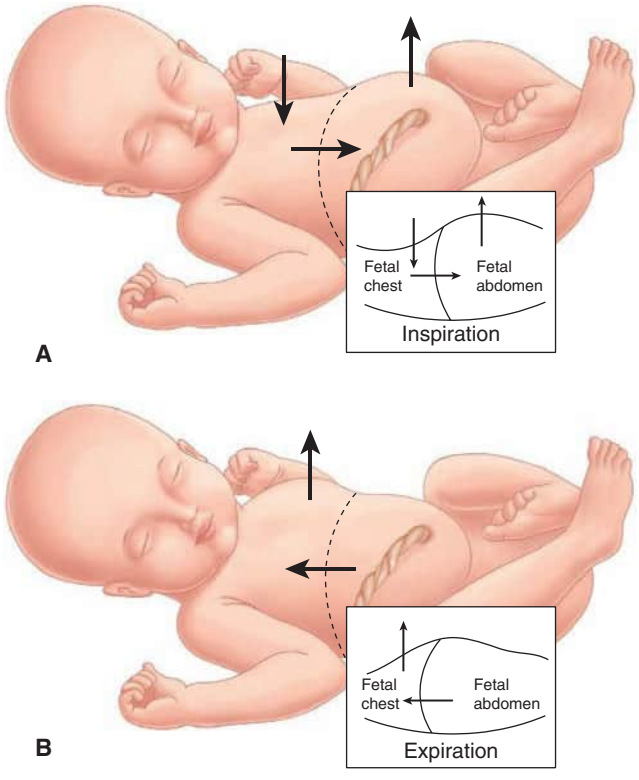

FIGURE 20-3 Paradoxical chest movement with fetal respiration. During inspiration **(A)**, the chest wall paradoxically *collapses* and the abdomen protrudes, whereas during expiration **(B)**, the chest wall *expands*.

and associates (1993) studied the maturation of normal fetal breathing using color flow and spectral Doppler analysis of nasal fluid flow as an index of lung function. They suggested that fetal respiratory rate declined in conjunction with increasing respiratory volume at 33 to 36 weeks' gestation and coincided with lung maturation.

Many investigators have used sonography to determine whether chest wall movements might reflect fetal health. Several variables in addition to hypoxia affect these movements. These include maternal hypoglycemia, sound stimuli, cigarette smoking, amniocentesis, impending preterm labor, gestational age, fetal heart rate, and labor—during which it is normal for fetal respiration to cease.

Because fetal breathing movements are episodic, interpretation of fetal health when respirations are absent may be difficult. Patrick and coworkers (1980) performed continuous 24-hour observation using sonography to characterize fetal breathing patterns during the last 10 weeks of pregnancy. A total of 1224 hours of fetal observation in 51 pregnancies were collected. Figure 20-4 displays the percentages of time spent breathing near term. Substantively diminished breathing during the night suggests a diurnal pattern. In addition, breathing activity is enhanced somewhat following maternal meals. Total absence of breathing was observed in some of these normal fetuses for up to 122 minutes, indicating that fetal evaluation to diagnose absent respiratory motion may require long periods of observation.

The potential for breathing activity to be an important sole marker of fetal health is unfulfilled because of the multiple

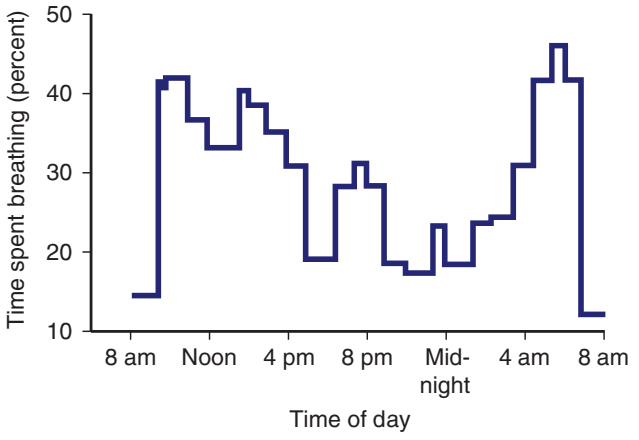

FIGURE 20-4 The percentage of time spent breathing by 11 fetuses at 38 to 39 weeks' gestation. Fetal breathing activity significantly increases after breakfast. Breathing activity diminished during the day and reached its minimum between 20:00 and 24:00 hours. The percentage of time spent breathing rose significantly between 04:00 and 07:00 hours, when mothers were asleep. (Adapted with permission from Patrick J, Campbell K, Carmichael L, et al: Patterns of human fetal breathing during the last 10 weeks of pregnancy, Obstet Gynecol. 1980 Jul;56(1):24–30.)

factors that affect breathing. Most clinical applications couple fetal breathing with other biophysical indices. For example, fetal breathing is one component of the biophysical profile (p. 389).

CONTRACTION STRESS TEST

During a uterine contraction, pressures generated by the myometrium exceed the collapsing pressure of the vessels coursing through it. This ultimately lowers blood flow to the placenta's intervillous space. Brief periods of impaired oxygen exchange result. If uteroplacental pathology is present, oxygen exchange to the fetus is further diminished, and *late fetal heart rate decelerations* appear (Chap. 24, p. 452). These downward-sloping heart-rate waveforms begin with the onset of the uterine contraction waveform or just beyond its acme. Instead, contractions may produce variable decelerations as a result of cord compression. This suggests oligohydramnios, which is often comorbid with placental insufficiency.

Ray and associates (1972) used this concept in 66 complicated pregnancies and developed the *oxytocin challenge test,* which was later called the *contraction stress test (CST).* A positive test result, that is, an abnormal result, is uniform repetitive late fetal heart rate decelerations. In their study, the tests were repeated weekly, and the authors concluded that negative CST results, that is, normal results, forecasted fetal health.

To perform the test, contractions are induced with either intravenous oxytocin or nipple stimulation. If at least three spontaneous contractions of 40 seconds or longer are present in a 10-minute span, no uterine stimulation is necessary (American College of Obstetricians and Gynecologists, 2021a). The fetal heart rate and uterine contractions are recorded simultaneously by external monitors. With oxytocin, a dilute intravenous infusion is used to establish a satisfactory contraction pattern (Freeman, 1975). At Parkland Hospital, 20 units of oxytocin are mixed in 1 liter of Ringer solution and initiated at a rate of 6 mU/min. The rate is increased by 6 mU/min every 40 minutes to achieve the just-discussed contraction pattern.

Nipple stimulation to induce uterine contractions for a CST is usually successful (Huddleston, 1984). One method involves a woman rubbing one nipple through her clothing for 2 minutes or until a contraction begins. This 2-minute nipple stimulation ideally will induce a pattern of three contractions per 10 minutes. If not, after a 5-minute rest interval, she is instructed to retry nipple stimulation to achieve the desired pattern. If this is unsuccessful, dilute oxytocin may be used.

CST results are interpreted according to the criteria shown in Table 20-1. Disadvantageously, the average CST requires 90 minutes to complete. Compared with oxytocin, nipple stimulation shortens testing time and costs less. During a CST, some have reported unpredictable uterine hyperstimulation and fetal distress, whereas others did not find excessive activity to be harmful (Frager, 1987; Schellpfeffer, 1985). Relative contraindications to a CST include those conditions that contraindicate vaginal delivery.

NONSTRESS TEST

The *nonstress test (NST)* also is used to assess fetal well-being and employs the phenomenon of fetal heart rate acceleration in response to fetal movement (Freeman, 1975; Lee, 1975). During an NST, these accelerations are correlated with fetal movements perceived by the mother.

Compared with a CST, an NST is easier to perform, and normal results can be used to further define false-positive CST results. Simplistically, the NST is primarily a test of *fetal condition,* and it differs from the CST, which is considered a test of *uteroplacental function.* Currently, NST is the most widely used primary testing method for assessment of fetal well-being. It has also been incorporated into the biophysical profile, discussed later (p. 389).

TABLE 20-1. Criteria for Interpretation of the Contraction Stress Test

Negative: no late or significant variable decelerations
Positive: late decelerations following 50% or more of contractions (even if the contraction frequency is fewer than three in 10 minutes)
Equivocal-suspicious: intermittent late decelerations or significant variable decelerations
Equivocal-hyperstimulatory: fetal heart rate decelerations that occur in the presence of contractions more frequent than every 2 minutes or lasting longer than 90 seconds
Unsatisfactory: fewer than three contractions in 10 minutes or an uninterpretable tracing

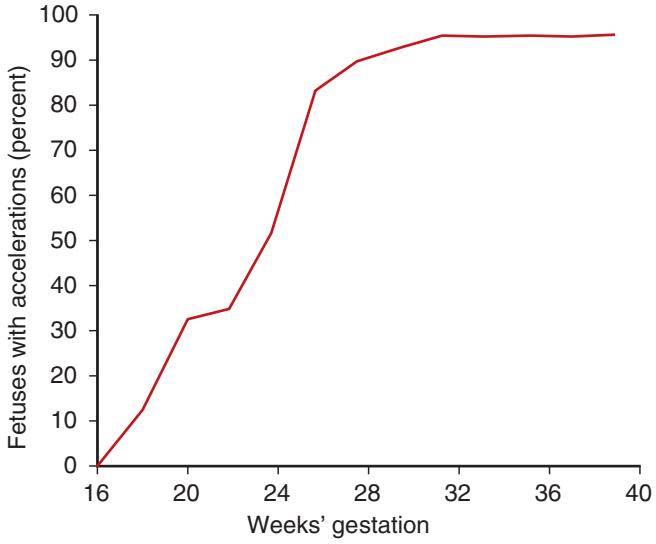

FIGURE 20-5 Percentage of fetuses with at least one acceleration of 15 bpm sustained for 15 seconds concurrent with fetal movement. (Redrawn from Pillai M, James D: The development of fetal heart rate patterns during normal pregnancy, Obstet Gynecol. 1990 Nov;76(5 Pt 1):812–816.)

Fetal Heart Rate Acceleration

Autonomic influences are mediated by sympathetic or parasympathetic impulses from brainstem centers to normally raise or slow the fetal heart rate. The NST is based on the hypothesis that the heart rate of a fetus that is not acidemic as a result of hypoxia or neurological depression will temporarily accelerate in response to fetal movement (American College of Obstetricians and Gynecologists, 2019; Lee, 1975). Fetal movements during testing are identified by maternal perception and self-recorded. As hypoxia develops, fetal heart rate accelerations diminish (Smith, 1988).

Gestational age influences acceleration of the fetal heart rate. Pillai and James (1990b) studied patterns of fetal heart rate acceleration during normal pregnancy. The percentage of body movements accompanied by accelerations and the amplitude of these waveforms both increase with gestational age (Fig. 20-5).

Accordingly, the National Institute of Child Health and Human Development Fetal Monitoring Workshop defined acceleration waveforms based on gestational age (Macones, 2008). In fetuses at or beyond 32 weeks' gestation, the acceleration acme is ≥15 beats per minute (bpm) above the baseline rate, and the acceleration lasts ≥15 seconds but <2 minutes. Before 32 weeks, accelerations are defined as having a rise ≥10 bpm above baseline for ≥10 seconds. In one study of 188 normal fetuses at 25 and 28 weeks' gestation, only 70 percent demonstrated the required ≥15 bpm during heart rate accelerations. Accelerations of 10 bpm occurred in 90 percent (Guinn, 1998). Cousins and associates (2012) compared the Workshop criteria recommended before 32 weeks with the standard 15 bpm/15 second criteria in a randomized trial of 143 women. They found no differences in perinatal outcomes.

Reactive (Normal) Nonstress Tests

A normal NST is termed *reactive* and requires two or more accelerations within 20 minutes of beginning the test (Fig. 20-6) (American College of Obstetricians and Gynecologists, 2021a). Accelerations are accepted irrespective of fetal movement. Before concluding that a test is *nonreactive*, a 40-minute or longer tracing should be performed. This threshold accounts for fetal sleep cycles (Paul, 1995). Miller and coworkers (1996b) reviewed outcomes in fetuses with NST results that were considered nonreactive because only one acceleration was recorded. They concluded that one acceleration was as reliable as two in predicting healthy fetal status. NSTs are more likely to be reactive and have a shorter testing time in the evening compared with the morning (Babazadeh, 2005; Petrikovsky, 1996).

Loud external sounds have been used to startle the fetus and thereby provoke heart rate acceleration. A commercially available acoustic stimulator is positioned on the maternal abdomen, and a stimulus of 1 to 2 seconds is applied (Eller, 1995). This may be repeated up to three times for up to 3 seconds (American College of Obstetricians and Gynecologists, 2021a). In a randomized trial of 113 women undergoing NST, vibroacoustic stimulation lowered the average testing time and incidence of nonreactive test results (Perez-Delboy, 2002; Turitz, 2012). One case report described a fetal tachyarrhythmia that was provoked with vibroacoustic stimulation in a fetus with known premature atrial contractions (Laventhal, 2003).

Although a normal number and amplitude of accelerations seems to reflect fetal well-being, their absence does not

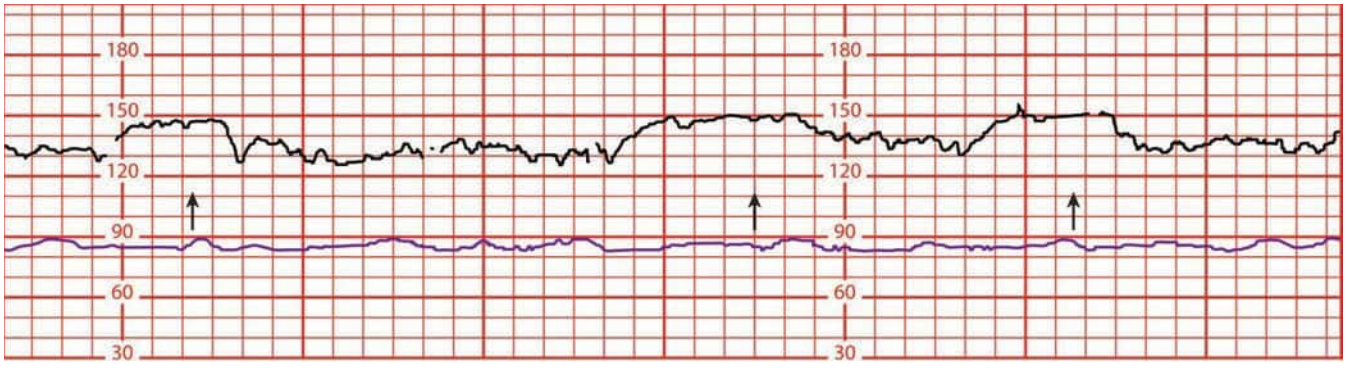

FIGURE 20-6 Reactive nonstress test. Notice there are at least two fetal heart rate accelerations (*arrows*) of more than 15 beats/min for longer than 15 seconds. The black line reflects fetal heart rate, whereas the purple line reflects the mother's.

invariably predict fetal compromise. Indeed, some investigators have reported false-positive rates ≥90 percent (Devoe, 1986). Because healthy fetuses may not move for up to 75 minutes, some have considered that a longer NST duration might increase the positive predictive value of the NST (Brown, 1981). In this scheme, either the test became reactive during a period up to 80 minutes or the test remained nonreactive for 120 minutes, which indicated a very ill fetus. Therefore, prolonged fetal heart rate monitoring is undertaken if an NST remains nonreactive after 40 minutes.

Nonreactive (Abnormal) Nonstress Tests

Based on the foregoing, a nonreactive NST is not always ominous and can be seen with a sleeping fetus. An NST result can also revert to normal as the fetal condition changes. An example is shown in Figure 20-7. Instead, a reactive NST result can become abnormal if the fetal condition deteriorates.

Some abnormal patterns reliably forecast severe fetal jeopardy (Fig. 20-8). For example, Devoe and colleagues (1985) concluded that >90 percent of NST results that were nonreactive for 90 minutes or more were associated with significant perinatal pathology. Specifically, Visser and associates (1980) described a *terminal cardiotocogram,* which included:

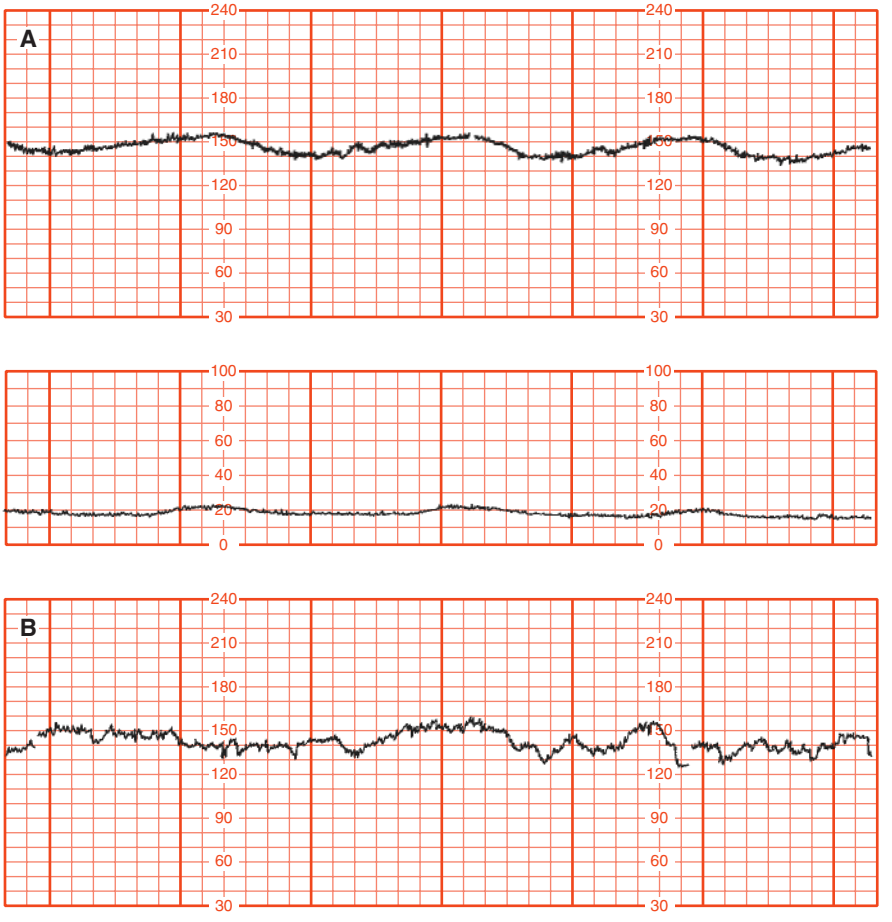

FIGURE 20-7 Two antepartum fetal heart rate (FHR) tracings in a 28-week pregnant woman with diabetic ketoacidosis. **A.** FHR tracing (*upper panel*) and accompanying contraction tracing (*second panel*). Tracing, obtained during maternal and fetal acidemia, shows absence of accelerations, diminished variability, and late decelerations with weak spontaneous contractions. **B.** Fetal heart rate tracing shows return of normal accelerations and variability of the fetal heart rate following correction of maternal acidemia.

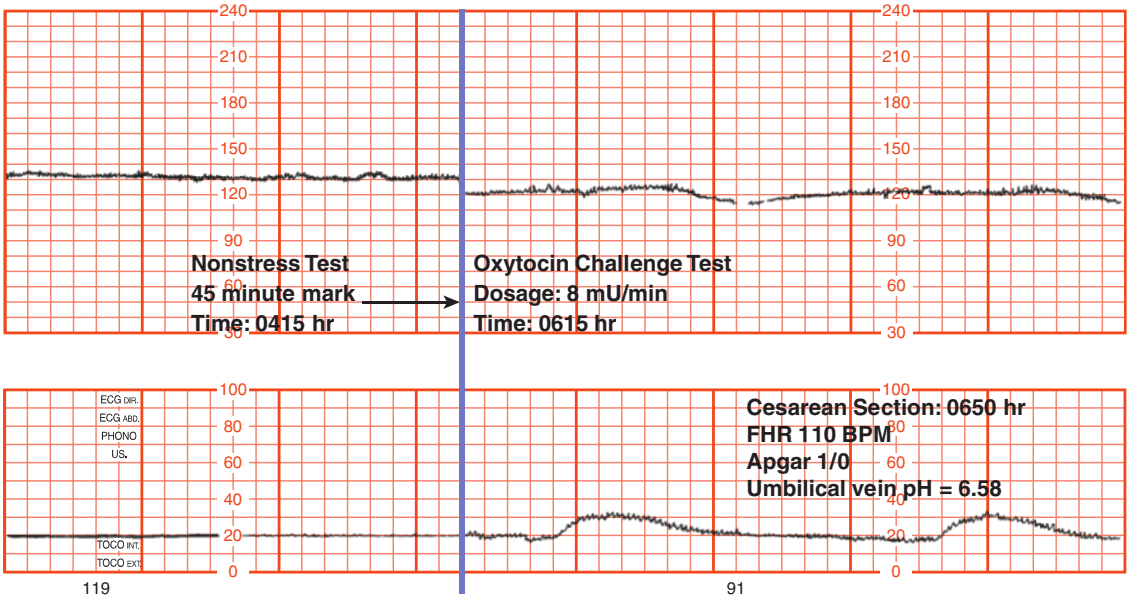

FIGURE 20-8 Nonreactive nonstress test (*left side of tracing*) followed by contraction stress test showing mild, late decelerations (*right side of tracing*). Cesarean delivery was performed, and the severely acidemic fetus could not be resuscitated.

(1) baseline variability <5 bpm, (2) absent accelerations, and (3) late decelerations with spontaneous uterine contractions. These mirrored experiences from Parkland Hospital in which absence of accelerations during an 80-minute recording period in 27 fetuses was associated consistently with evidence of uteroplacental pathology (Leveno, 1983). The latter included fetal-growth restriction in 75 percent, oligohydramnios in 80 percent, fetal acidemia in 40 percent, meconium in 30 percent, and placental infarction in 93 percent.

Interval Between Testing

Set originally and arbitrarily at 7 days, the interval between NSTs varies based on indication (Paul, 1995). According to the American College of Obstetricians and Gynecologists (2021a), weekly testing is undertaken in the setting of stable maternal medical conditions such as pregestational diabetes, chronic hypertension, or lupus. For high-risk conditions such as preeclampsia remote from term, some perform NSTs daily. Fetal conditions require individualized periodic testing based on the fetal complication. Fetal-growth restriction is a common indication for which testing intervals vary (Fig. 47-6, p. 829).

Decelerations During Nonstress Testing

Fetal movements commonly produce heart rate decelerations. In one study of 16 near-term fetuses, one half to two thirds of NST tracings had decelerations, depending on the vigor of the fetal motion (Timor-Tritsch, 1978). This high incidence of decelerations inevitably makes interpretation of their significance problematic. Indeed, Meis and coworkers (1986) reported that variable fetal heart rate decelerations during NSTs were not a sign of fetal compromise. The American College of Obstetricians and Gynecologists (2021a) has concluded that variable decelerations, if nonrepetitive and brief—less than 30 seconds—do not indicate fetal compromise or the need for obstetrical intervention. Repetitive variable decelerations—at least three in 20 minutes—have been associated with a greater risk of cesarean delivery for fetal distress. Decelerations lasting ≥1 minute are reported to have an even worse fetal prognosis (Bourgeois, 1984; Druzin, 1981; Pazos, 1982).

Hoskins and associates (1991) attempted to refine interpretation of tests that showed variable decelerations by adding sonographic estimation of amnionic fluid volume. The incidence of cesarean delivery for intrapartum fetal distress progressively rose concurrently with the decline of amnionic fluid volume. Variable decelerations during an NST plus oligohydramnios resulted in a 75-percent cesarean delivery rate. Fetal distress in labor, however, also frequently developed in those pregnancies with variable decelerations but with normal amounts of amnionic fluid. Others report similar results (Grubb, 1992).

False-reactive Nonstress Tests

In one review of fetal death within 7 days of a reactive NST, the most frequent indication for testing was postterm pregnancy (Smith, 1987). The mean interval between testing and death was 4 days, with a range of 1 to 7 days. The single most common autopsy finding was meconium aspiration, often associated with some type of umbilical cord abnormality. The authors concluded that acute asphyxia had provoked fetal gasping. They considered an NST inadequate to preclude an acute asphyxial event, but viewed amnionic fluid volume assessment as valuable. Other ascribed frequent causes of fetal death despite a false-reactive NST included intrauterine infection, abnormal cord position, fetal malformations, and placental abruption.

BIOPHYSICAL PROFILE

Assessing five specific fetal biophysical variables more accurately predicts fetal health (Manning, 1980). These include heart rate acceleration, breathing, movement, tone, and amnionic fluid volume (Table 20-2). In the commonly used *biophysical profile (BPP)*, each normal variable is assigned a score of 2, and abnormal variables are given a score of 0. Thus, the highest score possible for a normal fetus is 10. Because fetal breathing and movement are episodic, 30 minutes are allotted to perform a BPP before a score of 0 is assigned to any component. Figure 20-9 shows color Doppler evidence of amnionic fluid flowing through the nares with fetal breathing. In one study, BPP scores were higher if a test was performed in late evening compared with the morning (Ozkaya, 2012). Narcotics and sedatives can significantly lower the score (Kopecky, 2000).

Using the BPP interpretation and management strategy shown in Table 20-3, Manning and colleagues (1987) evaluated more than 19,000 pregnancies. Greater than 97 percent of the tested pregnancies had normal results. They reported a

TABLE 20-2. Components and Scores for the Biophysical Profile

Component	Score 2	Score 0
Nonstress test[a]	≥2 accelerations within 20–40 min	0 or 1 acceleration within 20–40 min
Fetal breathing	≥1 episode of rhythmic breathing lasting ≥30 sec	<30 sec of breathing
Fetal movement	≥3 discrete body or limb movements	<3 discrete movements
Fetal tone	≥1 episode of extremity extension and subsequent return to flexion	0 extension/flexion events
Amnionic fluid volume[b]	A pocket of amnionic fluid that measures at least 2 cm in two planes perpendicular to each other (2 × 2 cm pocket)	Deepest single vertical pocket ≤2 cm

[a]May be omitted if all four sonographic components are normal.
[b]Further evaluation warranted, regardless of biophysical composite score, if deepest vertical amnionic fluid pocket ≤2 cm.

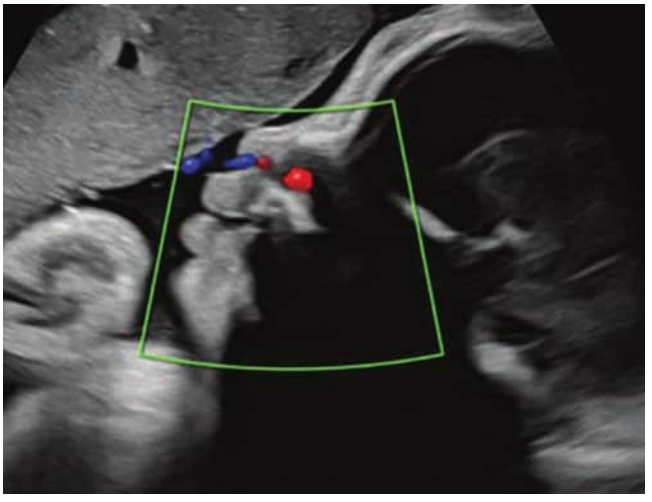

FIGURE 20-9 A sagittal color Doppler image displays the movement of amnionic fluid through the nares during fetal breathing.

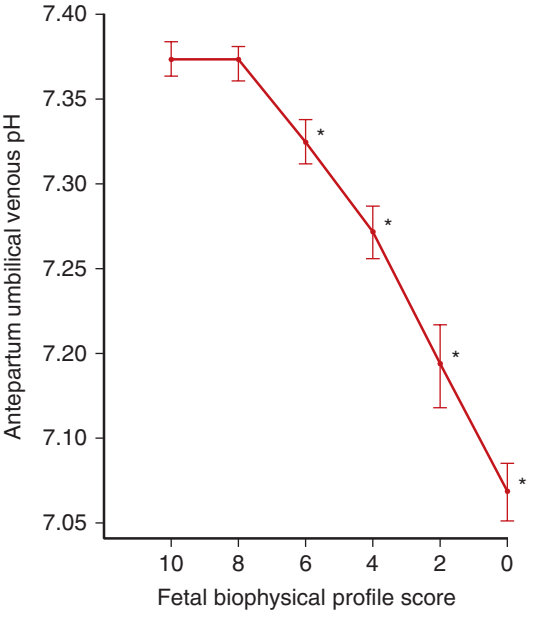

FIGURE 20-10 Mean umbilical vein pH (±2 SD) obtained by cordocentesis in relation to fetal biophysical profile score category. (Data from Manning, 1993.)

false-normal test rate—defined by an antepartum death of a structurally normal fetus—that approximated 1 per 1000. The most common identifiable causes of fetal death after a normal BPP score include fetomaternal hemorrhage, umbilical cord accident, and placental abruption (Dayal, 1999).

Subsequently, Manning and associates (1993) published a remarkable description of 493 fetuses in which BPP scores were correlated with umbilical venous blood pH values. This blood was being obtained via antepartum cordocentesis for other specific fetal indications. Namely, karyotyping of fetal-growth restricted fetuses constituted 20 percent, and the remainder had alloimmune hemolytic anemia requiring hemoglobin measurement. As shown in Figure 20-10, a BPP score of 0 was almost invariably associated with significant fetal acidemia, whereas a normal score of 8 or 10 was associated with normal pH. An equivocal test result—a score of 6—was a poor predictor of an abnormal outcome. A drop in the BPP score from 2 or 4 down to 0 more accurately predicted an abnormal fetal outcome. Overall, BPP scores provided poor sensitivity to predict cord blood pH. Similar studies have concluded the same (Salvesan, 1993; Weiner, 1996). Kaur and colleagues (2008) performed daily BPPs to ascertain the optimal delivery time in 48 growth-restricted preterm fetuses that weighed <1000 g. Despite scores of 8 in 27 fetuses and 6 in 13 others, 6 died and 21 were acidemic.

Modified Biophysical Profile

BPP performance is labor intensive and requires a trained sonographer. In response, Clark and coworkers (1989) created

TABLE 20-3. Interpretation of Biophysical Profile Score

Biophysical Profile Score	Interpretation	Recommended Management
10	Normal, nonasphyxiated fetus	No fetal indication for intervention; repeat test weekly
8/10 (Normal AFV) 8/8 (NST not done)	Normal, nonasphyxiated fetus	No fetal indication for intervention; repeat test weekly
8/10 (Decreased AFV)	Chronic fetal asphyxia suspected	If ≥36 weeks, deliver If <36 weeks, monitor per institution's protocol
6 (Normal AFV)	Equivocal	If ≥37 weeks, deliver If <37 weeks and normal fluid, repeat test in 24 hours If repeat test >6, monitor per institution's protocol
6 (Decreased AFV)	Possible fetal asphyxia	If 36–37 weeks, deliver If <36 weeks, monitor per institution's protocol
4	Probable fetal asphyxia	If ≥32 weeks, deliver If <32 weeks, individualize management based on maternal and fetal conditions
0 or 2	Almost certain fetal asphyxia	Deliver

AFV = amnionic fluid volume; NST = nonstress test.
Adapted from American College of Obstetricians and Gynecologists, 2021a; Liston, 2018; Manning, 2018.

an abbreviated BPP, in which an NST was coupled with amnionic fluid volume assessment. In 2628 singleton pregnancies, the NST was performed twice weekly. Described in the next section, amnionic fluid volume was measured by the amnionic fluid index (AFI), and values ≤5 cm were considered abnormal. This abbreviated BPP required approximately 10 minutes to perform. The authors considered it a superb antepartum surveillance method because no fetuses died unexpectedly.

From another study of 17,429 modified BPPs in 2774 women, investigators concluded that such testing was an excellent fetal surveillance tool (Nageotte, 1994). Miller and associates (1996a) reported results of more than 54,000 modified BPPs performed in 15,400 high-risk pregnancies. They described a false-negative rate of 0.8 per 1000 and a false-positive rate of 1.5 percent. The American College of Obstetricians and Gynecologists (2021a) has concluded that the BPP and modified BPP are comparable to other biophysical fetal surveillance approaches in predicting fetal well-being.

AMNIONIC FLUID VOLUME

The importance of amnionic fluid volume estimation is indicated by its inclusion into virtually all schemes of fetal health assessment (Frøen, 2008). Physiologically, diminished uteroplacental perfusion may lead to lower fetal renal blood flow, decreased urine production, and ultimately, oligohydramnios (Chap. 14, p. 260). Amnionic fluid volume is measured either by the AFI or by the single deepest vertical pocket (DVP). In one study of more than 1000 women in which both methods were compared, AFI led to a higher rate of oligohydramnios diagnoses and induction of labor. Despite this, perinatal outcomes were not improved (Kehl, 2016). The American College of Obstetricians and Gynecologists (2021a) concludes that DVP measurement, as opposed to AFI, is associated with fewer unnecessary interventions but comparable perinatal outcomes (Nabhan, 2008; Reddy, 2014). An AFI ≤5 cm and a DVP ≤2 cm is considered abnormal.

DOPPLER VELOCIMETRY

Blood flow velocity measured by Doppler ultrasound reflects downstream impedance (Chap. 14, p. 261). This Doppler velocimetry has been used to interrogate the umbilical artery, middle cerebral artery (MCA), and ductus venosus. With umbilical artery studies, abnormal waveforms correlated with placental villous hypovascularity. Specifically, of the small placental arterial channels, 60 to 70 percent must be obliterated before the umbilical artery Doppler waveform becomes abnormal. Such extensive placental vascular pathology has a major effect on fetal circulation. According to Trudinger (2007), because more than 40 percent of the combined fetal ventricular output is directed to the placenta, obliteration of placental vascular channel increases afterload and leads to fetal hypoxemia. This in turn leads to ventricular dilation and redistribution of MCA blood flow. Ultimately, pressure rises in the ductus venosus due to afterload in the right side of the fetal heart (Baschat, 2004). Clinically, abnormal Doppler waveforms in the ductus venosus are a late finding in the progression of fetal deterioration due to chronic hypoxemia. To predict placental dysfunction, maternal uterine artery Doppler velocimetry also has been assessed, with the goal to balance stillbirth against the risks of preterm delivery (Ghidini, 2007).

Umbilical Artery

The umbilical artery systolic-diastolic (S/D) ratio is considered abnormal if it is above the 95th percentile for gestational age or if diastolic flow is either absent or reversed (Chap. 14, p. 262). Absent or reversed end-diastolic flow signifies greater impedance to umbilical artery blood flow (Fig. 47-7, p. 830). It is reported to result from poorly vascularized placental villi and is seen in extreme cases of fetal-growth restriction (Todros, 1999). The perinatal mortality rate is increased when absent or reversed end-diastolic flow is present (Viero, 2004).

Umbilical artery Doppler velocimetry to evaluate fetal health has been extensively assessed in randomized trials. In one, 1360 women with a high risk for stillbirth underwent either an NST or Doppler velocimetry, and abnormal results prompted labor induction. More patients in the Doppler group required induction, yet the cesarean delivery rate for intrapartum fetal distress was 4.6 percent. This rate was significantly lower than the 8.7-percent cesarean rate for those receiving an NST (Williams, 2003). The authors believed that Doppler assessment, compared with an NST, identified a higher proportion of patients with early placental compromise. Identified early, these fetuses experienced less distress, which yielded a lower cesarean delivery rate. Similarly, Yoon and coworkers (1992) found that the BPP and umbilical artery Doppler measurements are comparable indicators of fetal acidosis. Introduction of Doppler velocimetry as a primary screening test must balance any advantages against its necessary training and associated costs.

In addition, umbilical artery Doppler velocimetry does not effectively predict fetal health in normal pregnancies (Alfirevic, 2015; Page, 2017). Gonzalez and associates (2007) found that abnormal umbilical artery Doppler findings in a cohort of growth-restricted fetuses were the best predictors of perinatal outcomes. The American College of Obstetricians and Gynecologists (2021a) has concluded that umbilical artery Doppler velocimetry has not proved valuable as a screening test, except in cases of fetal-growth restriction (Chap. 47, p. 830).

Ductus Venosus

Doppler ultrasound can also assess the fetal venous circulation, and as discussed earlier, an abnormal ductus venosus Doppler waveform indicates cardiac dysfunction. However, its routine use in surveillance of fetal-growth restriction is not recommended (Society for Maternal-Fetal Medicine, 2020).

Ductus venosus Doppler is also used in the staging of twin-twin transfusion syndrome (Quintero, 1999). Abnormal Doppler indices reflect myocardial dysfunction and predict a poorer outcome (Banek, 2003). Additionally, this Doppler method can help monitor fetuses with congenital heart defects and supraventricular tachycardia (SVT) (Seravalli, 2016). Namely, SVT can induce a reversible cardiomyopathy that may lead to hydrops.

Ductus venosus Doppler patterns may aid prediction and monitor improvement following treatment. Thus, ductus venosus Doppler may have a role in monitoring pregnancies at increased risk for fetal cardiovascular decline (Baschat, 2010).

Middle Cerebral Artery

Doppler velocimetry of the MCA is the primary method of detecting fetal anemia (Chap. 14, p. 263). With fetal anemia, the *peak systolic velocity* is enhanced due to greater cardiac output and decreased blood viscosity. However, to detect fetal compromise, Doppler velocimetry of the MCA is not recommended (Morris, 2012). In one randomized study of 665 women assigned to modified BPP alone or to modified BPP plus MCA and umbilical artery Doppler velocimetry, pregnancy outcomes did not differ (Ott, 1998).

Uterine Artery

Vascular resistance in the uterine circulation normally declines in the first half of pregnancy. This stems from trophoblast invasion and remodeling of maternal uterine vessels (Chap. 5, p. 90). Uterine artery Doppler velocimetry may be most helpful in assessing pregnancies at high risk of uteroplacental insufficiency (Abramowicz, 2008). Persistence or development of high-resistance patterns has been linked to various pregnancy complications (Sciscione, 2009; Velathur, 2014). In a study of 30,519 unselected British women, uterine artery velocimetry was assessed at 22 to 24 weeks' gestation (Smith, 2007). The risk of fetal death before 32 weeks, when associated with abruption, preeclampsia, or fetal-growth restriction, was significantly linked to high-resistance flow. However, technique standards and criteria to define an abnormal test are lacking. Thus, uterine artery Doppler studies are not considered standard practice in either low- or high-risk populations (Society for Maternal-Fetal Medicine, 2020).

ANTENATAL TESTING SUMMARY

Despite a continuous evolution of options, the precision of any given method is limited. Moreover, the wide range of normal biological fetal variation makes interpretation of test results challenging. This prompts many clinicians to use antenatal testing to forecast fetal *wellness* rather than *illness.*

Antenatal testing efficacy was reviewed between 1971 and 1985 at Los Angeles County Hospital (Platt, 1987). Nearly 17,000 women underwent antepartum testing of various types. Fetal surveillance rose from <1 percent of pregnancies in the early 1970s to 15 percent in the mid-1980s. These authors concluded that such testing was clearly beneficial because the fetal death rate was significantly less in the tested high-risk pregnancies compared with the rate in those not tested. The study, however, did not consider other innovations incorporated into practice during those years. Results from Ghana suggest that NSTs may be beneficial in low-resource countries (Lawrence, 2016). Namely, in an observational study of 316 pregnancies complicated by gestational hypertension, women undergoing an NST had a nonsignificant decreased risk for stillbirth compared with those not tested—3.6 versus 9.2 percent, respectively. However, the benefits of antenatal fetal testing have not been sufficiently evaluated in randomized trials.

Another important and unanswered question is whether antepartum fetal surveillance identifies fetal asphyxia early enough to prevent brain damage. Manning and associates (1998) studied the incidence of cerebral palsy in 26,290 high-risk pregnancies managed with serial BPP testing. These outcomes were compared with those of 58,657 low-risk pregnancies in which antepartum testing was not performed. The rate of cerebral palsy was 1.3 per 1000 in tested pregnancies compared with 4.7 per 1000 in untested women. Todd and colleagues (1992) attempted to correlate cognitive development in infants up to age 2 years following abnormal umbilical artery Doppler velocimetry or NST results. Only abnormal NST results were associated with marginally poorer cognitive outcomes. These investigators concluded that by the time fetal compromise is diagnosed with antenatal testing, fetal damage has already been sustained. Low and coworkers (2003) reached a similar conclusion.

Indications for antepartum testing include fetal and maternal conditions that increase the risk for stillbirth (Table 20-4) (American College of Obstetricians and Gynecologists, 2021b). According to the American College of Obstetricians and Gynecologists (2021a), a *normal* antepartum fetal test result is highly reassuring that a stillbirth will not occur within 1 week. This conclusion was reached after an analysis of reports of stillbirth rates associated with the various antepartum fetal heart rate tests (Table 20-5).

The most important consideration in deciding when to begin antepartum testing is the prognosis for neonatal survival. The severity of maternal disease is another. In general, with most high-risk pregnancies, testing begins by 32 to 34 weeks' gestation. Pregnancies with severe complications, such as

TABLE 20-4. Indications for Antepartum Testing

Maternal	Pregnancy-related
Chronic hypertension	Gestational hypertension
Pregestational DM	Preeclampsia
SLE	Insulin-requiring gestational DM
Antiphospholipid syndrome	Oligohydramnios
Hemoglobinopathies	Polyhydramnios
Cyanotic heart disease	Postterm pregnancy
Cardiomyopathy	Prior stillbirth
Cystic fibrosis	Isoimmunization
Restrictive lung disease	Cholestasis
Chronic renal disease	Velamentous cord insertion
Hyperthyroidism	Single umbilical artery
In vitro fertilization	**Fetal**
Substance abuse	Fetal-growth restriction
Chemotherapy (current)	Decreased fetal movement
Prepregnancy BMI ≥35	Multifetal gestation
Maternal age >35	

BMI = body mass index; DM = diabetes mellitus; SLE = systemic lupus erythematosus.

TABLE 20-5. Stillbirth Rates within 1 Week of a Normal Antepartum Fetal Surveillance Test

Antepartum Fetal Test	Stillbirth[a] Rate/1000	Number
Nonstress test	1.9	5861
Contraction stress test	0.3	12,656
Biophysical profile	0.8	44,828
Modified biophysical profile	0.8	54,617

[a]Corrected for lethal anomalies and unpredictable causes of fetal death such as abruption or cord accident.

fetal-growth restriction, might require testing as early as 26 to 28 weeks. The frequency for repeating tests is arbitrarily set at 7 days, but more frequent testing is often done.

SECTION 7

LABOR

CHAPTER 21

Physiology of Labor

Labor is characterized by forceful and painful uterine contractions that effect cervical dilation and cause the fetus to descend through the birth canal. However, extensive preparations take place in both the uterus and cervix long before this. During the first 36 to 38 weeks of normal gestation, the myometrium is in a preparatory yet unresponsive state. Concurrently, the cervix begins an early stage of remodeling yet maintains structural integrity. Following uterine quiescence, a transitional phase begins during which myometrial unresponsiveness is suspended and the cervix undergoes ripening, effacement, and loss of structural cohesion.

The physiological processes that regulate *parturition* and the onset of labor continue to be defined. Three theories describe labor initiation. Viewed simplistically, the first is the *functional loss of pregnancy maintenance factors.* The second focuses on *synthesis of factors that induce parturition*. The third suggests that the mature fetus is the source of the initial *signal for parturition commencement*. Research supports a model that draws from all three themes. Thus, labor onset represents the culmination of a series of biochemical changes in the uterus and cervix. These result from endocrine and paracrine signals emanating from both mother and fetus. Their relative contributions vary between species, and it is these differences that complicate elucidation of the exact factors that regulate human parturition. When parturition is abnormal, preterm labor, dystocia, or postterm pregnancy may result.

MATERNAL AND FETAL COMPARTMENTS

Uterus and Cervix

The myometrial layer of the uterus is composed of bundles of smooth muscle cells surrounded by connective tissue. In contrast to skeletal or cardiac muscle, the smooth muscle cell is not terminally differentiated and therefore is readily adaptable to environmental changes. Varied stimuli such as mechanical stretch, inflammation, and endocrine and paracrine signals modulate the transition of the smooth muscle cell into phenotypes that provide cell growth, proliferation, secretion, and contractility.

Additionally, several smooth muscle qualities confer advantages for uterine contraction efficiency and fetal delivery. First, the degree of smooth muscle cell shortening with contractions may be one order of magnitude greater than that attained in striated muscle cells. Second, forces can be exerted in smooth muscle cells in multiple directions. This differs from the contraction force generated by skeletal muscle, which is always aligned with the axis of the muscle fibers. Third, the thick and thin filaments of smooth muscle are found in long, random bundles throughout the cells. This plexiform arrangement aids augmented shortening and force-generating capacity. Last, greater multidirectional force generation in the uterine fundus

compared with that of the lower uterine segment helps optimize expulsive force vectors.

Lining the thick muscular uterine walls, the endometrium is transformed by pregnancy hormones and is then termed *decidua*. Composed of stromal cells and maternal immune cells, the decidua serves to maintain the pregnancy via unique immunoregulatory functions that suppress inflammatory signals during gestation. However, at the end of pregnancy, the decidua transitions to induce inflammatory signals and withdraw active immunosuppression, contributing to parturition initiation.

During pregnancy, the cervix has multiple functions that include: (1) maintaining the epithelial barrier to protect the reproductive tract from infection, (2) sustaining cervical competence despite greater gravitational forces as the fetus grows, and (3) orchestrating extracellular matrix (ECM) changes that allow progressively greater tissue compliance.

In nonpregnant women, the cervix is closed and firm, and its consistency is similar to nasal cartilage. By the end of pregnancy, the cervix is easily distensible, and its consistency is similar to the lips of the oral cavity. The cervix has a high ratio of fibroblasts to smooth muscle cells, and ECM contributes significantly to overall tissue mass. Vink and colleagues (2016) showed that the smooth muscle cells in the cervix have a spatial gradient. Specifically, smooth muscle cells make up approximately 50 percent of stromal cells at the internal os but only 10 percent at the external os. Also, three-dimensional sonography and magnetic resonance imaging show increases in the cross-sectional area of the cervical canal and changes in ECM structure from early to late pregnancy (House, 2009; Lang, 2010; Pizzella, 2020). Concurrent with expansion of the stroma, the cervical epithelia proliferate and exert a pregnancy-specific immunoprotection.

Placenta

In addition to providing the exchange of nutrients and waste between mother and fetus, the placenta is a key source of steroid hormones, growth factors, and other mediators that maintain pregnancy and potentially aid the transition to parturition. The fetal membranes—amnion and chorion—and adjacent decidua serve as a physiologic, immunologic, and metabolic shield to protect against untimely parturition initiation.

The amnion provides virtually all of the fetal membranes' tensile strength to resist membrane tearing and rupture (Chap. 5, p. 94). This avascular tissue is highly resistant to penetration by leukocytes, microorganisms, and neoplastic cells (Fig. 21-1). It also constitutes a selective filter to prevent fetal particulate-bound lung and skin secretions from reaching the maternal compartment. In this manner, maternal tissues are protected from amnionic fluid constituents that could prematurely accelerate decidual or myometrial activation or could promote adverse events such as amnionic fluid embolism.

The chorion is a primarily protective tissue layer and provides immunological acceptance. It is also enriched with enzymes that inactivate *uterotonins*, which are agents that stimulate contractions. Inactivating enzymes include prostaglandin dehydrogenase, oxytocinase, and enkephalinase (Cheung, 1990; Germain, 1994; Mizutani, 2011).

SEX STEROID HORMONE ROLE

In many species, the role of sex steroid hormones is clear—estrogen promotes and progesterone inhibits the events leading to parturition. The removal of progesterone, that is, *progesterone withdrawal*, directly precedes progression of parturition. In addition, providing progesterone to some species will delay parturition via a decline in myometrial activity and continued cervical competency (Challis, 1994). In humans, however, both estrogen and progesterone are components of a broader molecular system that maintains uterine quiescence.

Plasma levels of estrogen and progesterone in normal pregnancy are enormous and in great excess of the affinity constants for their receptors. For this reason, it is difficult to comprehend how relatively subtle changes in the ratio of their concentrations could modulate physiological processes during pregnancy. The evidence, however, for an increased progesterone-to-estrogen ratio in the maintenance of pregnancy and a decline in this ratio for parturition is overwhelming. In all species studied, including humans, administration of the progesterone-receptor antagonists *mifepristone (RU-486)* or *onapristone* will promote some or all key features of parturition. These include cervical ripening, greater cervical distensibility, and augmented uterine sensitivity to uterotonins (Bygdeman, 1994; Chwalisz, 1994b; Wolf, 1993). The exact role of estrogen in regulation of human uterine quiescence and cervical competency is less well understood. That said, estrogen can advance progesterone responsiveness and, at the end of pregnancy, aid in processes that mediate uterine activation and cervical ripening.

Both progesterone and estrogen bind to nuclear receptors that regulate gene transcription. Two nuclear receptors for estrogen are estrogen receptor α (ERα) and estrogen receptor

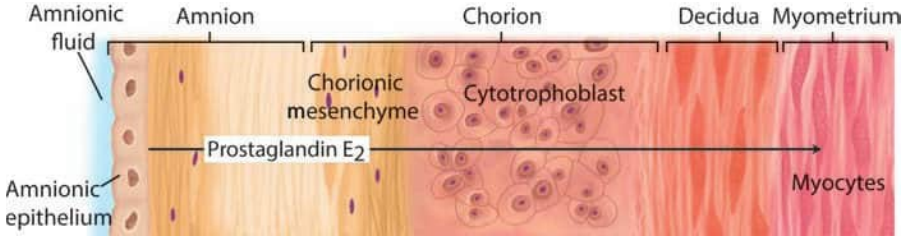

FIGURE 21-1 The amnion synthesizes prostaglandins, and late in pregnancy, synthesis is augmented by increased phospholipase A_2 and prostaglandin H synthase, type 2 (PGHS-2) activity. The transport of prostaglandins from the amnion to maternal tissues is limited by expression of the inactivating enzyme, prostaglandin dehydrogenase (PGDH), in the chorion. During labor, PGDH levels decline, and amnion-derived prostaglandins can influence membrane rupture and uterine contractility. The role of decidual activation in parturition is unclear but may involve local progesterone metabolism and higher prostaglandin receptor concentrations, thus enhancing uterine prostaglandin actions and cytokine production. (Redrawn from Smith R: Parturition. N Engl J Med. 2007 Jan 18;356(3):271–283.)

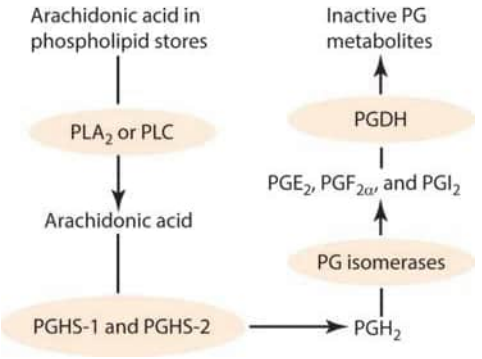

FIGURE 21-2 Overview of the prostaglandin biosynthetic pathway. PG = prostaglandin; PGDH = prostaglandin dehydrogenase; PGE_2 = prostaglandin E_2; $PGF_{2\alpha}$ = prostaglandin $F_{2\alpha}$; PGH_2 = prostaglandin H_2; PGHS = prostaglandin H synthase; PGI_2 = prostaglandin I_2; PLA_2 = phospholipase A_2; PLC = phospholipase C.

β (ERβ). Nuclear receptor isoforms of the progesterone receptor (PR-A and PR-B) are encoded by differing transcripts from a single gene (Patel, 2015).

PROSTAGLANDINS ROLE

Prostaglandins are lipid molecules with varied hormone-like actions. In parturition, they play a prominent role in myometrial contractility, relaxation, and inflammation. Prostaglandins interact with a family of eight different G protein–coupled receptors (p. 403), several of which are expressed in the myometrium and the cervix (Konopka, 2015; Myatt, 2004).

The major synthetic pathway involved in prostaglandin biosynthesis is shown in Figure 21-2. Prostaglandins are produced using plasma membrane–derived arachidonic acid, which usually is released by the action of phospholipase A_2 or C. The enzymes type 1 and 2 prostaglandin H synthase (PGHS-1 and -2), also known as cyclooxygenase 1 and 2 (COX-1 and -2), convert arachidonic acid to prostaglandin H_2 (PGH_2). These enzymes are the target of many nonsteroidal antiinflammatory drugs (NSAIDs). The tocolytic actions of specific COX inhibitors, as discussed in Chapter 45 (p. 806), were considered promising until they were shown to have adverse fetal effects (Loudon, 2003; Olson, 2007).

Through prostaglandin isomerases, PGH_2 is converted to active prostaglandins. These include prostaglandins E_2 (PGE_2), $F_{2\alpha}$ ($PGF_{2\alpha}$), and I_2 (PGI_2). Isomerase expression is tissue-specific and thereby controls the relative production of various prostaglandins. Another important control point for prostaglandin activity is its metabolism, which most often is through the action of 15-hydroxyprostaglandin dehydrogenase (PGDH). Expression of this enzyme is upregulated during pregnancy in the uterus and cervix, which provides the important ability to rapidly inactivate prostaglandins (Giannoulias, 2002; Kishore, 2017). Thus, myometrial responses to prostaglandins stem from a balance between prostaglandin synthesis versus metabolism, from the relative expression of various prostaglandin receptors, or from a switch in receptor-signaling pathways (Kandola, 2014; Lyall, 2002; Olson, 2007; Smith, 2001). It is possible that prostanoids contribute to myometrial relaxation at one stage of pregnancy and to myometrial contractions after parturition initiation (Myatt, 2004).

In addition to the myometrium, the amnion synthesizes several bioactive peptides and prostaglandins that cause myometrial relaxation or contraction (see Fig. 21-1). Late in pregnancy, amnionic prostaglandin biosynthesis of PGE_2 and $PGF_{2\alpha}$ is increased, and phospholipase A_2 and PGHS-2 show greater activity (Peiris, 2020). The amnion is likely the major source for amnionic fluid prostaglandins, and their role in the activation of cascades that promote membrane rupture is clear. However, the influence of amnion-derived prostaglandins on uterine quiescence and activation is less clear because their access to maternal tissues is limited by expression of PGDH.

PHASE 1: UTERINE QUIESCENCE AND CERVICAL SOFTENING

Parturition can be arbitrarily divided into four overlapping phases that correspond to the major physiological transitions of the myometrium and cervix during pregnancy (Fig. 21-3) (Casey, 1997; Shynlova, 2020; Vink, 2018). These include: (1) the prelude, (2) the preparation, (3) the process itself, and (4) the recovery. Importantly, the *phases of parturition* should not be confused with the *clinical stages of labor*. The first, second, and third stages of labor make up phase 3 of parturition (Fig. 21-4).

Beginning even before implantation, a remarkably effective period of myometrial quiescence is imposed. This phase 1 normally constitutes 95 percent of pregnancy and is characterized by uterine smooth muscle tranquility with maintenance of cervical structural integrity (Fig. 21-5). All manner of molecular systems—neural, endocrine, paracrine, and autocrine—are likely called to implement and coordinate a state of relative uterine unresponsiveness. Moreover, a complementary "fail-safe" system that protects the uterus against agents that could perturb the tranquility of phase 1 also must be in place.

During phase 1, the uterus must initiate extensive changes in its size and vascularity to accommodate fetal growth. Concurrently, myometrial cells undergo

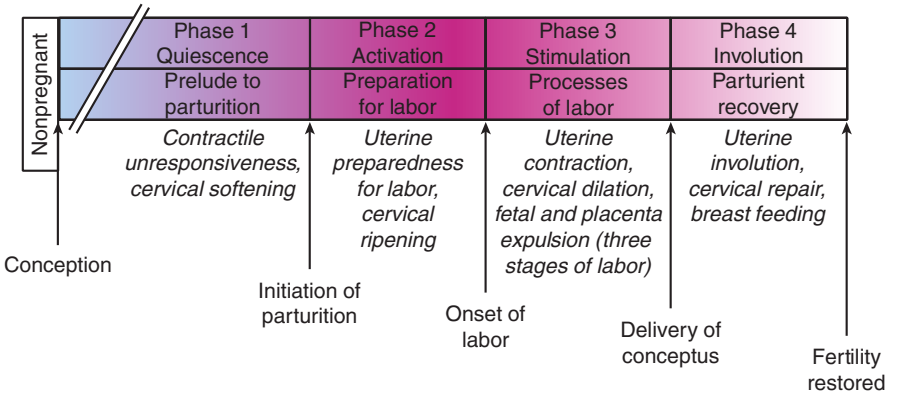

FIGURE 21-3 The phases of parturition.

a phenotypic modification to a noncontractile state, and uterine muscle is rendered unresponsive to natural stimuli. Although this unresponsiveness continues until near the end of pregnancy, some low-intensity myometrial contractions are felt during the quiescent phase. These contractions do not normally cause cervical dilation, and they are common toward the end of pregnancy, especially in multiparas. They are referred to as *Braxton Hicks contractions* or *false labor* (Chap. 4, p. 52).

The quiescence of phase 1 likely stems from: (1) actions of estrogen and progesterone via intracellular receptors, (2) myometrial-cell plasma membrane receptor–mediated increases in cyclic adenosine monophosphate (cAMP), (3) generation of cyclic guanosine monophosphate, and (4) other systems, including modification of myometrial-cell ion channels.

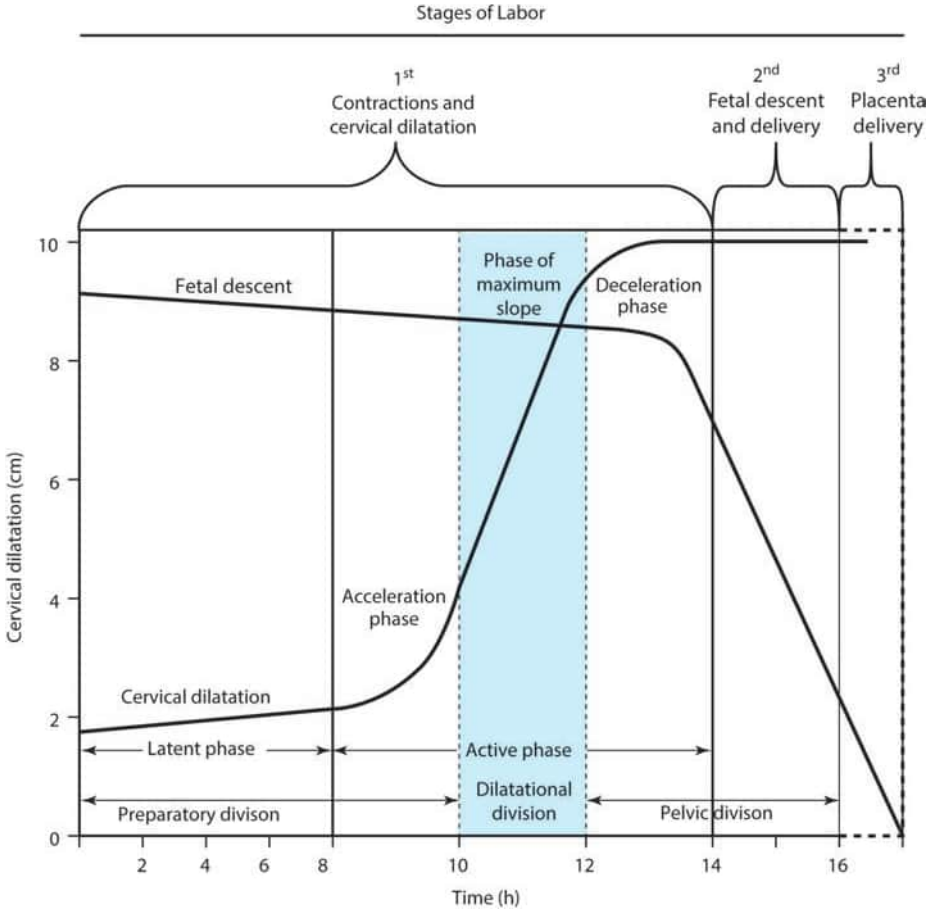

FIGURE 21-4 Labor course divided on the basis of expected evolution of the dilatation and descent curves into three functional divisions. The preparatory division includes the latent and active phases. The dilatational division is the phase of maximum slope of dilatation. The pelvic division encompasses both the deceleration phase and the second stage, which is concurrent with the phase of maximum slope of fetal descent. (Redrawn from Friedman EA: Labor: Clinical Evaluation and Management, 2nd ed. New York, Appleton-Century-Crofts, 1978.)

Myometrial Relaxation and Contraction

The balance between myometrial relaxation and contraction is controlled by steroid- and peptide-hormone transcriptional regulation of key genes and their protein products (Wray, 2019). Quiescence is achieved in part by: (1) diminished intracellular crosstalk and reduced intracellular Ca^{2+} ($[Ca^{2+}]_i$) levels, (2) ion-channel regulation of cell membrane potential, (3) activation of the stress–unfolded protein response by the uterine endoplasmic reticulum, and (4) uterotonin degradation. In contrast, contractility results from: (1) enhanced interactions between the actin and myosin proteins, (2) heightened excitability of individual myometrial cells, and (3) promotion of intracellular crosstalk that allows synchronous contractions to develop.

Actin–Myosin Interactions

Actin and myosin proteins are essential to muscle contraction. For this, actin must be converted from a globular to a filamentous form. Indeed, a potential mechanism for maintenance of relaxation is the promotion of actin into a globular form rather than into fibrils, which are required for contraction. Moreover, actin must be attached to the cytoskeleton at focal points in the cell membrane to allow tension to develop.

Actin must partner with myosin, which is composed of multiple light and heavy chains (Fig. 21-6). This interaction is brought about by enzymatic phosphorylation of the 20-kDa light chain of myosin (Stull, 1998). This is catalyzed by the enzyme *myosin light-chain kinase*, which is activated by calcium (Ca^{2+}).

Thus, logically, uterine relaxation ordinarily is promoted by conditions that lower concentrations of $(Ca^{2+})_i$. In contrast, agents that prompt contraction act on myometrial cells to augment $(Ca^{2+})_i$ levels. Or, they allow an influx of extracellular calcium through ligand- or voltage-regulated calcium channels (see Fig. 21-6). For example, $PGF_{2\alpha}$ and oxytocin bind their respective receptors during labor to open ligand-activated calcium channels. Activation of these receptors also releases calcium from the sarcoplasmic reticulum. Additionally, greater localization of nonselective cation channels on the cell membrane promotes Ca^{2+} entry (Ying, 2015). The rise in $(Ca^{2+})_i$ levels is often transient. But, contractions can be prolonged by inhibition of myosin phosphatase, an enzyme that dephosphorylates myosin (Woodcock, 2004).

Regulation of Membrane Potentials

As just noted, myocyte excitability is regulated in part by changes in the electrochemical potential gradient across the plasma membrane. Before labor, myocytes maintain a relatively high interior electronegativity. Maintenance of a hyperpolarized membrane potential attenuates smooth muscle cell excitation and is regulated by ion channels.

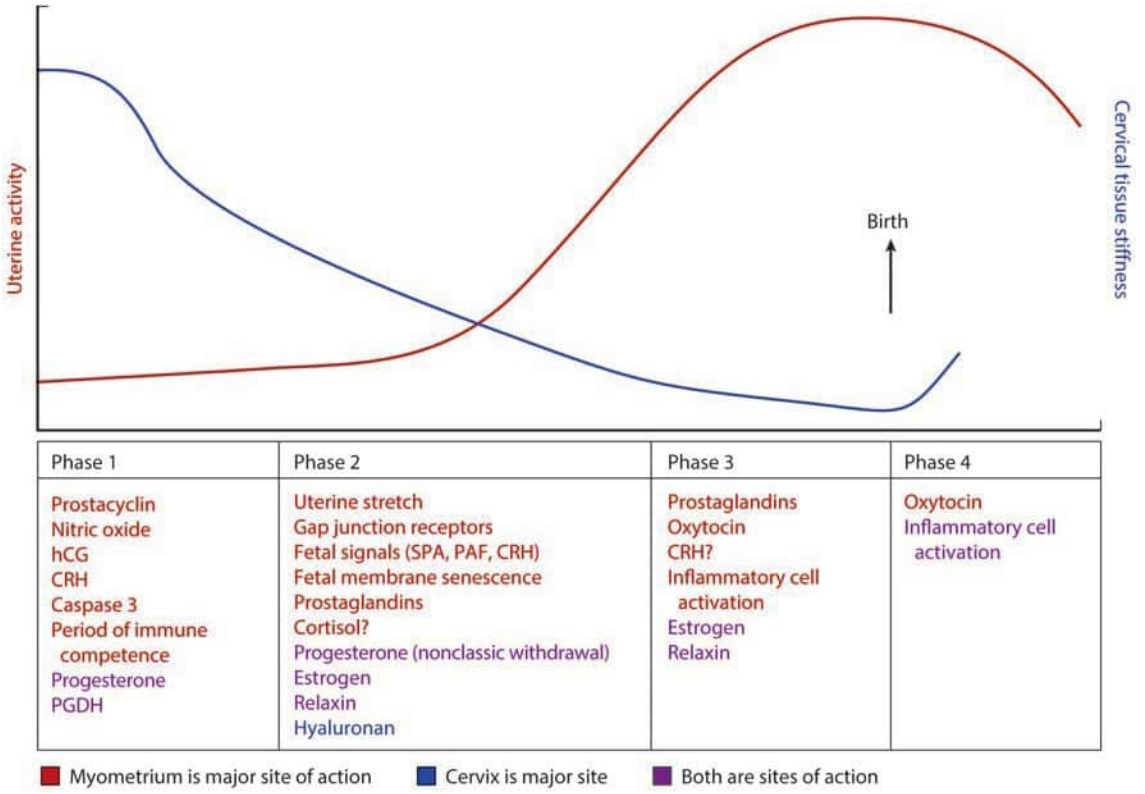

FIGURE 21-5 The key factors thought to regulate the phases of human parturition. CRH = corticotropin-releasing hormone; hCG = human chorionic gonadotropin; PAF = platelet-activating factor; PGDH = prostaglandin dehydrogenase; SPA = surfactant protein A.

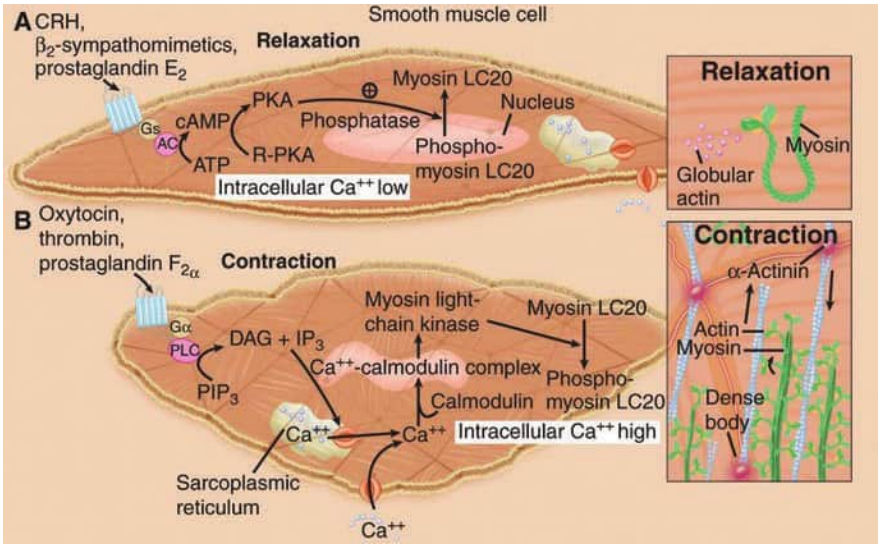

FIGURE 21-6 Uterine myocyte relaxation and contraction. **A.** Uterine relaxation is maintained by factors that increase myocyte cyclic adenosine monophosphate (cAMP) levels. This activates protein kinase A (PKA) to promote phosphodiesterase activity with dephosphorylation of myosin light-chain kinase (MLCK). Other processes serve to maintain actin in a globular form and thus to prevent the fibril formation necessary for contractions. **B.** Uterine contractions result from reversal of these sequences. Actin now assumes a fibrillar form, and calcium enters the cell to combine with calmodulin to form complexes. These complexes activate MLCK to bring about phosphorylation of the myosin light chains. This generates ATPase activity to cause sliding of myosin over the actin fibrils, which is a uterine contraction. AC = adenylyl cyclase; Ca^{2+} = calcium; DAG = diacylglycerol; Gs and Gα = G-receptor proteins; IP_3 = inositol triphosphate; LC20 = light chain 20; PIP_3 = phosphatidylinositol 3,4,5–triphosphate; PLC = phospholipase C; R-PKA = inactive protein kinase. (Redrawn from Smith R: Parturition. N Engl J Med. 2007 Jan 18;356(3):271–283.)

Numerous ion channels control sodium (Na^+) and calcium (Ca^{2+}) influx and potassium (K^+) efflux to collectively regulate membrane potential. Sodium leak channels (NALCN) are important to normal uterine function (Reinl, 2018). Another key regulator is the large-conductance voltage- and Ca^{2+}-activated K^+ channel (BK_{Ca}) (Pérez, 1993). The BK_{Ca} channel is abundantly expressed in the myometrium and plays dual promoting and opposing roles to maintain a balance between uterine quiescence and contractility. Opening the BK_{Ca} channel allows potassium to leave the cell to maintain interior electronegativity, thus preventing voltage-gated Ca^{2+} influx and contraction. Inhibition of the BK_{Ca} channel augments myometrial contractility. Regulation of uterine contractility from early to late gestation may result from temporal changes in expression of the BK_{Ca} channel and/or BK_{Ca} interacting partners (Wakle-Prabagaran, 2016).

Myometrial Gap Junctions

Cellular signals that control myometrial contraction and relaxation can be effectively transferred between cells through

intercellular junctional channels. Communication is established between myocytes by gap junctions, which aid the passage of electrical or ionic coupling currents as well as metabolite coupling. The connexin family of proteins form cell-type specific gap junctions (Solan, 2018). Connexin-43 is expressed in the myometrium, and concentrations rise near labor onset. Six connexin subunits form a *connexon*, and two adjacent connexons establish a conduit between communicating cells. This permits exchange of small molecules that can be nutrients, waste, metabolites, second messengers, or ions. Optimal numbers and types of gap junctions are believed to be important for electrical myometrial synchrony.

Progesterone promotes uterine quiescence in part by lowering expression of contraction-associated proteins (CAPs) and maintaining expression of anticontractile agents such as *caspase 3* (Ingles, 2018; Kyathanahalli, 2015). CAPs include the oxytocin receptor, prostaglandin F receptor, and connexin-43. Also, at the end of pregnancy, increased stretch, metabolism of progesterone by the enzyme 20α-hydroxysteroid dehydrogenase (20α-HSD), loss of progesterone-mediated repression of CAP genes, and greater estrogen dominance raise CAP levels. Integration of diverse regulatory pathways culminates in released inhibition of connexin-43 and oxytocin receptor levels to promote greater uterine contractility (Anamthathmakula, 2019; Mendelson, 2019; Peavey, 2021).

G Protein–Coupled Receptors

In addition to ion-channel linked receptors, G protein–coupled receptors regulate myocyte contractility. These receptors together with appropriate ligands may act with sex steroid hormones to maintain uterine quiescence (Price, 2000; Sanborn, 1998). Examples are the luteinizing hormone (LH) receptor and corticotropin-releasing hormone receptor 1 (CRHR1), both described in this section (Fig. 21-7). Other G protein–coupled myometrial receptors, instead, are associated with uterine contractility. G protein–mediated activation of phospholipase C, which releases arachidonic acid, is one example. Ligands for the G protein–coupled receptors include numerous neuropeptides, hormones, and autacoids. Many of these are available to the myometrium during pregnancy in high concentration via *endocrine* or *autocrine* mechanisms.

LH and human chorionic gonadotropin (hCG) hormones share the same LH-hCG receptor. This G protein–coupled receptor is found in myometrial smooth muscle and blood vessels, and levels during pregnancy are greater before labor (Ziecik, 1992). hCG acts to activate adenylyl cyclase by way of a plasma membrane receptor $G_{\alpha s}$-linked system. This lessens contraction frequency and force and lowers the number of tissue-specific myometrial cell gap junctions (Ambrus, 1994; Eta, 1994). Thus, high circulating levels of hCG may be one mechanism of uterine quiescence. β-Adrenergic receptors mediate $G_{\alpha s}$-stimulated myometrial cell relaxation. Agents binding to these receptors have been used for tocolysis of preterm labor and include ritodrine and terbutaline (Chap. 45, p. 805). The rate-limiting factor is likely the number of receptors expressed and the level of adenylyl cyclase expression.

Prostaglandin E_2 mediates its diverse cellular effects through four G protein–coupled receptors. Specifically, prostaglandin E receptors 1 through 4 (EP_1-EP_4) are expressed in the

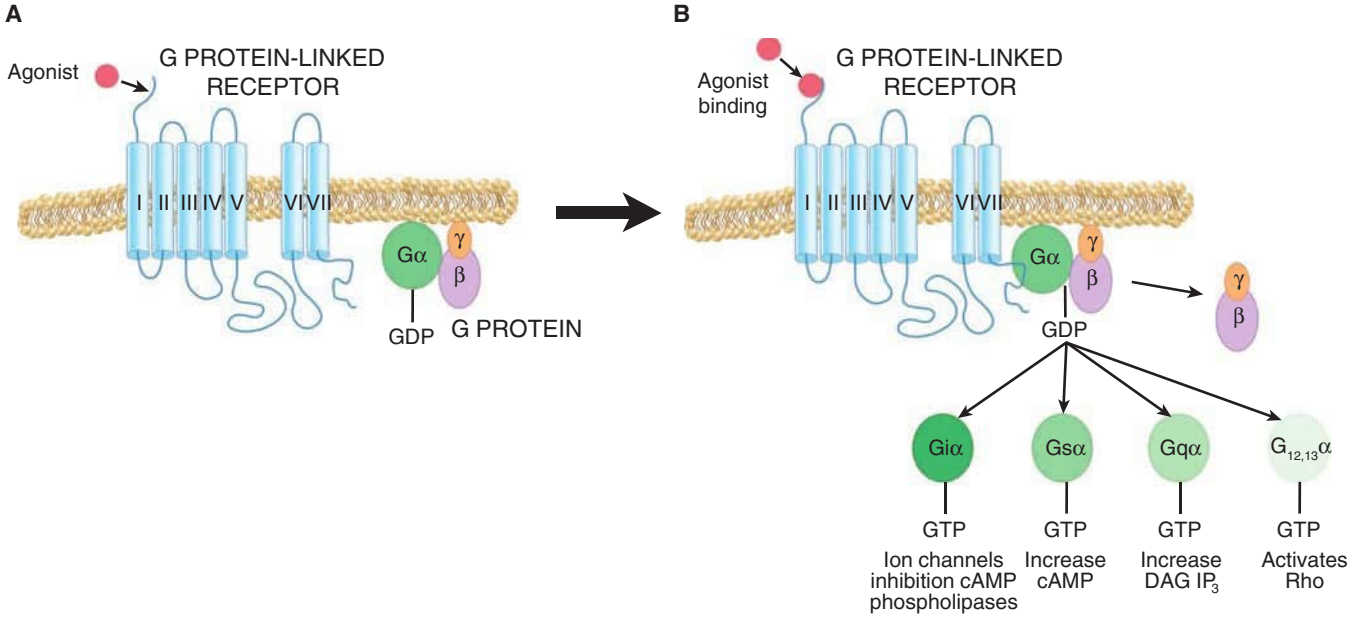

FIGURE 21-7 G protein–coupled receptor signal transduction pathways. **A.** Receptors coupled to heterotrimeric guanosine-triphosphate (GTP)-binding proteins (G proteins) are integral transmembrane proteins that transduce extracellular signals to the cell interior. G protein–coupled receptors exhibit a common structural motif consisting of seven membrane-spanning regions. **B.** Receptor occupation promotes interaction between the receptor and the G protein on the interior surface of the membrane. An exchange of guanosine diphosphate (GDP) for GTP on the G protein α subunit and dissociation of the α subunit from the βγ heterodimer occurs. Depending on its isoform, the GTP-α subunit complex mediates intracellular signaling either indirectly by acting on effector molecules such as adenylyl cyclase (AC) or phospholipase C (PLC), or directly by regulating ion channel or kinase function. cAMP = cyclic adenosine monophosphate; DAG = diacylglycerol; IP_3 = inositol triphosphate.

myometrium during pregnancy and with labor onset (Astle, 2005; Leonhardt, 2003). EP_2 and EP_4 act through $G_\alpha s$ to maintain myometrial cell quiescence but switch to a $G_\alpha q/11$ calcium-activating pathway during labor (Kandola, 2014). EP_1 and EP_3 receptors act through $G_\alpha q$ and $G_\alpha i$ to augment intracellular Ca^{2+} and contractility.

The peptide hormone relaxin binds to the G protein–coupled receptor named *relaxin family peptide receptor 1 (RXFP1)*. Binding activates adenylyl cyclase, which in turn prevents increased intracellular Ca^{2+}, and thus promotes uterine quiescence (Downing, 1993; Meera, 1995). The *H1* relaxin gene is primarily expressed in the decidua, trophoblast, and prostate, whereas the *H2* gene is primarily expressed in the corpus luteum. Relaxin plasma levels peak at approximately 1 ng/mL between 8 and 12 weeks' gestation. Thereafter, they decline until term.

Corticotropin-releasing hormone (CRH) is synthesized in the placenta and hypothalamus. Discussed on page 408, CRH plasma levels rise dramatically during the final 6 to 8 weeks of normal pregnancy and are implicated in mechanisms that control the timing of human parturition (Smith, 2007; Wadhwa, 1998; Wang, 2019). CRH appears to promote myometrial quiescence during most of pregnancy but then aids contractions with parturition onset. Studies suggest that these opposing actions are achieved by differential actions of CRH via its receptor CRHR1. In nonlaboring myometrium at term, the interaction of CRH with CRHR1 activates the Gs-adenylate cyclase-cAMP signaling pathway. This results in inhibition of inositol triphosphate (IP_3) and stabilization of $(Ca^{2+})_i$ levels (You, 2012). However, in term laboring myometrium, $(Ca^{2+})_i$ concentrations are augmented by CRH activation of G proteins Gq and Gi and prompts stimulation of IP_3 production and greater contractility.

Cyclic Guanosine Monophosphate

As noted, cAMP is an important mediator of myometrial relaxation. However, activation of guanylyl cyclase raises intracellular cyclic guanosine monophosphate (cGMP) levels. This also promotes smooth muscle relaxation (Word, 1993). Intracellular cGMP levels are increased in the pregnant myometrium and can be stimulated by atrial natriuretic peptide, brain natriuretic peptide, and nitric oxide (Guerra, 2019; Telfer, 2001). All of these factors and their receptors are expressed in the pregnant uterus.

Accelerated Uterotonin Degradation

The activity of enzymes that degrade or inactivate endogenously produced uterotonins also is strikingly increased in phase 1. Pairs of some degrading enzymes and their respective targets include PGDH and prostaglandins; enkephalinase and endothelins; oxytocinase and oxytocin; diamine oxidase and histamine; catechol *O*-methyltransferase and catecholamines; angiotensinases and angiotensin II; and platelet-activating factor (PAF) and PAF acetylhydrolase. Levels of several of these enzymes decline late in gestation (Germain, 1994).

Decidua

To ensure uterine quiescence, the synthesis in the decidua of prostaglandins, in particular $PGF_{2\alpha}$, is markedly suppressed. Suppression of prostaglandin production here persists throughout most of pregnancy, and suppression withdrawal is a prerequisite for parturition (Norwitz, 2015).

The mother and fetus come in direct contact at the decidua basalis and decidua parietalis. At this interface, myeloid and lymphoid immune cells such as natural killer cells, macrophages, dendritic cells, and T cells undergo dynamic changes in number and phenotype to achieve a balanced microenvironment (Ander, 2019; Solano, 2019; van der Zwan, 2020). This is a critical site for immune tolerance in phase 1 and for decidual activation in phase 2 of parturition (see Fig. 21-5). In phase 1 of parturition, these cells, in collaboration with decidual cells, promote an environment of immune tolerance to protect the fetus. Immune cells with innate and adaptive immune responses support vascular and tissue remodeling, immune surveillance and defense, and trophoblast invasion in phase 1 (Fig. 21-8).

During phase 2, decidual stromal cells and fetal membranes undergo an aging process termed cellular senescence. Noninflammatory signals precipitate senescence, which in turn leads to synthesis of proinflammatory cytokines, augmented

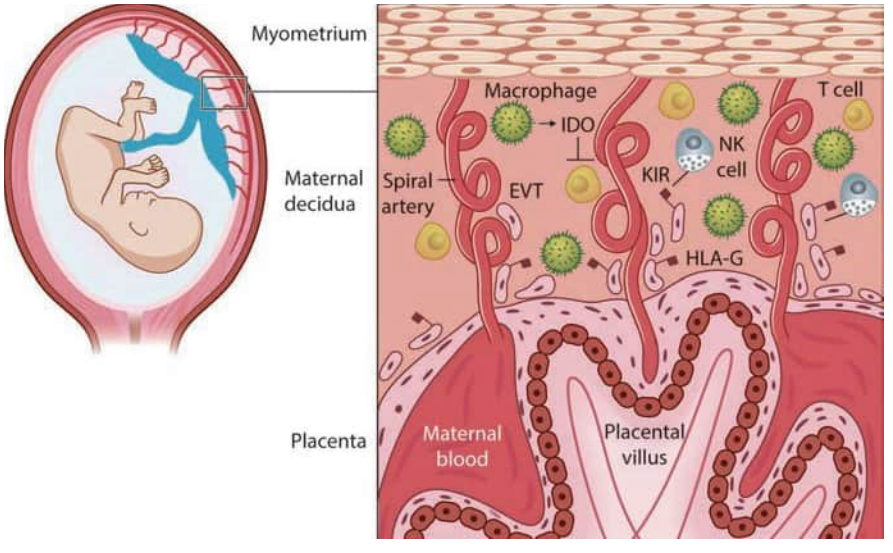

FIGURE 21-8 Immune tolerance and activation at the maternal fetal interface. In the antepartum period, dNK cells are abundant and their maturation is promoted by release of uterine IL-15. These cells promote decidual remodeling, blastocyst implantation, and EVT invasion. The cytotoxicity of dNK cells is regulated by the interaction of its KIR receptor with HLA-G on EVTs. Decidual macrophages—primary antigen-presenting cells—produce the enzyme IDO, which limits T cell activation. Changes in the intrapartum period are less understood, but the number of dNK cells decline and decidual macrophages are activated to a proinflammatory phenotype. dNK = decidual natural killer; EVT = extravillous trophoblasts; HLA = human leukocyte antigen; IL = interleukin; IDO = indoleamine 2,3-dioxygenase; KIR = killer-cell immunoglobulin-like receptors.

prostaglandin production, and increased protease expression. These proteins and hormones break down fetal membranes.

Cervical Softening

The initial stage of cervical remodeling—termed *softening*—begins in phase 1 of parturition. It is characterized by greater tissue compliance, yet the cervix remains firm and unyielding. Hegar (1895) first described palpable softening of the lower uterine segment at 4 to 6 weeks' gestation, and this sign was once used to diagnose pregnancy. Clinically, the maintenance of cervical anatomical and structural integrity is essential for pregnancy to continue to term. Preterm cervical dilation, structural insufficiency, or both may forecast delivery.

Cervical Connective Tissue

Cervical softening is an active molecular process that balances tissue competence against slow, progressive compositional and structural changes in the extracellular matrix (ECM) to increase compliance (Myers, 2015; Nallasamy, 2017; Vink, 2018). Constituents of the ECM include type I and III fibrillar collagens, matricellular proteins, glycosaminoglycans, proteoglycans, and elastic fibers. Key to matrix changes, collagen, which is the main structural protein in the cervix, undergoes conformational changes that alter tissue stiffness and flexibility (Zhang, 2012). Specifically, collagen processing and the number or type of stable covalent cross-links between collagen's triple helices are altered. Beginning in early pregnancy, mature cross-links between newly synthesized collagen monomers are reduced due to diminished expression and activity of the cross-link-forming enzymes (Akins, 2011; Yoshida, 2014). These enzymes are lysyl hydroxylase and lysyl oxidase. Gradual turnover of collagen during pregnancy replaces mature cross-linked collagen fibrils with poorly linked fibrils. The result is a collagen with reduced stiffness. The collagen-binding proteoglycans—decorin and biglycan—ensure the new, poorly cross-linked collagen is appropriately assembled and deposited in the ECM. Data from human and mouse studies support the theory that a balance in the synthesis and breakdown of collagen, rather than loss of collagen, achieves cervical remodeling (Fig. 21-9) (Akins, 2011; Myers, 2008; Read, 2007; Yoshida, 2014).

Clinical evidence for the importance of matrix changes to cervical softening is supported by in vivo mechanical evaluation of the cervix (Badir, 2013; Parra-Saavedra, 2011). The prevalence of cervical insufficiency is also higher in those with inherited defects in the synthesis or assembly of collagen or elastic fibers (Anum, 2009; Hermanns-Le, 2005; Volozonoka, 2020).

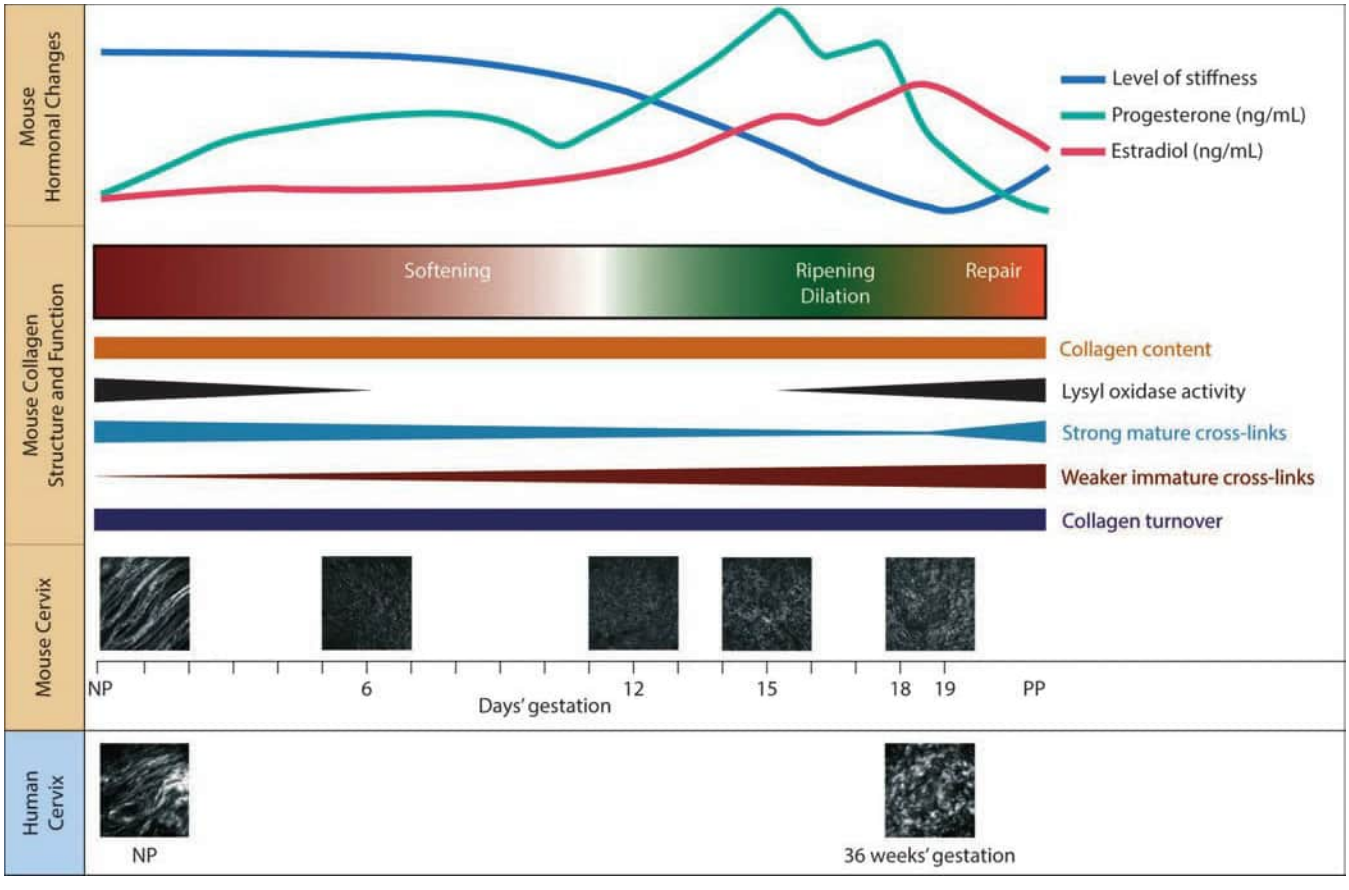

FIGURE 21-9 Mouse studies identify molecular changes in collagen structure and function during cervical remodeling. These changes are regulated by steroid hormones and result in a gradual loss of tissue stiffness. During the softening phase, the decline in lysyl oxidase activity in conjunction with high collagen turnover results in the replacement of strong cross-linked collagen fibers with weakly cross-linked collagen fibers. Second harmonic generation images in the mouse and human cervix show the corresponding gradual decline in mechanical function of the cervix. (Compiled from Akins, 2010, 2011; Ozasa, 1981; Read, 2007; Yoshida, 2014; Zhang, 2012.)

Examples are Ehlers-Danlos and Marfan syndromes, discussed in Chapter 62 (p. 1121). Concurrent with matrix remodeling in the softening period, genes involved in cervical dilation and parturition are actively repressed (Kishore, 2012).

PHASE 2: PREPARATION FOR LABOR

To prepare for labor, the myometrial tranquility of phase 1 of parturition must be suspended. This so-called *uterine awakening* or *activation* in phase 2 of parturition is a progression of uterine changes during the last few weeks of pregnancy. Importantly, shifting events associated with phase 2 can cause either preterm or delayed labor.

Progesterone Withdrawal

Key factors in uterine activation are depicted in Figure 21-5. In species that exhibit progesterone withdrawal, parturition progression to labor can be blocked by administering progesterone to the mother. Whether progesterone administration in the absence of classic progesterone withdrawal can delay the timely onset of parturition or prevent preterm labor remains unclear. The possibility that progesterone may prevent preterm labor has been studied, but its use in preventing preterm birth continues to be debated (Chap. 45, p. 795).

Classic progesterone withdrawal from decreased secretion does not occur in human parturition. However, a mechanism for progesterone inactivation, whereby the myometrium and cervix become refractory to progesterone's inhibitory actions, is supported by studies using progesterone-receptor antagonists. Mifepristone is a classic steroid antagonist, acting at the level of the progesterone receptor. Although less effective in inducing abortion or labor later in pregnancy, mifepristone appears to have some effect on cervical ripening and on increasing myometrial sensitivity to uterotonins (Berkane, 2005; Chwalisz, 1994a).

The diverse mechanisms by which functional progesterone withdrawal or antagonism is achieved is an active area of research. These include: (1) changes in the relative expression of the nuclear progesterone-receptor (PR) isoforms, (2) differential interaction of PR isoforms A and B with enhancers and inhibitors of gene expression, (3) altered PR activity through changes in the expression of coactivators or corepressors of receptor function, (4) local progesterone inactivation by steroid-metabolizing enzymes or synthesis of a natural antagonist, and (5) microRNA regulation of progesterone-metabolizing enzymes and transcription factors that modulate uterine quiescence (Chen, 2017; Condon, 2003; Mahendroo, 1999; Mesiano, 2002; Nadeem, 2016; Peavey, 2021; Renthal, 2010; Williams, 2012). Thus, multiple pathways exist to create functional progesterone withdrawal.

Myometrial Changes

Phase 2 changes in the myometrium prepare it for labor contractions. Changes result from a shift in the expression of proteins that control uterine quiescence to an expression of CAPs, described earlier (p. 403) (Mendelson, 2019; Renthal, 2015; Stanfield, 2019). These CAPs increase uterine responsiveness to uterotonins.

Another critical change in phase 2 is formation of the lower uterine segment from the isthmus. With this development, the fetal head often descends to or even through the pelvic inlet—*lightening*. The abdomen commonly undergoes a shape change, sometimes described by women as "the baby dropped." It is also likely that the lower segment myometrium is unique from that in the upper uterine segment, and leads to distinct roles for each near term and during labor. This is supported by human studies that demonstrate differential expression of prostaglandin receptors and CAPs within the upper- and lower-segment myometrial regions (Astle, 2005; Blanks, 2003; Sparey, 1999). Near term, elevated expression of the *HoxA13* gene in the lower myometrial segment compared with the upper segment also induces CAP expression and regionalized contractility of the lower segment (Li, 2016).

Oxytocin Receptors

Because of its long-standing application for labor induction, it seemed logical that oxytocin must play a central role in spontaneous human labor. Myometrial oxytocin receptor levels do rise during phase 2 of parturition, and the level of oxytocin receptor mRNA in human myometrium at term is greater than that found in preterm myometrium (Wathes, 1999). However, it is unclear whether oxytocin plays a role in the early phases of uterine activation or whether its sole function is in the expulsive phase of labor. Most studies of regulation of myometrial oxytocin receptor synthesis have been performed in rodents. Disruption of the oxytocin receptor gene in the mouse does not affect parturition. This suggests that, at least in this species, multiple systems likely ensure that parturition occurs.

Progesterone inhibits and estradiol induces oxytocin receptor expression. Through interaction with PR-B, progesterone regulates numerous genes in the oxytocin signaling pathway (Peavey, 2021). Progesterone may also act within the myometrial cell to enhance oxytocin receptor degradation (Bogacki, 2002). These data indicate that one of the mechanisms whereby progesterone maintains uterine quiescence is through inhibition of a myometrial oxytocin signaling pathway.

Cervical Ripening

Before contractions begin, the cervix must shift from a state of competence to one of compliance. This eventually leads to the cervix yielding and dilating from forceful uterine contractions. Cervical modifications during phase 2 principally involve connective tissue changes—termed *cervical ripening*. The transition from the softening to the ripening phase begins weeks or days before labor. The understanding of this cervical matrix transformation remains incomplete. However, it is clear that levels of *glycosaminoglycans*, which are large linear polysaccharides, are uniquely increased in phase 2.

Glycosaminoglycans and Proteoglycans

Hyaluronan is a high-molecular-weight polysaccharide that functions alone, but most other glycosaminoglycans (GAGs)

complex with proteins to form proteoglycans. Hyaluronan is a hydrophilic, space-filling molecule, and thus greater hyaluronan production during cervical ripening is thought to increase viscoelasticity, hydration, and matrix disorganization. Hyaluronan synthesis is carried out by hyaluronan synthase isoenzymes, and expression of these enzymes is elevated in the cervix during ripening (Akgul, 2012; Straach, 2005).

Inflammatory Changes

In phase 2, resident immune cells are localized to the cervical stroma, although a functional role for them in this phase has not been demonstrated. For example, studies of gene expression patterns at term both before and after cervical ripening show little rise in proinflammatory gene expression. However, once labor is underway, activation of neutrophils, proinflammatory M1 macrophages, and tissue repair M2 macrophages in the cervix is augmented. Moreover, proinflammatory and immunosuppressive gene expression in the cervix increases markedly after delivery (Bollapragada, 2009; Hassan, 2006, 2009). This suggests a role for inflammatory cells in postpartum cervical remodeling and repair (Mahendroo, 2012).

Induction of Cervical Ripening

No therapies prevent premature cervical ripening. In contrast, treatment to promote cervical ripening for labor induction includes direct application of PGE_2 and $PGF_{2\alpha}$ (Chap. 26, p. 489). Prostaglandins likely modify ECM structure to aid ripening, although their role in the normal physiology of cervical ripening remains unclear.

In some nonhuman species, events that allow cervical ripening are induced by dropping serum progesterone concentrations. And in humans, administration of progesterone antagonists causes cervical ripening.

Endocervical Epithelia

In addition to matrix changes during pregnancy, endocervical epithelial cells proliferate such that endocervical glands account for a significant percentage of cervical mass. The endocervical canal is lined with mucus-secreting columnar and stratified squamous epithelia. These cells form both a mucosal barrier and a tight junctional barrier that protect against microbial invasion (Akgul, 2014; Blaskewicz, 2011; Timmons, 2007). The mucosal epithelium recognizes and deters pathogen invasion via expression of toll-like receptors that identify pathogens and via antimicrobial peptides and protease inhibitors. These epithelia also express signals to underlying immune cells when a pathogenic challenge exceeds their protective capacity (Wira, 2005).

■ Fetal Contributions to Parturition

It is intriguing to envision that the mature human fetus provides the signal to initiate parturition, and evidence for fetal signaling is mounting (Mendelson, 2017). The fetus may give signals through blood-borne agents that act on the placenta or through secretion into the amniotic fluid.

Uterine Stretch

Fetal growth is an important component of uterine activation in phase 2 of parturition. With uterine activation, stretch is required for induction of specific CAPs. Namely, stretch increases expression of connexin-43 and oxytocin receptors. Levels of gastrin-releasing peptide, a stimulatory agonist for smooth muscle, also are augmented by stretch in the myometrium (Tattersall, 2012).

Clinical clues for a role of stretch come from the observation that multifetal pregnancies carry a much greater risk for preterm labor than singleton ones. Preterm labor is also more common in pregnancies complicated by hydramnios. Although the mechanisms causing preterm birth in these two are debated, a role for uterine stretch must be considered.

Cell signaling systems are influenced by stretch to regulate the myometrial cell. This process—*mechanotransduction*—may include activation of cell-surface receptors or ion channels, transmission of signals through ECM, or release of autocrine molecules that act directly on myometrium (Shynlova, 2007; Young, 2011).

Fetal Endocrine Cascades

The ability of the fetus to provide endocrine signals that initiate parturition has been demonstrated in several species. However, evidence suggests that it is not regulated in the same manner in humans. That said, the human fetal hypothalamic-pituitary-adrenal-placental axis is considered a critical component of normal parturition. Moreover, premature activation of this axis is considered to prompt many cases of preterm labor (Challis, 2000, 2001). Steroid products of the human fetal adrenal gland are believed to have effects on the placenta and membranes that eventually transform the myometrium from a quiescent to a contractile state.

A key component in the human may be the unique ability of the placenta to produce large amounts of CRH that is identical to maternal and fetal hypothalamic CRH (Grino, 1987; Saijonmaa, 1988) (Fig. 21-10). However, unlike hypothalamic CRH, which is under glucocorticoid negative feedback, cortisol

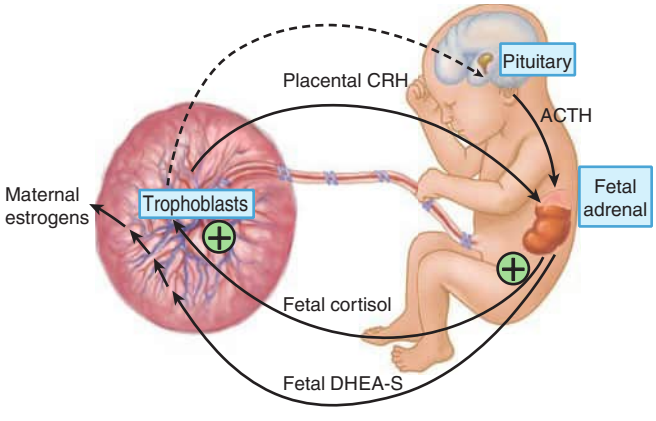

FIGURE 21-10 The placental–fetal adrenal endocrine cascade. In late gestation, placental corticotropin-releasing hormone (CRH) stimulates fetal adrenal production of dehydroepiandrosterone sulfate (DHEA-S) and cortisol. The latter stimulates production of placental CRH, which leads to a feed-forward cascade that enhances adrenal steroid hormone production. ACTH = adrenocorticotropic hormone.

instead *stimulates* placental CRH production. This ability makes it possible to create a feed-forward endocrine cascade that does not end until delivery.

Maternal plasma CRH levels are low in the first trimester and rise from midgestation to term. In the last 12 weeks, CRH plasma levels rise exponentially, peak during labor, and then fall precipitously after delivery (Frim, 1988; Sasaki, 1987). Amnionic fluid CRH concentrations similarly increase in late gestation. CRH is the only trophic hormone-releasing factor to have a specific serum binding protein. During most of pregnancy, CRH-binding protein (CRH-BP) binds most maternal circulating CRH, and this inactivates it (Lowry, 1993). During later pregnancy, however, CRH-BP levels in both maternal plasma and amnionic fluid decline, leading to markedly greater levels of bioavailable CRH (Perkins, 1995; Petraglia, 1997).

In pregnancies in which the fetus can be considered "stressed" from various complications, concentrations of CRH in fetal plasma, amnionic fluid, and maternal plasma are greater than those seen in normal gestation (Berkowitz, 1996; McGrath, 2002). The placenta is the likely source of this elevated CRH concentration. For example, placental CRH content is fourfold higher in placentas from women with preeclampsia than in those from normal pregnancies (Perkins, 1995).

Placental CRH is thought to play several roles in parturition regulation. It may enhance fetal cortisol production to provide positive feedback so that the placenta produces more CRH. Late in pregnancy—phase 2 or 3 of parturition—modification in the CRH receptor favors a switch from cAMP formation instead to increased myometrial cell calcium levels via protein kinase C activation (You, 2012). Oxytocin acts to attenuate CRH-stimulated accumulation of cAMP in myometrial tissue. CRH acts to augment myometrial contractile force in response to $PGF_{2\alpha}$ (Benedetto, 1994). Last, CRH stimulates fetal adrenal C_{19}-steroid synthesis, thereby increasing substrate for placental aromatization.

Some have proposed that the rising CRH level at the end of gestation reflects a *fetal-placental clock* (McLean, 1995). CRH concentrations vary greatly among women, and the rate of rise in maternal CRH levels is a more accurate predictor of pregnancy outcome than is a single measurement (Leung, 2001; McGrath, 2002). In this regard, the placenta and fetus, through endocrinological events, influence parturition timing at the end of normal gestation.

Fetal Lung Surfactant and Platelet-activating Factor

Surfactant protein A (SP-A) produced by the fetal lung is required for lung maturation. SP-A is expressed by the human amnion and decidua, is present in the amnionic fluid, and prompts signaling pathways in human myometrial cells (Garcia-Verdugo, 2008; Lee, 2010; Snegovskikh, 2011). The exact mechanisms by which SP-A activates myometrial contractility in women, however, remain to be clarified. One mode may be its effects on prostaglandins. Namely, SP-A selectively inhibits $PGF_{2\alpha}$ in the term decidua, but SP-A levels drop in the amnionic fluid at term (Chaiworapongsa, 2008). The fetal lung also makes the uterotonic agent platelet-activating factor (Frenkel, 1996; Toyoshima, 1995). This factor and SP-A play a role in fetal–maternal signaling for parturition (Gao, 2015).

Fetal Membrane Senescence

Toward the end of pregnancy, fetal membranes undergo cellular senescence (Menon, 2016). In human and animal fetal membranes, stretch and oxidative stress induce senescent fetal membrane to manifest a form of sterile inflammation termed senescent-associated secretory phenotype (SASP). This in turn propagates inflammatory signals that further weaken the fetal membrane and activate signals in the decidua and myometrium to initiate parturition. Thus, as the functional necessity of fetal membranes declines at term, they are able to promote signals that contribute to parturition initiation.

Fetal Anomalies and Delayed Parturition

Some evidence shows that pregnancies with markedly diminished estrogen production may be associated with prolonged gestation. These include women with inherited placental sulfatase deficiency and fetal anencephaly with adrenal hypoplasia. The broad range of gestational length seen with these disorders, however, calls into question the exact role of estrogen in human parturition initiation.

Some brain anomalies of the fetal calf, fetal lamb, and sometimes the human fetus delay the normal timing of parturition. In particular, the association between fetal anencephaly and prolonged gestation is well described (Rea, 1898; Malpas, 1933). Malpas concluded that the prolonged gestation was attributable to anomalous fetal brain-pituitary-adrenal function. Indeed, the adrenal glands of the anencephalic fetus are very small and, at term, may be only 5 to 10 percent as large as those of a normal fetus. This is caused by developmental failure of the fetal zone that normally accounts for most of fetal adrenal mass and production of C_{19}-steroid hormones (Chap. 5, p. 101). Such pregnancies are associated with delayed labor and suggest that the fetal adrenal glands are important for the timely onset of parturition.

Other fetal abnormalities that prevent or severely reduce the entry of fetal urine or lung secretions into amnionic fluid do not prolong human pregnancy. Examples are renal agenesis and pulmonary hypoplasia, respectively. Thus, a fetal signal through the paracrine arm of the fetal–maternal communication system does not appear to be mandated for parturition initiation.

PHASE 3: LABOR

This phase is synonymous with active labor, which is customarily divided into three stages (see Figure 21-4). The first stage begins when spaced uterine contractions of sufficient frequency, intensity, and duration are attained to bring about cervical thinning, termed *effacement*. Several uterotonins may be important to the success of this stage of active labor (see Fig. 21-5). These have been shown to stimulate smooth muscle contraction through G-protein coupling. This labor stage ends when the cervix is fully dilated—about 10 cm—to allow passage of the term-sized fetus. The first stage of labor, therefore, is the *stage of cervical effacement and dilation*. The second stage begins when cervical dilation is complete and ends with delivery. Thus, the second stage of labor is the *stage of fetal expulsion*. Last, the third stage begins immediately after delivery of the

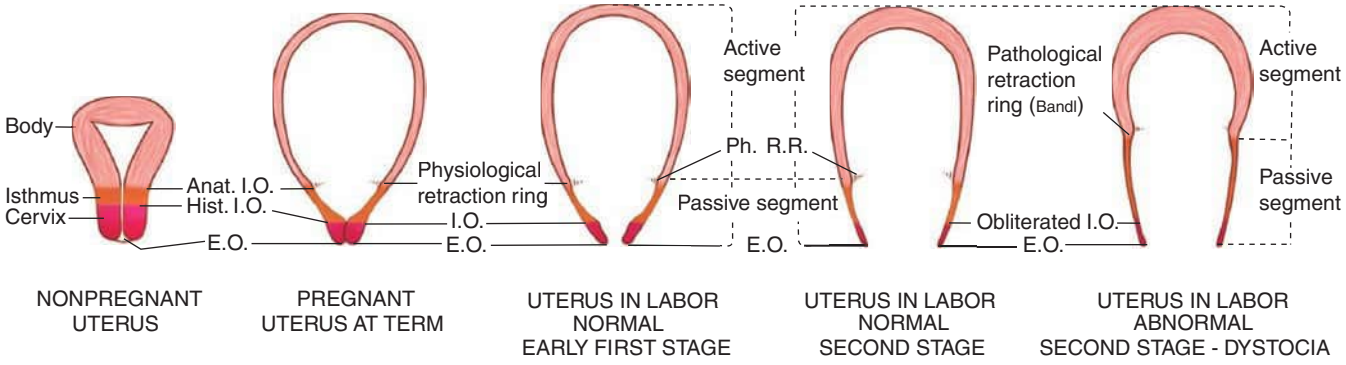

FIGURE 21-11 Sequence of development of the segments and rings in the uterus at term and in labor. Note comparison between the nonpregnant uterus, the uterus at term, and the uterus during labor. The passive lower uterine segment is derived from the isthmus, and the physiological retraction ring develops at the junction of the upper and lower uterine segments. The pathological retraction ring develops from the physiological ring. Anat. I.O. = anatomical internal os; E.O. = external os; Hist. I.O. = histological internal os; Ph.R.R. = physiological retraction ring.

fetus and ends with the delivery of the placenta. This stage of labor is the *stage of placental separation and expulsion*.

First Stage: Clinical Onset of Labor

Uterine Labor Contractions

In some women, forceful uterine contractions that effect delivery begin suddenly. In others, labor initiation is heralded by spontaneous release of a small amount of blood-tinged mucus from the vagina. This extrusion of the mucus plug that had previously filled the cervical canal during pregnancy is referred to as "bloody show." Its passage indicates that labor is already in progress or likely will ensue in hours to days.

Unique among physiological muscular contractions, those of uterine smooth muscle during labor are painful. Suggested causes are: (1) hypoxia of the contracted myometrium—such as that with angina pectoris; (2) compression of nerve ganglia in the cervix and lower uterus by contracted interlocking muscle bundles; (3) cervical stretching during dilation; and (4) stretching of the peritoneum overlying the fundus.

Of these, compression of nerve ganglia in the cervix and lower uterine segment by the contracting myometrium is an especially attractive hypothesis. Paracervical infiltration with local anesthetic usually produces appreciable pain relief with contractions (Chap. 25, p. 472). Uterine contractions are involuntary and, for the most part, independent of extrauterine control. Neural blockade from epidural analgesia does not diminish their frequency or intensity. In other examples, myometrial contractions in paraplegic women and in women after bilateral lumbar sympathectomy are normal but painless.

Mechanical stretching of the cervix enhances uterine activity in several species, including humans. This phenomenon is the *Ferguson reflex* (Ferguson, 1941). Its exact mechanism is unclear, and release of oxytocin has been suggested but not proven. Manipulation of the cervix and "stripping" the fetal membranes are associated with a rise in blood levels of prostaglandin $F_{2\alpha}$ metabolites.

The interval between contractions narrows gradually from approximately 10 minutes at the onset of first-stage labor to as little as 1 minute or less in the second stage. Periods of relaxation between contractions, however, are essential for fetal welfare. Unremitting contractions compromise uteroplacental blood flow sufficiently to cause fetal hypoxemia. In active-phase labor, the duration of each contraction ranges from 30 to 90 seconds and averages 1 minute. Contraction intensity varies appreciably during normal labor. Specifically, amnionic fluid pressures generated by contractions during spontaneous labor average 40 mm Hg, but vary from 20 to 60 mm Hg (Chap. 24, p. 462).

Distinct Lower and Upper Uterine Segments

During active labor, the anatomical uterine divisions that were initiated in phase 2 of parturition become increasingly evident (Figs. 21-11 and 21-12). By abdominal palpation, even before membrane rupture, the two segments can sometimes be

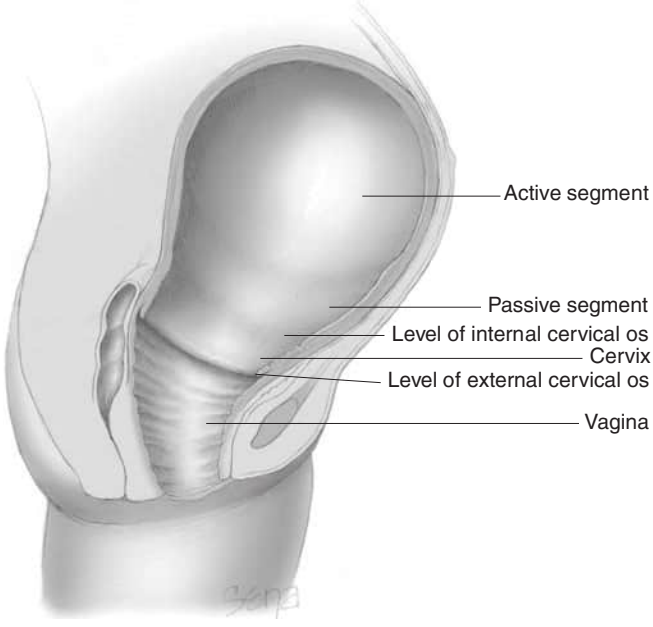

FIGURE 21-12 The uterus at the time of vaginal delivery. The active upper segment retracts around the presenting part as the fetus descends through the birth canal. In the passive lower segment, there is considerably less myometrial tone.

differentiated. The upper segment is firm during contractions, whereas the lower segment is softer, distended, and more passive. This mechanism is imperative because if the entire myometrium, including the lower uterine segment and cervix, were to contract simultaneously and with equal intensity, the net expulsive force would markedly decline. Thus, the upper segment contracts, retracts, and expels the fetus. In response to these contractions, the softened lower uterine segment and cervix dilate and thereby form a greatly expanded, thinned-out tube through which the fetus can pass.

The myometrium of the upper segment does not relax to its original length after contractions. Instead, it becomes relatively fixed at a shorter length. The upper active uterine segment contracts down on its diminishing contents, but myometrial tension remains constant. The net effect is to take up slack, thus maintaining the advantage gained in expulsion of the fetus. Concurrently, the uterine musculature is kept in firm contact with the uterine contents. As the consequence of retraction, each successive contraction commences where its predecessor left off. Thus, the upper part of the uterine cavity becomes slightly smaller with each successive contraction. Because of the successive shortening of the muscular fibers, the upper active segment becomes progressively thickened throughout first- and second-stage labor (see Fig. 21-11). This process continues and results in a tremendously thickened upper uterine segment immediately after delivery.

Clinically, it is important to understand that the phenomenon of upper segment retraction is contingent on a decrease in the volume of its contents. For this to happen, particularly early in labor when the entire uterus is virtually a closed sac with only minimal cervical dilation, the musculature of the lower segment must stretch. This permits a greater portion of the uterine contents to occupy the lower segment. The upper segment retracts only to the extent that the lower segment distends and the cervix dilates.

Relaxation of the lower uterine segment mirrors the same gradual progression of retraction. In the lower segment, successive lengthening of the fibers with labor is accompanied by thinning, normally to only a few millimeters in the thinnest part. With lower segment thinning and concomitant upper segment thickening, a boundary between the two is marked by a ridge on the inner uterine surface—the *physiological retraction ring*. When the thinning of the lower uterine segment is extreme, as in obstructed labor, the ring is prominent and forms a *pathological retraction ring*. This abnormal condition is also known as the *Bandl ring,* which is discussed further in Chapter 23 (p. 442).

Changes in Uterine Shape

Each contraction gradually elongates the ovoid uterine shape an estimated 5 to 10 cm and thereby narrows the horizontal diameter. This *fetal axis pressure* straightens the fetal vertebral column. It also presses the upper pole of the fetus firmly against the fundus, whereas the lower pole is thrust farther downward. With uterine lengthening, the longitudinal muscle fibers are drawn taut. As a result, the lower segment and cervix are the only parts of the uterus that are flexible, and these are pulled upward and around the lower pole of the fetus.

Ancillary Forces

After the cervix is dilated fully, the most important force in fetal expulsion is produced by maternal intraabdominal pressure. Contraction of the abdominal muscles simultaneously with forced respiratory efforts with the glottis closed is referred to as *pushing*. The force is similar to that with defecation, but the intensity usually is much greater. The importance of intraabdominal pressure is shown by the prolonged descent during labor in paraplegic women and in those with a dense epidural block.

Cervical Changes

As the result of contraction forces, two fundamental changes—effacement and dilation—occur in the ripened cervix. For an average-sized fetal head to pass through the cervix, it must completely or fully dilate to a diameter of approximately 10 cm. The fetus may not descend during cervical effacement. However, as the cervix dilates, the presenting fetal part typically does descend somewhat.

Cervical effacement is "obliteration" or "taking up" of the cervix. It is manifest clinically by shortening of the cervical canal from a length of approximately 3 cm to a mere circular orifice with almost paper-thin edges. The muscular fibers at the level of the internal cervical os are pulled upward, or "taken up," into the lower uterine segment. The condition of the external os remains temporarily unchanged (Fig. 21-13). Because of

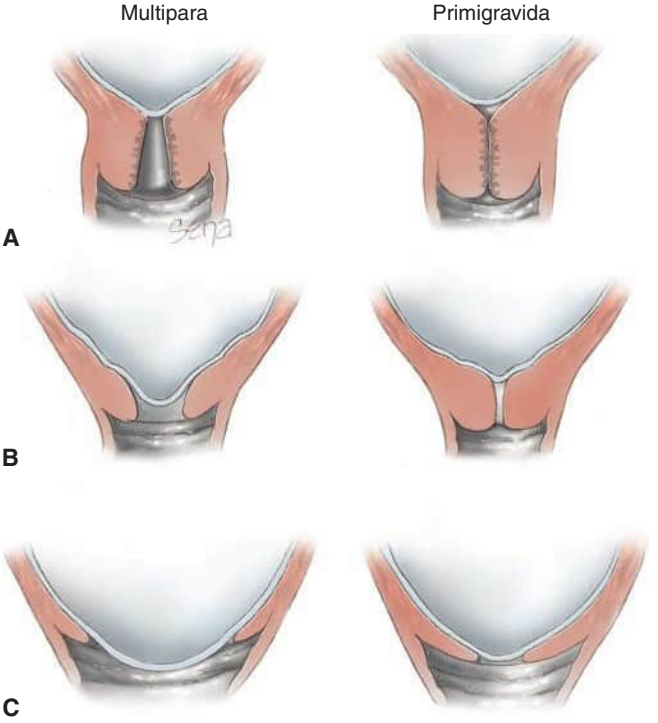

FIGURE 21-13 Schematic showing effacement and dilation. **A.** Before labor, the primigravid cervix is long and undilated in contrast to that of the multipara, which has dilation of the internal and external os. **B.** As effacement begins, the multiparous cervix shows more dilation and funneling of the internal os compared with the primigravid cervix. **C.** As complete effacement is achieved in the primigravid cervix, dilation is minimal. The reverse is true in the multipara.

growing myometrial activity during uterine preparedness for labor, appreciable effacement of a softened cervix sometimes is accomplished before active labor begins. Effacement causes expulsion of the mucous plug as the cervical canal is shortened.

Because the lower segment and cervix have less resistance during a contraction, a centrifugal pull is exerted on the cervix and creates *cervical dilation* (Fig. 21-14). As uterine contractions cause pressure on the membranes, the hydrostatic action of the amnionic sac in turn dilates the cervical canal like a wedge. The process of cervical effacement and dilation causes formation of the *forebag* of amnionic fluid. This is the leading portion of fluid and amnionic sac located in front of the presenting part. In the absence of intact membranes, the pressure of the presenting fetal part against the cervix and lower uterine segment is a similar wedge. Early rupture of the membranes does not retard cervical dilation so long as the presenting fetal part is positioned to exert pressure against the cervix and lower segment.

Referring back to Figure 21-4, recall that cervical dilation is divided into latent and active phases. The duration of the latent phase is more variable and sensitive to extraneous factors. For example, sedation may prolong the latent phase, and myometrial stimulation shortens it. The latent phase duration has little bearing on the subsequent course of labor, whereas the characteristics of the active phase are usually predictive of labor outcome. Normal and abnormal labor curves are fully described in Chapters 22 and 23.

Second Stage: Fetal Descent

In many nulliparas, engagement of the head is accomplished before labor begins. That said, the head may not descend further until late in labor. In the descent pattern of normal labor, a typical hyperbolic curve is formed when the station of the fetal head is plotted as a function of labor duration (see Fig. 21-4). *Station* describes descent of the fetal biparietal diameter in relation to a line drawn between maternal ischial spines (Chap. 22, p. 427). Active descent usually takes place after dilation has progressed for some time. During second-stage labor, the speed of descent is maximal and is maintained until the presenting part reaches the perineal floor (Friedman, 1978). In nulliparas, the presenting part typically descends slowly and steadily. In multiparas, however, descent may be rapid.

Pelvic Floor Changes

The birth canal is supported and functionally closed by the pelvic floor (Chap. 2, p. 19). The most important component of the floor is the levator ani muscle and the fibromuscular connective tissue that covers its upper and lower surfaces. The biomechanical properties of these structures and of the vaginal wall change markedly during parturition. These result from altered ECM structure or composition (Alperin, 2015; Lowder, 2007; Rahn, 2008).

In the first stage of labor, the membranes, when intact, and the fetal presenting part serve to dilate the upper vagina. The most marked change consists of stretching levator ani muscle fibers. This is accompanied by thinning of the central portion

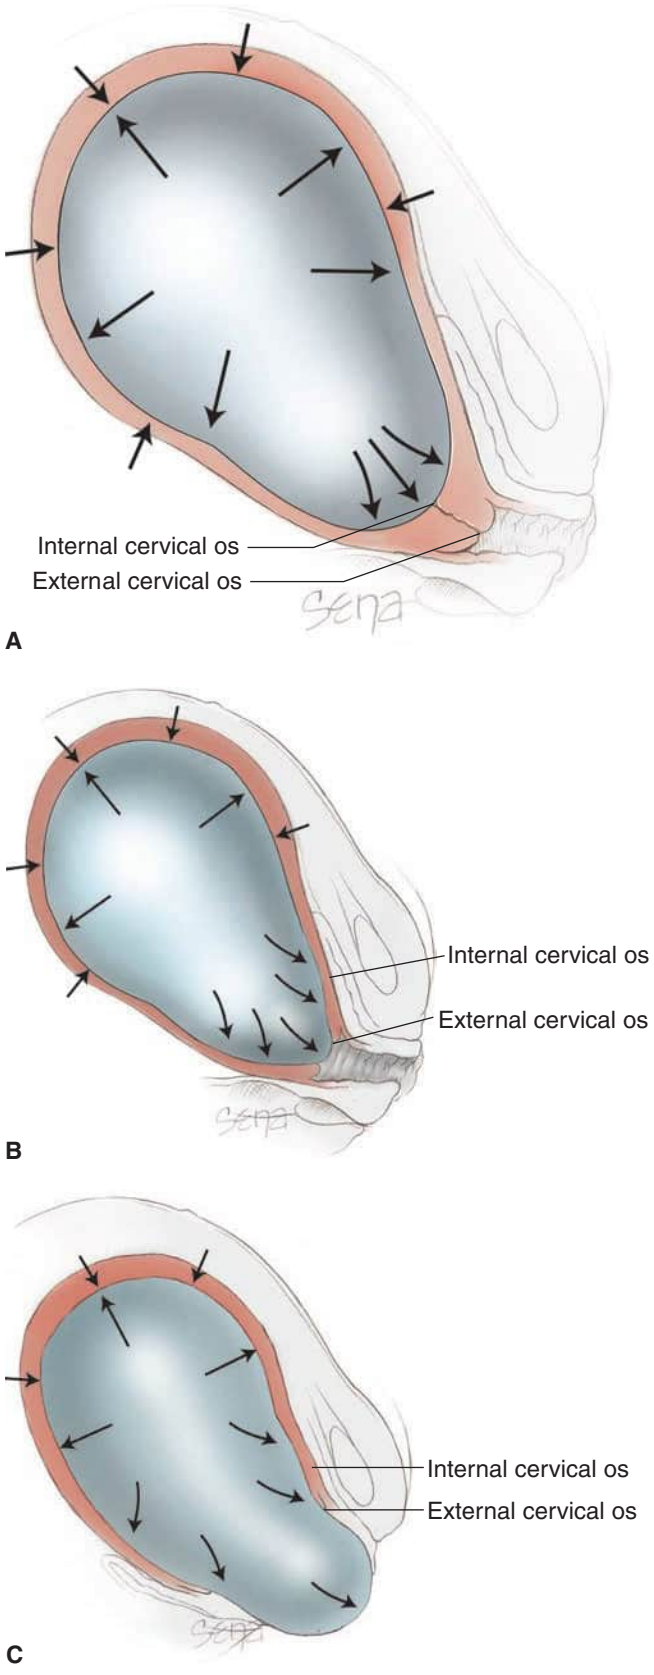

FIGURE 21-14 Hydrostatic action of membranes in effecting cervical effacement and dilation. With labor progression, note the changing relations of the internal and external os in **(A)**, **(B)**, and **(C)**. Although not shown in this diagram, with membrane rupture, the presenting part, applied to the cervix and the forming lower uterine segment, acts similarly.

of the perineum, which becomes transformed from a wedge-shaped, 5-cm-thick tissue mass to a thin, almost transparent membranous structure less than 1 cm thick. When the perineum is distended maximally, the anus becomes markedly dilated and presents an opening that varies from 2 to 3 cm in diameter and through which the anterior wall of the rectum bulges.

Third Stage: Delivery of Placenta and Membranes

This stage begins immediately after fetal delivery and involves separation and expulsion of the placenta and membranes. Normally, by the time the newborn is delivered, the uterine cavity is nearly obliterated and is an almost solid mass of muscle, several centimeters thick, above the thinner lower segment. The uterine fundus now lies just below the level of the umbilicus.

This sudden diminution in uterine size is inevitably accompanied by a decrease in the area of the placental implantation site (Fig. 21-15). For the placenta to accommodate itself to this reduced area, it thickens, but because of limited placental elasticity, it buckles. The resulting tension pulls the weakest layer—decidua spongiosa—from that site. Thus, placental separation follows the disproportion created between the relatively unchanged placental size and the reduced implantation site size.

Cleavage of the placenta is aided greatly by the loose structure of the spongy decidua. As detachment proceeds, a hematoma forms between the separating placenta and the adjacent decidua, which remains attached to the myometrium. The hematoma is usually the result rather than the cause of the separation, because in some cases bleeding is negligible.

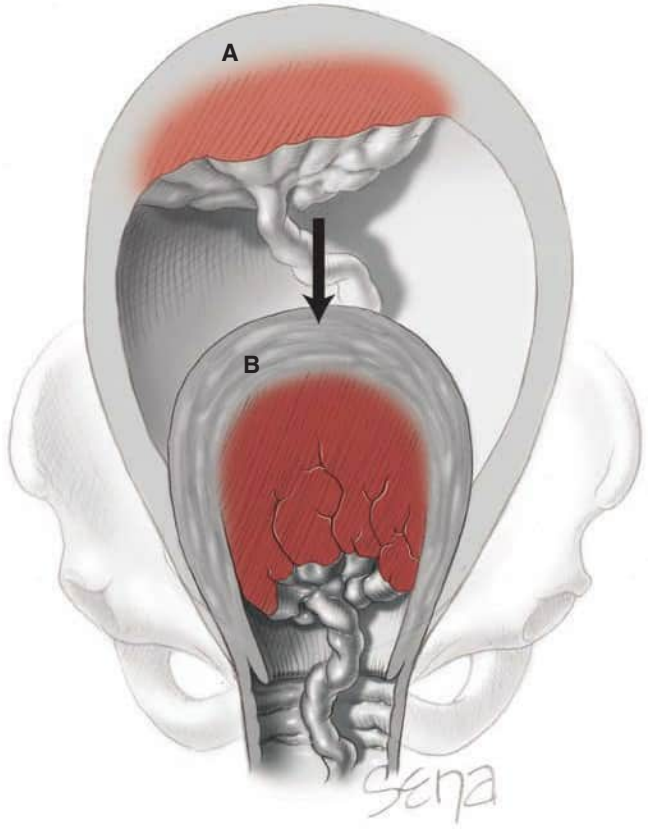

FIGURE 21-15 Diminution in size of the placental site after birth of the newborn. **A.** Spatial relations before birth. **B.** Placental spatial relations after birth.

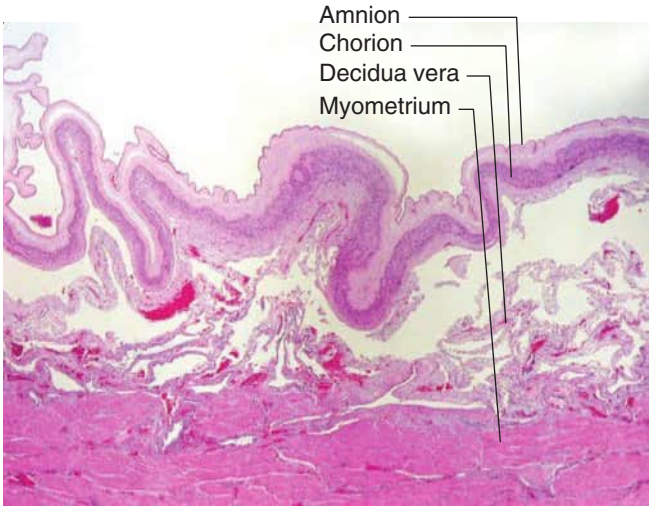

FIGURE 21-16 Postpartum, membranes are thrown up into folds as the uterine cavity decreases in size. (Reproduced with permission from Dr. Kelley S. Carrick.)

The great decline in uterine cavity surface area simultaneously throws the fetal membranes—the amniochorion and the parietal decidua—into innumerable folds (Fig. 21-16). Membranes usually remain in situ until placental separation is nearly completed. These are then peeled off the uterine wall, partly by further contraction of the myometrium and partly by traction that is exerted by the separated placenta as it descends during expulsion.

After the placenta has detached, it can be expelled by increased abdominal pressure. Completion of the third stage is also accomplished by alternately compressing and elevating the fundus, while exerting minimal traction on the umbilical cord. The retroplacental hematoma either follows the placenta or is found within the inverted sac formed by the membranes. In this process, known as the *Schultze mechanism* of placental expulsion, blood from the placental site pours into the membrane sac and does not escape externally until after extrusion of the placenta. In the other form of placental extrusion, known as the *Duncan mechanism*, the placenta separates first at the periphery and blood collects between the membranes and the uterine wall and escapes from the vagina. In this circumstance, the placenta descends sideways, and its maternal surface appears first.

UTEROTONINS IN PARTURITION PHASE 3

Oxytocin

This nanopeptide is synthesized in the magnocellular neurons of the supraoptic and paraventricular neurons. The prohormone is transported with its carrier protein, neurophysin, along the axons to the neural lobe of the posterior pituitary gland in membrane-bound vesicles for storage and later release. The prohormone is converted enzymatically to oxytocin during transport (Gainer, 1988; Leake, 1990).

Oxytocin—literally, *quick birth*—was the first uterotonin to be implicated in parturition initiation. Support for this role includes: (1) oxytocin receptor numbers strikingly rising in myometrial and decidual tissues near the end of gestation; (2) oxytocin acting on decidual tissue to promote prostaglandin release; and (3) oxytocin synthesis directly in decidual and extraembryonic fetal tissues and in the placenta (Chibbar, 1993; Zingg, 1995). Moreover, abundant data support oxytocin's important role during second-stage labor and in the puerperium, which is phase 4 of parturition. Specifically, maternal serum oxytocin levels are elevated: (1) during second-stage labor, which is the end of phase 3 of parturition; (2) in the early puerperium; and (3) during breastfeeding (Nissen, 1995). Immediately after delivery of the fetus and placenta, which completes parturition phase 3, firm and persistent uterine contractions induced by oxytocin are essential to prevent postpartum hemorrhage.

Prostaglandins

Prostaglandins play a critical role in phase 3 of parturition (MacDonald, 1993). First, levels of prostaglandins—or their metabolites—in amnionic fluid, maternal plasma, and maternal urine are increased during labor. Second, receptors for PGE_2 and $PGF_{2\alpha}$ are expressed in the uterus and cervix. Thus, if these tissues are exposed to prostaglandins, they will respond. Third, treatment of pregnant women with prostaglandins, by any of several administration routes, causes abortion or labor at all gestational ages. Moreover, administration of prostaglandin H synthase type 2 inhibitors to pregnant women will delay spontaneous labor onset and sometimes arrest preterm labor (Loudon, 2003).

During labor, prostaglandin production within the myometrium and decidua is an efficient mechanism of activating contractions. For example, prostaglandin synthesis is high and unchanging in the decidua during phase 2 and 3 of parturition. Moreover, the receptor level for $PGF_{2\alpha}$ is augmented in the decidua at term, and this increase most likely is the regulatory step in prostaglandin action in the uterus.

The fetal membranes and placenta also produce prostaglandins. Primarily PGE_2, but also $PGF_{2\alpha}$, are detected in amnionic fluid at all gestational ages. As the fetus grows, prostaglandin levels in the amnionic fluid rise gradually. Their greatest elevation in concentration within amnionic fluid, however, is demonstrable after labor begins. These higher levels likely result as the cervix dilates and exposes decidual tissue (Fig. 21-17). These higher levels in the forebag, compared with those in the upper compartment, are believed to follow an inflammatory response that signals the events leading to active labor. Together, the rise in cytokine and prostaglandin concentrations further degrade the ECM, thus weakening fetal membranes.

Endothelin 1

The endothelins are a family of 21-amino-acid peptides that powerfully induce myometrial contraction (Word, 1990). The endothelin A receptor is preferentially expressed in smooth muscle, and when activated, it effects a rise in intracellular calcium.

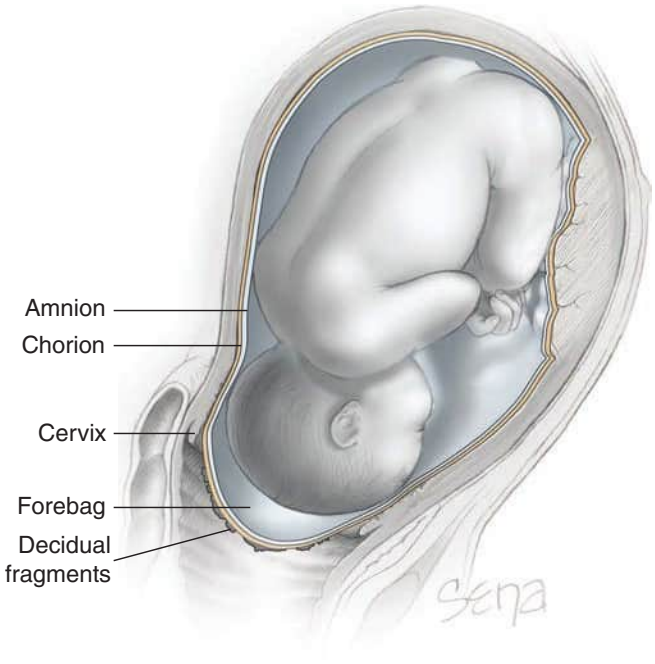

FIGURE 21-17 Sagittal view of the exposed forebag and attached decidual fragments after cervical dilation during labor. (Redrawn from MacDonald PC, Casey ML: Preterm birth. Sci Am 3:42, 1996.)

Endothelin 1 is produced in myometrium of term gestations and is able to induce synthesis of other contractile factors such as prostaglandins and inflammatory mediators (Momohara, 2004; Sutcliffe, 2009). The requirement of endothelin 1 in normal parturition physiology remains to be established.

Angiotensin II

Modulation of uteroplacental blood flow is regulated by angiotensin II, a potent vasoconstrictor. Although, in pregnancy, circulating levels of angiotensin II are increased, vascular resistance is reduced and vasodilation is enhanced. Two angiotensin II receptors are expressed in the uterus—AT_1R and AT_2R. In nonpregnant women, the AT_1R receptor predominates, but the AT_2R receptor is preferentially expressed in gravidas (Cox, 1993). During normotensive pregnancy, AT_2R-mediated effects on vascular smooth muscle lead to vasodilation, which contributes to the pregnancy-associated rise in uterine arterial blood flow. Decreased AT_2R expression is associated with preeclamptic pregnancies (Mishra, 2018; Rosenfeld, 2012) (Chap. 4, p. 65).

PHASE 4: THE PUERPERIUM

Immediately and for about an hour after delivery, the myometrium remains persistently contracted. This directly compresses large uterine vessels and allows thrombosis of their lumens to prevent hemorrhage. This is typically augmented by endogenous and pharmacological uterotonic agents (Chap. 27, p. 507).

Uterine involution and cervical repair are prompt remodeling processes that restore these organs to the nonpregnant state. These protect the reproductive tract from invasion by commensal microorganisms and restore endometrial responsiveness to normal hormonal cyclicity.

During the early puerperium, lactogenesis and milk let-down begin in mammary glands (Chap. 36, p. 639). Reinstitution of ovulation signals preparation for the next pregnancy. Ovulation generally occurs within 4 to 6 weeks after birth. However, it is dependent on the duration of breastfeeding and lactation-induced, prolactin-mediated anovulation and amenorrhea.

CHAPTER 22

Normal Labor

Labor is the process that leads to childbirth. It begins with the onset of regular uterine contractions and ends with delivery of the newborn and expulsion of the placenta. Pregnancy and birth are physiological processes. Thus, labor and delivery should be considered normal for most women.

FETAL ORIENTATION

Fetal Lie

Fetal position within the birth canal is critical to labor progress and to the delivery route. It should be determined in early labor, and sonography can be implemented for unclear cases. Important relationships include fetal lie, presentation, attitude, and position.

Of these, *fetal lie* describes the relationship of the fetal long axis to that of the mother. In more than 99 percent of labors at term, the fetal lie is *longitudinal*. A *transverse lie* is less frequent. Occasionally, the fetal and maternal axes may cross at a 45-degree angle to form an *oblique lie*. This is unstable and becomes longitudinal or transverse during labor.

Fetal Presentation

The *presenting part* is the portion of the fetal body either within or in closest proximity to the birth canal. It usually can be felt through the cervix on vaginal examination. In longitudinal lies, the presenting part is either the fetal head or the breech, creating cephalic and breech presentations, respectively. When the fetus lies with the long axis transversely, the shoulder is considered the presenting part.

Cephalic presentations are subclassified according to the relationship between the head and body of the fetus (Fig. 22-1). Ordinarily, the head is flexed sharply so that the chin contacts the thorax. The occipital fontanel is the presenting part, and this presentation is referred to as a *vertex* or *occiput presentation*. Much less often, the fetal neck may be sharply extended so that the occiput and back come into contact, and the face is foremost in the birth canal—*face presentation*. The fetal head may assume a position between these extremes. When the neck is only partly flexed, the anterior (large) fontanel may present—*sinciput presentation*. When the neck is only partially extended, the brow may emerge—*brow presentation*. These latter two are usually transient. As labor progresses, sinciput and brow presentations almost always convert into occiput or face presentations by neck flexion or extension, respectively. If not, dystocia can develop (Chap. 23, p. 441).

The fetus at term usually presents occiput rather than breech. Although the fetal head at term is slightly larger than the breech, the entire *podalic pole* of the fetus—that is, the breech and extremities—is bulkier and more mobile than the cephalic pole. The *cephalic pole* is composed of the fetal head only. Logically, the fetus orients its polarity to make use of the roomier fundus for its bulkier and more mobile podalic pole. The breech presentation rate drops with gestational age, but 2

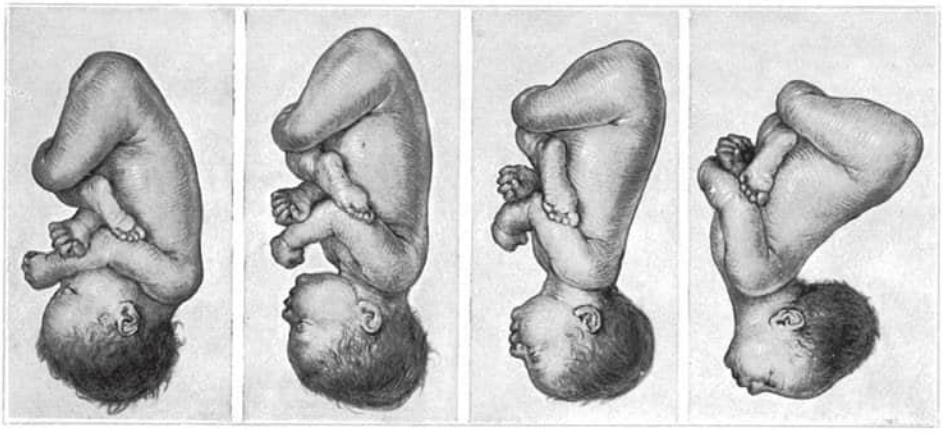

FIGURE 22-1 Longitudinal lie, cephalic presentation. Differences in attitude of the fetal body in **(A)** occiput, **(B)** sinciput, **(C)** brow, and **(D)** face presentations. Note changes in fetal attitude as the fetal head becomes less flexed.

to 3 percent of singletons are breech at delivery (Bin, 2016; Toijonen, 2020). The three general breech configurations are *frank*, *complete*, and *footling presentations*. Management of the breech presenting fetus and of those with transverse lie is found in Chapters 28 and 23, respectively.

Fetal Attitude

In the later months of pregnancy, the fetus assumes a characteristic posture described as attitude or habitus. As a rule, the fetus forms an ovoid mass that corresponds roughly to the shape of the uterine cavity (see Fig. 22-1A). The fetus becomes folded upon itself to create a convex back. The head is sharply flexed, the chin nearly contacts with the chest, the thighs are flexed over the abdomen, and the legs bend at the knee. In cephalic presentations, the arms usually lie across the thorax or parallel to the sides. The umbilical cord fills the space between the extremities. This posture results from fetal growth and accommodation to the uterine cavity.

Exceptions form as the fetal head becomes progressively more extended from occiput to face presentations. This results in a progressive change in fetal attitude from a convex (flexed) to a concave (extended) contour of the vertebral column. This progression is seen in Figure 22-1, panels B through D.

Fetal Position

Position refers to the relationship of a defined portion of the fetal presenting part to either the right or left side of the birth canal. The fetal occiput, chin (mentum), and sacrum are the defined landmarks in occiput, face, and breech presentations, respectively. Because the defined presenting part may be on either the mother's left or right side, possible designations are left and right occipital (LO and RO), left and right mental (LM and RM), and left and right sacral (LS and RS). Further, the relationship of the defined landmark to the anterior (A), transverse (T), or posterior (P) portion of the maternal pelvis is considered (Fig. 22-2).

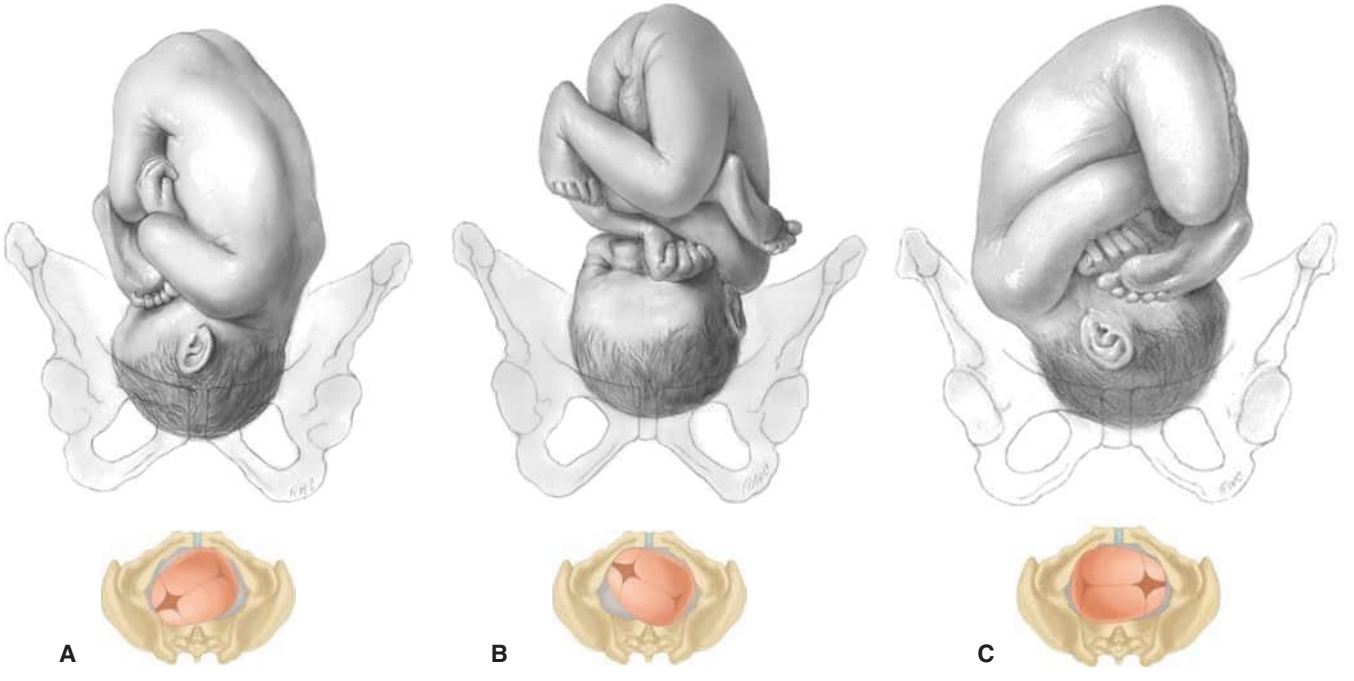

FIGURE 22-2 Longitudinal lie, occiput presentation. **A.** Left occiput anterior (LOA) position. **B.** Left occiput posterior (LOP) position. **C.** Right occiput transverse (ROT) position.

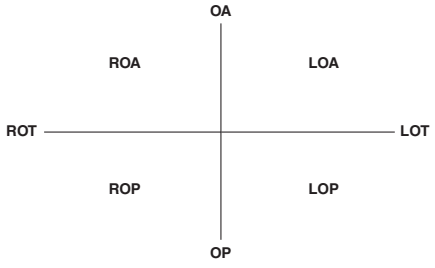
Thus, in an occiput presentation, the presentation and position may be abbreviated in clockwise fashion as shown.



In shoulder presentations, the acromion process of the scapula is the portion of the fetus arbitrarily chosen for its orientation to the mother's right or left side. In addition, the back may be directed anteriorly or posteriorly and also superiorly or inferiorly. Thus, it is customary to further distinguish right or left varieties as dorsoanterior and dorsoposterior (Fig. 23-7, p. 442). Another term used is *transverse lie*, with *back up* or *back down*, which is clinically important when deciding incision type for cesarean delivery.

Diagnosis

To diagnose fetal presentation and position, Leopold maneuvers, vaginal examination, and sonography are primary tools. First, abdominal examination can be conducted systematically employing the four maneuvers described by Leopold in 1894 (Fig. 22-3). The mother lies supine and comfortably positioned with her abdomen bared. Leopold maneuvers can be performed throughout the latter months of pregnancy and during and between the contractions of labor. These may be difficult if not impossible to perform and interpret if the patient is obese, if amnionic fluid volume is excessive, or if the placenta is anteriorly implanted.

The first maneuver assesses the uterine fundus. It permits identification of fetal lie and presentation. The breech feels large and nodular, whereas the head is large, hard, and round.

The second maneuver can help define the presenting part's position. Palms are placed on either side of the maternal abdomen, and gentle but deep pressure is exerted. On one side, a hard, resistant structure is felt—the back. On the other, numerous small, irregular, mobile parts are felt—the fetal extremities. These may move in response to palpation. The back indicates the side on which the occiput lies. In occiput anterior positions, the convex back is felt. In occiput posterior positions, nodular extremity parts are appreciated.

The third maneuver aids confirmation of fetal presentation. The thumb and fingers of one hand grasp the lower portion of the maternal abdomen just above the symphysis pubis. If the presenting part is not engaged, a movable mass will be felt, usually the head. The differentiation between head and breech is made as in the first maneuver.

The fourth maneuver helps determine the degree of descent. The examiner faces the mother's feet, and the fingertips of both hands are positioned on either side of the presenting part. They exert inward pressure and then slide caudad along the axis of the pelvic inlet. In many instances, when the head has descended into the pelvis, the anterior shoulder or the space created by the neck may be differentiated readily from the hard head.

At least in the past, experienced clinicians have accurately identified fetal malpresentation using Leopold maneuvers with a high sensitivity—88 percent, specificity—94 percent, positive predictive value—74 percent, and negative predictive value—97 percent (Lydon-Rochelle, 1993). With experience, it is possible to estimate the size of the fetus with these maneuvers (Field, 1995). However, and especially with an obese woman, estimates by palpation and actual birth weights often correlate poorly (Fox, 2009; Preyer, 2019).

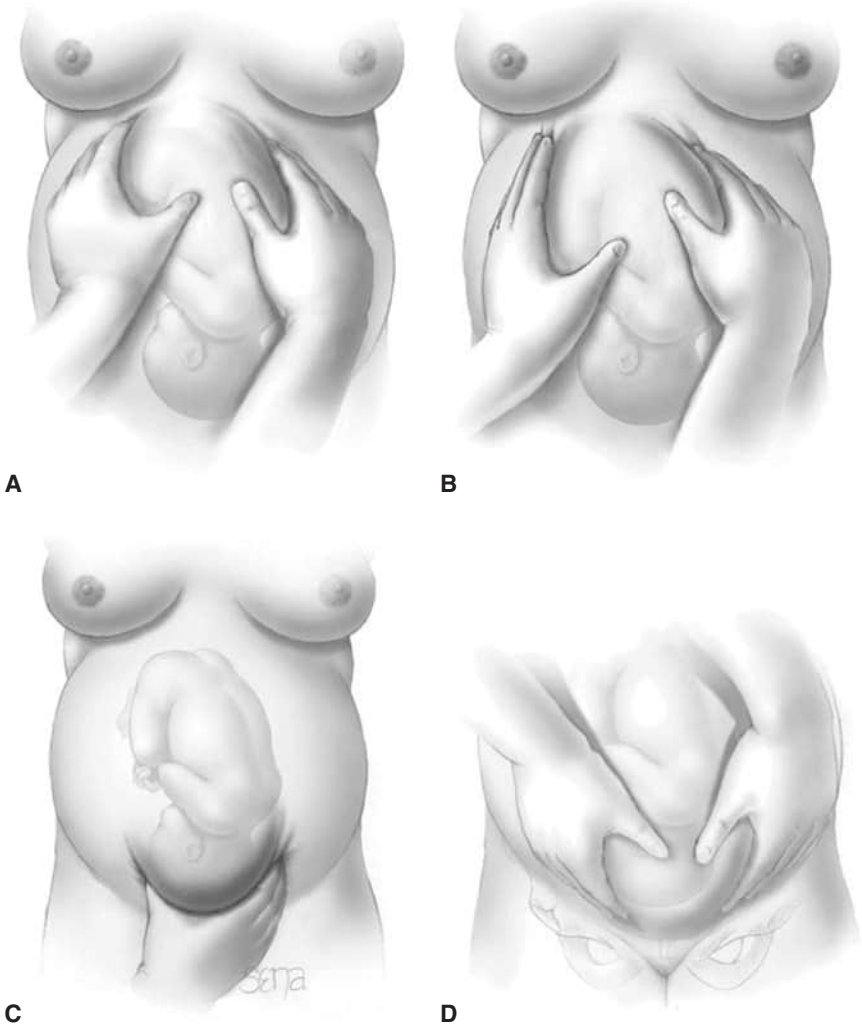


FIGURE 22-3 Leopold maneuvers **(A-D)** performed in fetus with a longitudinal lie and left occiput anterior (LOA) position.

Vaginal examination complements Leopold maneuvers. Before labor, the diagnosis of fetal presentation and position by vaginal examination is challenging because the presenting part must be palpated through a closed cervix and lower uterine segment. However, with labor and cervical dilation, cephalic presentations and their positions are recognized by palpation of the various fetal sutures and fontanels (Fig. 29-1, p. 534). Palpation of facial features signals a face presentation, whereas digital delineation of the fetal sacrum and perineum suggests breech presentation. With a transverse lie, ribs, scapula, or clavicle may be identified. Sonography is used to confirm suspected abnormal fetal presentation or lie.

Sonography can also help clarify fetal position. For the occiput presenting fetus, a transducer is placed transversely on the lower maternal abdomen and moved toward the symphysis. In a fetus positioned occiput anterior, its spine is identified anteriorly and followed to its union with its occiput. The angle between the two is wide and increases as the head flexes and descends into the maternal pelvis. In occiput posterior positions, fetal orbits and nasal bridge lie anteriorly (Bellussi, 2017). Compared with digital interrogation, sonography for fetal head position determination during second-stage labor is more accurate (Ramphul, 2014; Wiafe, 2016).

MECHANISMS OF LABOR

Positional changes of the presenting part are needed for the fetus to navigate through the pelvic canal. Called the mechanisms of labor or *cardinal movements of labor*, these are engagement, descent, flexion, internal rotation, extension, external rotation, and expulsion. During labor, these movements show great temporal overlap. For example, as part of engagement, the head both flexes and descends (Fig. 22-4). Concurrently, uterine contractions effect important modifications in fetal attitude, especially after the head has descended into the pelvis. These changes consist mainly of fetal straightening, loss of dorsal convexity, and closer application of the extremities to the body. As a result, the fetal ovoid is transformed into a cylinder, with the smallest possible cross section typically passing through the birth canal.

Engagement

In an occiput presentation, passage of the biparietal diameter through the pelvic inlet defines *engagement*. The fetal head may engage during the last few weeks of pregnancy or not until after labor commences. In many multiparas and some nulliparas, the fetal head is freely movable above the pelvic inlet at labor onset and is often referred to as "floating." In one study of 5341 nulliparas, lack of fetal head engagement before labor onset did not affect vaginal delivery rates in either spontaneous or induced labor (Segel, 2012).

In most cases, the vertex enters the pelvis with the sagittal suture lying in the transverse pelvic diameter. Left occiput transverse (LOT) position is slightly more common than right occiput transverse (ROT) position (Caldwell, 1934). However, the sagittal suture may not lie exactly midway between the symphysis and the sacral promontory. The sagittal suture frequently is deflected off the midline, either posteriorly toward the promontory or anteriorly toward the symphysis (Fig. 22-5). Such lateral deflection to a more anterior or posterior position in the pelvis is called *asynclitism*. If the sagittal suture approaches the sacral promontory, more of the anterior parietal bone presents itself to the examining fingers, and the condition is called *anterior asynclitism*. If, however, the sagittal suture lies close to the symphysis, more of the posterior parietal bone will present, and the condition is called *posterior asynclitism*. With extreme asynclitism, an ear may be palpable.

Moderate degrees of asynclitism are the rule in normal labor. Successive fetal head shifting from posterior to anterior asynclitism aids descent. However, if severe, the condition is a common reason for cephalopelvic disproportion even with an otherwise normal-sized pelvis.

Descent

This movement is the first requisite for vaginal birth. In nulliparas, engagement may take place before labor onset, and further descent may not follow until second-stage labor. In multiparas, descent usually begins with engagement. Descent stems from one or more of three forces: (1) direct myometrial pressure of the fundus upon the breech with contractions, (2) bearing-down efforts of maternal abdominal muscles, and (3) extension and straightening of the fetal body.

Flexion

As soon as the descending head meets resistance, whether from the cervix, pelvic walls, or pelvic floor, it normally flexes. With this movement, the chin draws closer to the fetal thorax, and the appreciably shorter suboccipitobregmatic diameter replaces the longer occipitofrontal diameter (Fig. 29-1, p. 534). This is an essential requisite for descent because it allows the smallest head diameter to progress.

Internal Rotation

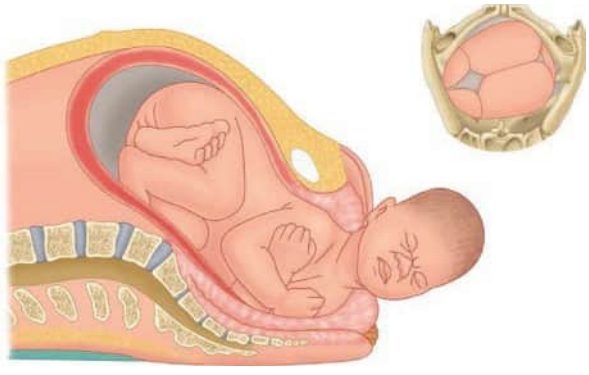
This movement turns the occiput gradually away from the transverse axis. Usually the occiput rotates anteriorly toward the symphysis pubis. LOT positions transition to left occiput anterior (LOA) positions (Fig. 22-6). ROT positions rotate to right occiput anterior (ROA) positions. Less commonly, the head may rotate posteriorly toward the hollow of the sacrum to generate occiput posterior positions. Internal rotation is essential for completion of labor, except when the fetus is unusually small.

Calkins (1939) studied more than 5000 women in labor to ascertain the time of internal rotation. He concluded that in approximately two thirds, internal rotation is completed by the time the head reaches the pelvic floor; in about another fourth, internal rotation is completed shortly after the head reaches the pelvic floor; and in the remaining 5 percent, rotation does not take place. When the head fails to turn until reaching the pelvic floor, it typically rotates during the next one or two contractions

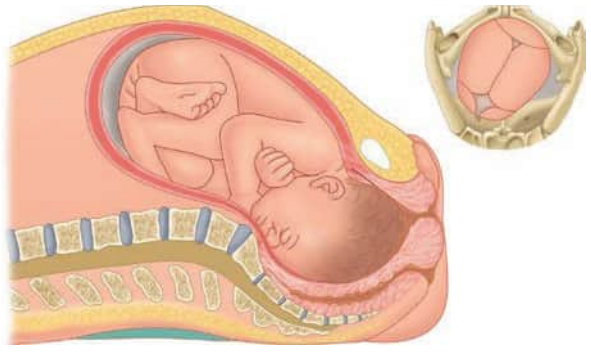
1. Head floating, before engagement

5. Complete extension

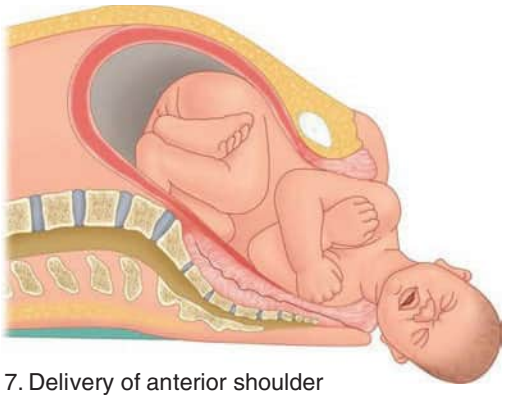
2. Engagement, descent, flexion



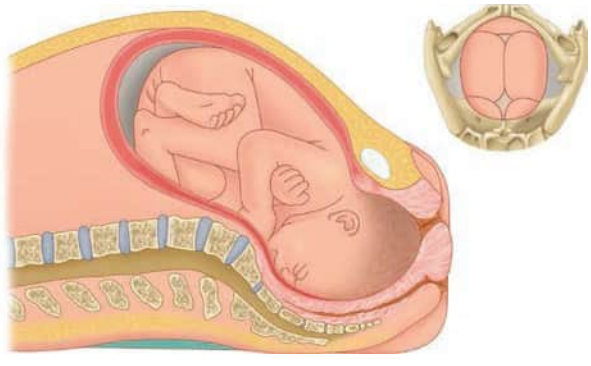
6. Restitution (external rotation)



3. Further descent, internal rotation



7. Delivery of anterior shoulder



4. Complete rotation, beginning extension

8. Delivery of posterior shoulder

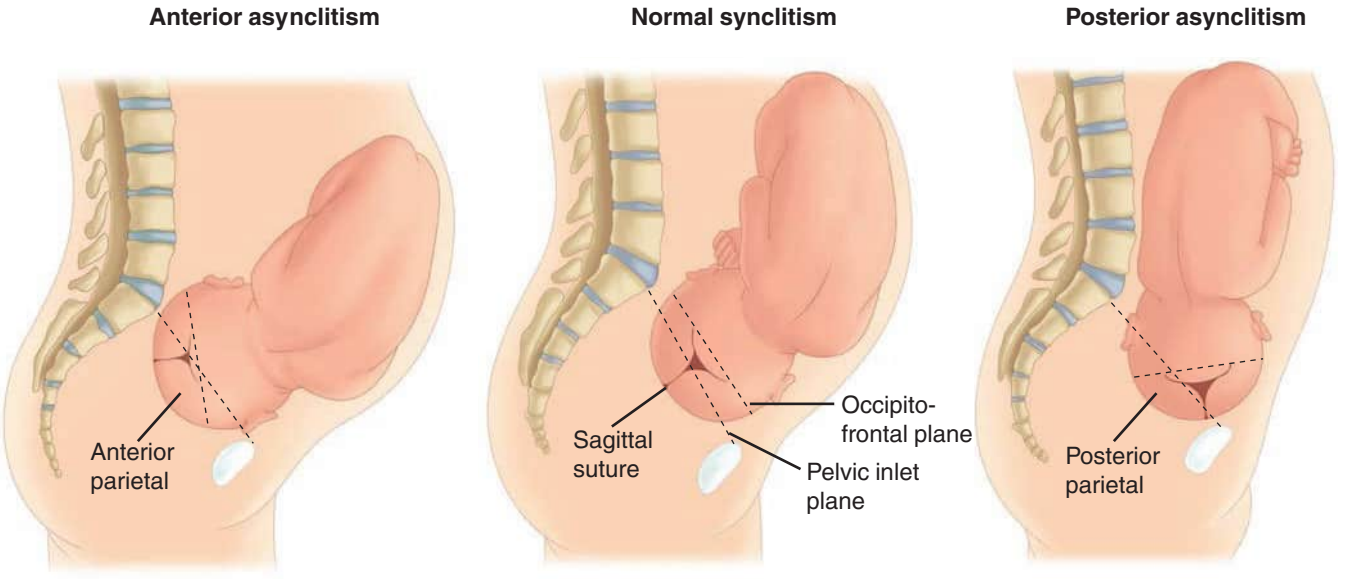

FIGURE 22-5 Synclitism and asynclitism.

in multiparas. In nulliparas, rotation usually occurs during the next three to five contractions.

Extension

After internal rotation, the sharply flexed head reaches the vulva and undergoes extension. If the sharply flexed head, on reaching the pelvic floor, did not extend but was driven farther downward, it would impinge on the posterior portion of the perineum and would eventually be forced through the perineal tissues. When the head presses on the pelvic floor, however, two forces come into play. The first force, exerted by the uterus, acts more posteriorly, and the second, supplied by the resistant pelvic floor and the symphysis, acts more anteriorly. The resultant vector is in the

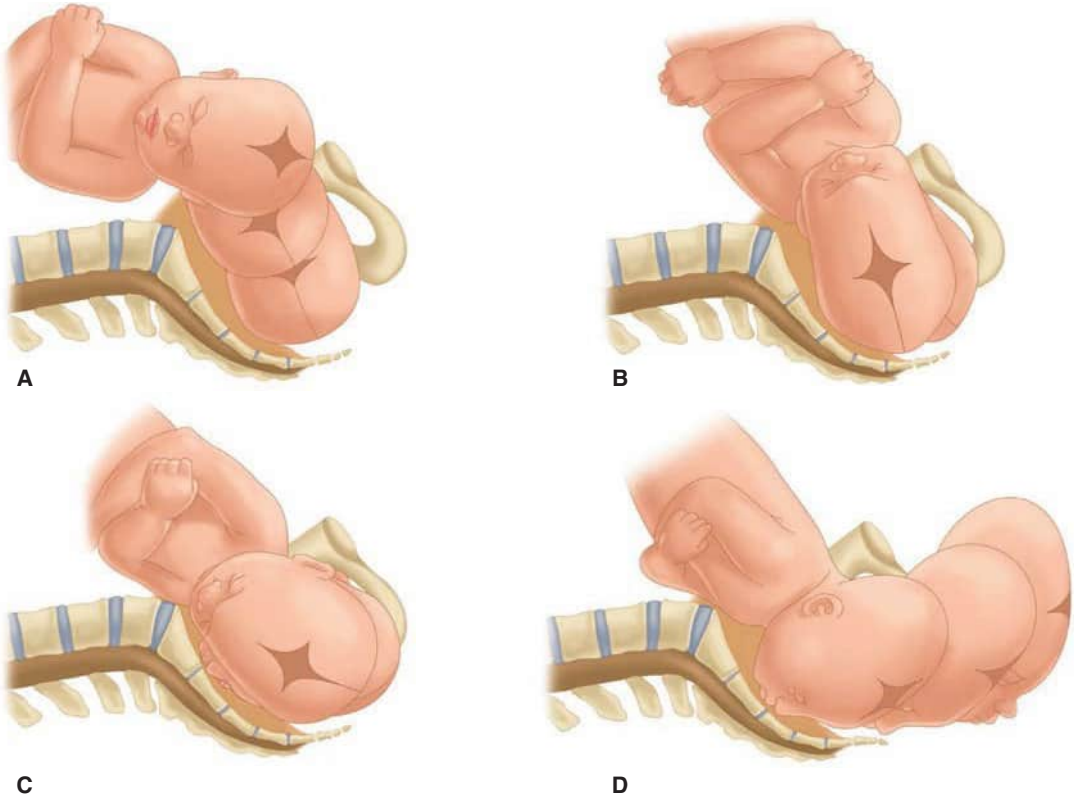

FIGURE 22-6 Mechanisms of labor for the left occiput transverse position, lateral view. **A.** Engagement with posterior asynclitism at the pelvic brim. During descent, the sagittal suture is then deflected toward the sacrum. **B.**This leads to anterior asynclitism. This corrects during additional descent **C.** Internal rotation moves the occiput toward the symphysis. Farther simultaneous descent. **D.** Additional descent with extension of the neck.

direction of the vulvar opening, thereby causing head extension. This brings the base of the occiput into direct contact with the inferior margin of the symphysis pubis (see Fig. 22-6).

With progressive distention of the perineum and vaginal opening, an increasingly large portion of the occiput gradually appears. The head is born as the occiput, anterior fontanel, brow, nose, mouth, and chin pass successively over the perineal body. Immediately after its delivery, the head drops so that the chin lies over the maternal anus.

External Rotation

The delivered head next undergoes *restitution* (see Fig. 22-4). If the occiput was originally directed toward the maternal left, it rotates toward the mother's left ischial tuberosity. If it was originally directed toward the right, the occiput rotates to the right. With restitution, the head reaches a transverse position. The fetal body aligns its bisacromial diameter, which is the distance across the shoulders, with the anteroposterior diameter of the pelvic outlet. Thus, one shoulder is anterior behind the symphysis and the other is posterior.

Expulsion

Almost immediately after external rotation, the anterior shoulder appears under the symphysis pubis, and the perineum soon becomes distended by the posterior shoulder. After delivery of the shoulders, the rest of the body quickly passes. If the anterior shoulder tightly wedges behind the symphysis, *shoulder dystocia* is diagnosed and is described in Chapter 27 (p. 501).

Occiput Posterior Position

In approximately 20 percent of labors, the fetus enters the pelvis in an *occiput posterior (OP)* position (Caldwell, 1934). It appears likely from radiographic evidence that posterior positions are more often associated with a narrow forepelvis (Gardberg, 1994a). Effective contractions, adequate head flexion, and average fetal size together permit most posteriorly positioned occiputs to rotate anteriorly toward the symphysis promptly as soon as they reach the pelvic floor. In perhaps 5 to 10 percent of cases, however, rotation may be incomplete or may not take place at all, especially if the fetus is large (Gardberg, 1994b). Poor contractions, faulty head flexion, or epidural analgesia, which diminishes maternal muscular pushing and relaxes pelvic floor muscles, may predispose to incomplete rotation. If rotation is incomplete, *transverse arrest* may result. If no rotation toward the symphysis proceeds, the occiput may remain in the direct OP position, a condition known as *persistent occiput posterior*. Both can lead to dystocia and cesarean delivery. Risk factors and labor management of a persistent OP position are found in Chapter 27 (p. 500). Techniques to manually rotate from OP to OA positions are illustrated in Chapter 29 (p. 540).

Fetal Head Shape Changes

In occiput presentations, labor forces alter fetal head shape. In prolonged labors before complete cervical dilation, the portion of the fetal scalp immediately over the cervical os becomes edematous. This swelling is called *caput succedaneum*. It usually attains a thickness of only a few millimeters, but in prolonged labors it may be sufficiently extensive to prevent differentiation of the various sutures and fontanels. More commonly, the caput is formed when the head is in the lower portion of the birth canal and frequently only after the resistance of a rigid vaginal outlet is encountered. Because it develops over the most dependent area of the head, one may deduce the original fetal head position. In cases of marked asynclitism and dystocia, the caput succedaneum may form far from the sagittal midline (Fig. 22-7).

Molding refers to changes in the bony fetal head shape as a result of external compressive forces (see Fig. 22-7B). Possibly related to Braxton Hicks contractions, some molding develops before labor. Despite these shape changes, most studies indicate that the parietal bones seldom overlap. A "locking" mechanism

FIGURE 22-7 Fetal head molding and caput succedaneum formation. **A.** This newborn was delivered by cesarean for failure to progress and active labor arrest. The obvious caput succedaneum, which developed far from and to the left of the sagittal midline (*arrow*), reflects marked asynclitism during labor. **B.** This neonate after vaginal birth shows significant caput succedaneum and elongated molding.

at the coronal and lambdoidal sutures actually prevents such overlapping (Carlan, 1991).

Molding yields a shortened suboccipitobregmatic diameter. Of greatest importance in women with contracted pelves or asynclitism, the degree to which the head can mold may determine the difference between vaginal and cesarean birth.

Some older literature implicated severe head molding as a cause for possible cerebral trauma. Because of the many associated factors, for example, prolonged labor with fetal sepsis and acidosis, it is impossible to link molding to any alleged fetal or neonatal neurological sequelae. Most molding resolves within the week following delivery, although persistent cases have been described (Graham, 2006). Differentiation of molding, caput succedaneum, and cephalohematoma is discussed in Chapter 33 (p. 608).

NORMAL LABOR CHARACTERISTICS

The greatest impediment to understanding normal labor is recognizing its start. The strict definition describes uterine contractions that bring about demonstrable cervical effacement and dilation. Pinpointing when labor actually begins, however, is challenging because determination is retrospective. Several methods are used to mark its start. Despite these, a recent systematic review of labor definitions emphasizes the lack of consensus regarding definitions of labor onset (Hanley, 2016).

One method defines onset as the clock time when painful contractions become regular. However, uterine activity that causes discomfort but that does not represent true labor may develop at any time during pregnancy. False labor eventually wanes spontaneously, whereas the contractions of true labor typically progress to an effective, regular pattern.

A second method defines the onset of labor as beginning at the time of admission to a labor unit. In the United States, admission for labor is frequently based on the extent of cervical dilation accompanied by painful contractions. If a woman has intact membranes, a cervical dilation of 3 to 4 cm or greater and frequent painful contractions are reasonably reliable diagnostic criteria.

First Stage of Labor

For labor progression, Friedman (1954) described a characteristic sigmoid pattern by graphing cervical dilation against time. With Friedman's concept, the first stage of labor contains three functional labor divisions, each with its own physiological characteristics (Fig. 22-8). First, during the *preparatory division*, although the cervix dilates little, its connective tissue components change considerably (Chap. 21, p. 406). Sedation and conduction analgesia are capable of arresting this labor division. The *dilatational division*, during which dilation proceeds at its most rapid rate, is unaffected by sedation. Last, the *pelvic division* commences with the deceleration phase of cervical dilation. The cardinal movements of labor take place principally during this pelvic division. In actual practice, however, the onset of the pelvic division is seldom clearly identifiable.

Two phases of cervical dilation are defined. The *latent phase* corresponds to the preparatory division, and the *active phase* to the dilational division. Friedman further subdivided the active phase into the *acceleration phase*, the *phase of maximum slope*, and the *deceleration phase* (Fig. 22-9).

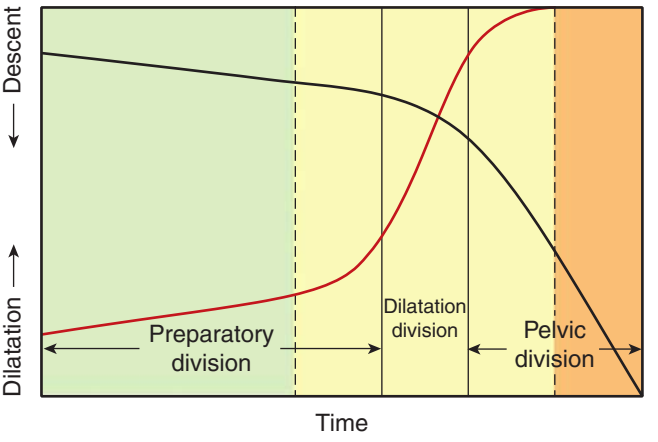

FIGURE 22-8 Labor progress is described by dilatation and descent curves and is partitioned into: (1) a preparatory division, including latent and acceleration phases; (2) a dilatational division, which contains the phase of maximum slope; and (3) a pelvic division, which encompasses both the deceleration phase and second-stage labor as well as the phase of maximum slope of descent.

Latent Phase

The onset of latent labor, as defined by Friedman (1972), is the point at which the mother perceives regular contractions. For most women, this phase ends once cervical dilation of 4 cm is achieved. This threshold may be clinically useful, for it defines dilation limits beyond which active labor can be expected. More recently, the American College of Obstetricians and Gynecologists and Society for Maternal-Fetal Medicine (2019c) has redefined active labor to begin at 6 cm. A fuller discussion of these labor changes is found in Chapter 23 (p. 436).

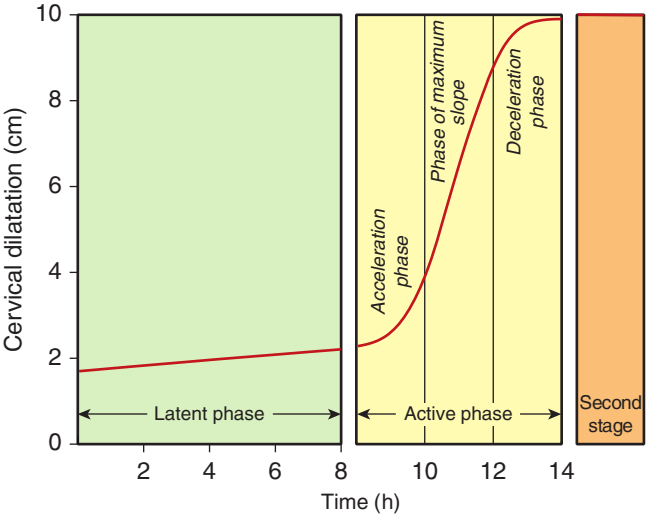

FIGURE 22-9 Composite of the average dilatation curve for nulliparous labor. The first stage is divided into a relatively flat latent phase and a rapidly progressive active phase. The active phase contains an acceleration phase, a phase of maximum slope, and a deceleration phase.

A *prolonged latent phase* was defined as one exceeding 20 hours in the nullipara and 14 hours in the multipara by Friedman and Sachtleben (1963). These times corresponded to the 95th percentiles. Factors that affected latent phase duration include excessive sedation or epidural analgesia; unfavorable cervical condition, that is, thick, uneffaced, or undilated; and false labor. Of women in latent labor who had been administered heavy sedation, 85 percent eventually entered active labor. In another 10 percent, uterine contractions ceased, which suggests false labor. In the remaining 5 percent, an abnormal latent phase persisted and required oxytocin stimulation. Amniotomy was discouraged because of the 10-percent incidence of false labor.

Friedman (1972) later reported that latent phase prolongation did not adversely influence fetal or maternal morbidity or mortality rates. However, prolongation of the latent phase appears associated with longer active labor duration and greater likelihood of obstetrical interventions (Ängeby, 2018; Chelmow, 1993; Tilden, 2020).

Active Phase

The progress of labor in nulliparas has particular significance because these curves all reveal a rapid change in the slope of cervical dilation rates between 3 and 5 cm (see Fig. 22-9). *Thus, cervical dilation of 3 to 6 cm or more, in the presence of uterine contractions, can be taken to reliably represent the threshold for active labor*. Similarly, these curves provide useful guideposts for labor management.

Turning again to Friedman (1955), the mean duration of active-phase labor in nulliparas was 4.9 hours. But, the standard deviation of 3.4 hours is large, hence, the active phase was reported to have a statistical maximum of 11.7 hours. Indeed, rates of cervical dilation ranged from a minimum of 1.2 up to 6.8 cm/hr. Friedman (1972) also found that multiparas progress somewhat faster in active-phase labor, with a *minimum* normal rate of 1.5 cm/hr. His analysis of active-phase labor concomitantly describes rates of fetal descent and cervical dilation (see Fig. 22-8). Descent begins in the later stage of active dilation, commencing at 7 to 8 cm in nulliparas and becoming most rapid after 8 cm.

Others have reassessed the Friedman labor curves. Zhang and associates (2010) studied electronic labor records from 62,415 parturients with spontaneous labor at term and vaginal birth. For primiparas, the median time to progress from 4 to 5 cm was 1.3 hours, from 5 to 6 cm 0.8 hours, and thereafter, additional centimeters were gained approximately each 0.5 hours. They found that normal labor may take >6 hours to progress from 4 to 5 cm and >3 hours to progress from 5 to 6 cm dilation. Rates for multiparas were similar to nulliparas from 4 to 6 cm, but then, labor accelerated much faster in multiparas. Data from this study form the foundation for new guidelines regarding cesarean delivery indications for labor arrest put forth in the American College of Obstetricians and Gynecologists' Obstetric Care Consensus (2019c). These are described in Chapter 23 (p. 436).

Second Stage of Labor

This stage begins with complete cervical dilation and ends with fetal delivery. The median duration is approximately 50 minutes for nulliparas and about 20 minutes for multiparas, but it is highly variable (Kilpatrick, 1989). In a woman of higher parity with a previously dilated vagina and perineum, two or three expulsive efforts after full cervical dilation may suffice to complete delivery. Conversely, in a woman with a contracted pelvis, with a large fetus, or with impaired expulsive efforts from conduction analgesia or sedation, the second stage may become abnormally long. Nulliparas with high starting fetal station may experience a longer second stage (Ashwal, 2021). Greater maternal body mass index does not interfere with second-stage labor (Carlhäll, 2013; Robinson, 2011).

Labor Duration

The normal duration of labor may be clouded by the many clinical variables that affect the conduct of labor in modern obstetrical units. Kilpatrick and Laros (1989) reported that the mean length of first- and second-stage labors approximates 9 hours in nulliparas without regional analgesia and that the 95th percentile upper limit was 18.5 hours. Corresponding times for multiparas were a mean of 6 hours and a 95th percentile maximum of 13.5 hours. These authors defined labor onset as the time when a woman recalled regular, painful contractions every 3 to 5 minutes that led to cervical change.

Spontaneous labor was analyzed in nearly 25,000 women delivered at term at Parkland Hospital in the early 1990s. Almost 80 percent of women were admitted with a cervical dilation of ≤5 cm. Parity—nulliparous versus multiparous—and cervical dilation at admission were significant determinants of spontaneous labor length. The median time from admission to spontaneous delivery for all parturients was 3.5 hours, and 95 percent of all women delivered within 10.1 hours. These results suggest that normal human active labor is relatively short.

MANAGEMENT OF NORMAL LABOR

Birthing is a normal physiological process that most women experience without complications. However, unexpected intrapartum complications can arise quickly. Thus, every woman and her supporters should feel welcomed and comfortable, yet safety measures must be in place for the mother and her newborn if complications suddenly develop. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) have collaborated in the development of *Guidelines for Perinatal Care*. These provide detailed information on the appropriate content of intrapartum care, including both personnel and facility requirements. Labor and delivery outside the hospital is elected by some parturients. This option is discussed in Chapter 27 (p. 504).

Emergency Medical Treatment and Labor Act—EMTALA

By law, all Medicare-participating hospitals with emergency services must provide an appropriate screening examination for any pregnant woman experiencing contractions and presenting to the emergency department for evaluation. The definition of an emergency condition makes specific reference to a pregnant

woman who is having contractions. Labor is defined as "the process of childbirth beginning with the latent phase of labor continuing through delivery of the placenta. A woman experiencing contractions is in true labor unless a physician certifies that after a reasonable time of observation the woman is in false labor." A woman in true labor is considered "unstable" for interhospital transfer purposes until the newborn and placenta are delivered. A stable woman may, however, be transferred at the direction of the patient or by a physician who certifies that the benefits of treatment at another facility outweigh the transfer risks.

Identification of Labor

Pregnant women are urged to report early in labor rather than to procrastinate until delivery is imminent. Early admittance is important if during antepartum care, the woman, her fetus, or both are found to carry risks for intrapartum complications.

Although the differentiation between false and true labor is difficult at times, the diagnosis usually can be clarified by cervical dilation and by contraction frequency and intensity. Pates and associates (2007) studied one commonly used recommendation given to pregnant women. Namely, in the absence of ruptured membranes or bleeding, uterine contractions 5 minutes apart for 1 hour—that is, ≥12 contractions in 1 hour—may signify labor onset. Among 768 women in this study at Parkland Hospital, active labor defined as cervical dilation ≥4 cm was diagnosed within 24 hours in three fourths of women with ≥12 contractions per hour.

In those instances when a diagnosis of labor cannot be established with certainty, observation for a longer period is reasonable. Women who present to Parkland Hospital for labor symptoms at $\geq 24^{0/7}$ weeks gestation are routinely evaluated in a labor triage unit, which is contiguous to our labor and delivery unit. All women in the triage unit are evaluated by nurse practitioners and certified nurse midwives using written protocols. For those with uncomplicated pregnancies, women with intact membranes and cervical dilation <4 cm receive continuous external fetal monitoring for up to 2 hours. Women diagnosed with labor by either cervical change or persistent uterine contractions are admitted. After review by a physician, women without cervical change or with abatement of contractions return home with a diagnosis of false labor. In a recent study, a total of 3949 women with uncomplicated pregnancies between $37^{0/7}$ and $41^{6/7}$ weeks' gestation were diagnosed with false labor. The mean interval from hospital discharge to when they again presented was 4.9 days (Nelson, 2017). Within this protocol, hospital discharge with false labor at term was not associated with higher rates of adverse neonatal outcomes or cesarean delivery. The American College of Obstetricians and Gynecologists (2020a) has endorsed hospital-based obstetrical triage units.

Instead of false labor, labor in the latent phase may be diagnosed. In this phase, some women may require admission for pain management. However, for women without antepartum risks and with reassuring maternofetal status, expectant care during latent labor is reasonable (American College of Obstetricians and Gynecologists, 2019a). Studies support the value of this approach to potentially lower rates of interventions that include oxytocin, antibiotics for intrapartum fever, and cesarean delivery (Bailiet, 2005; Wood, 2016). Instructions on coping and self-care during this time have value (Hosek, 2014). Moreover, a mutually agreed upon time is set for reevaluation.

Initial Evaluation

For the gravida presenting with symptoms of labor, blood pressure, temperature, pulse, and respiratory rate are recorded. Fetal heart rate is evaluated using a portable Doppler device, sonography, or fetoscope. Our practice uses extended electronic fetal monitoring to assess initial fetal status. The pregnancy record is promptly reviewed to identify complications. A vaginal examination is performed unless there is a known placenta previa or vasa previa. The gloved index and second fingers are introduced into the vagina while avoiding the anal region.

Ruptured Membranes

During prenatal care, the woman is instructed to be aware of fluid leakage from the vagina and to report this event promptly. Rupture of the membranes is significant for three reasons. First, if the presenting part is not fixed in the pelvis, the umbilical cord can prolapse and be compressed. Second, labor is likely to begin soon if the pregnancy is at or near term. Third, if delivery is delayed after membrane rupture, intrauterine and neonatal infection is more likely as the time interval lengthens (Herbst, 2007).

During sterile speculum examination, ruptured membranes are diagnosed if amnionic fluid pools in the posterior fornix or clear fluid flows from the cervical canal. If the diagnosis remains uncertain, one method involves pH determination of vaginal fluid. The pH of vaginal secretions normally ranges from 4.5 to 5.5, whereas the pH of amnionic fluid is usually >7.0. The use of the indicator *nitrazine* to identify ruptured membranes is a simple and fairly reliable method. Test papers are impregnated with the dye, and the color of the reaction between these paper strips and vaginal fluids is interpreted by comparison with a standard color chart posted on the strip's container. A pH above 6.5 is consistent with ruptured membranes. False-positive test results may stem from blood, semen, or bacterial vaginosis, which raise pH. Scant fluid can yield a false-negative test result.

Another test to identify amnionic fluid microscopically evaluates vaginal fluid that is dried on a slide. Arborization or a fern pattern suggests amnionic rather than cervical fluid. Amnionic fluid crystallizes and ferns due to its concentrations of sodium chloride, proteins, and carbohydrates.

Of other methods, detection of alpha-fetoprotein in the vaginal vault has been used to identify amnionic fluid (Yamada, 1998). Rarely required, identification may also follow injection of 1 to 4 mL of a 5-percent sodium fluorescein solution into the amnionic sac via abdominal amniocentesis (Ireland, 2017).

Last, specific amnionic fluid proteins can be sought using point-of-care assays. These include *AmniSure*, which binds placental alpha microglobulin-1; *Actim PROM*, with binds insulin growth factor binding protein-1 (IGFBP-1); and *ROM Plus*, which detects IGFBP-1 plus alpha-fetoprotein (Eleje, 2017; Palacio, 2014). False-positive and false-negative results are not uncommon. The Food and Drug Administration (2018)

emphasizes the need to incorporate clinical findings if these methods are used.

Cervical Assessment

Progress during labor produces specific cervical changes. *Cervical dilation* is assessed by sweeping the examining finger from the inner cervical rim on one side of the opening to the opposite inner rim. The diameter traversed is estimated in centimeters. Effective labor will dilate the cervix, which is considered fully dilated when the diameter measures 10 cm. The presenting part of a term-size newborn usually can pass through a cervix this widely dilated.

Cervical effacement is the length of the cervical canal compared with that of an unlabored cervix. When the length of the cervix is reduced by one half, it is 50-percent effaced. When the cervix becomes as thin as the adjacent lower uterine segment, it is completely, or 100-percent, effaced.

Cervical position reflects the relationship of the cervical os to the center point of the presenting part. It is categorized as posterior, midposition, or anterior. Fetal descent will gradually move the cervix anteriorly. Along with position, the *consistency* of the cervix is determined to be soft, firm, or intermediate between these two. Cervical softening aids dilation and effacement.

Fetal station describes the presenting fetal part's leading edge in the birth canal in relationship to the ischial spines. These spines lie halfway between the pelvic inlet and the pelvic outlet and lie at the level of the midpelvis. When the lowermost portion of the presenting fetal part reaches the spines, it is designated as being at zero (0) station.

In the past, the long axis of the birth canal above and below the ischial spines was arbitrarily divided into thirds by some and into fifths (approximately 1 cm) by other groups. In 1989, the American College of Obstetricians and Gynecologists adopted the classification of station that divides the pelvis above and below the spines into fifths. Each fifth represents 1 cm above or below the spines. Thus, as the presenting fetal part descends from the inlet *toward* the ischial spines, the designation is –5, –4, –3, –2, –1, and then 0 station. Below the spines, as the presenting fetal part descends, it passes +1, +2, +3, +4, and +5 stations to delivery. Station +5 cm corresponds to the fetal head being visible at the introitus.

If the leading part of the fetal head is at 0 station or below, most often the fetal head has engaged—thus, the biparietal plane has passed through the pelvic inlet. If the head is unusually molded or if caput succedaneum formation is extensive, or both, engagement might not have taken place although the *scalp* is at 0 station.

In addition to charting the progress of labor, these five characteristics—cervical dilation, effacement, consistency, position, and fetal station—are assessed when tabulating the Bishop score. This score is commonly used to predict labor induction outcome and is discussed in Chapter 26 (p. 488). Taken together, these factors suggest the subjective "favorability" of the cervix for induction success.

Laboratory Studies

When a woman is admitted in labor, most often the hematocrit or hemoglobin concentration is rechecked. The hematocrit can be measured easily and quickly. At Parkland Hospital, blood is collected in a standard collection tube with anticoagulant. From this, a heparinized capillary tube is filled to spin in a microhematocrit centrifuge in the labor and delivery unit. This provides a hematocrit value within 3 minutes. The initial collection tube is also sent to the hematology laboratory for evaluation if the point-of-care hematocrit is <30 volume percent. Another labeled tube of blood is allowed to clot and sent to the blood bank for blood type and antibody screen. Some states, for example, Texas, require routine testing for syphilis, hepatitis B, and HIV in all women admitted to labor and delivery units, even if these were done during prenatal care. In some labor units, a clean-catch voided specimen is examined in all women for protein and glucose. At Parkland Hospital, we obtain a urine specimen for protein determination in hypertensive women only (Chap. 40, p. 689).

■ Management of First-stage Labor

As soon as possible after admittance, the remainder of a general examination is completed. Whether a pregnancy is normal can best be determined when all examinations, including record and laboratory review, are completed. A rational plan for monitoring labor can then be established based on the needs of the fetus and the mother. Because labor lengths vary markedly among individuals, precise statements to the patient regarding anticipated labor duration are unwise.

Intrapartum Fetal Monitoring

This is discussed in detail in Chapter 24. Briefly, the American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2017) recommend that during first-stage labor, in the absence of any abnormalities, the fetal heart rate should be checked immediately after a contraction at least every 30 minutes and then every 15 minutes during second-stage labor. If continuous electronic monitoring is used, the tracing is evaluated at least every 30 minutes during the first stage and at least every 15 minutes during the second stage. For women with pregnancies at risk, fetal heart auscultation is performed at least every 15 minutes during first-stage labor and every 5 minutes during the second stage. Continuous electronic monitoring may be used with evaluation of the tracing every 15 minutes during the first stage of labor, and every 5 minutes during the second stage.

Maternal Monitoring

Temperature, pulse, and blood pressure are evaluated at least every 4 hours. If membranes have been ruptured for many hours or if there is a borderline temperature elevation, the temperature is checked hourly.

Although uterine contractions are usually assessed with electronic monitoring, they can be quantitatively and qualitatively evaluated manually. With the palm of the hand resting lightly on the uterus, the time of contraction onset is determined. Its intensity is gauged from the degree of muscle tone the uterus achieves. At the acme of effective contractions, the finger or thumb cannot readily indent the uterus during a "firm" contraction. The time at which the contraction disappears is noted next. This sequence is repeated to evaluate the frequency, duration, and intensity of contractions.

During the first stage of labor, the need for subsequent vaginal examinations to monitor cervical change and presenting part position will vary considerably. When the membranes rupture, an examination to exclude cord prolapse is performed expeditiously if the fetal head was not definitely engaged at the previous examination. The fetal heart rate is also checked immediately and during the next uterine contraction to help detect occult umbilical cord compression. At Parkland Hospital, periodic pelvic examinations are typically performed at 2- to 3-hour intervals for gravidas in active labor to evaluate labor progress. Evidence implicating the number of vaginal examinations in infection-related morbidity is conflicting (Cahill, 2012; Soper, 1989).

Maternal Position

In bed, the laboring woman may assume the position she finds most comfortable, and often this will be lateral recumbency. Lying supine is typically avoided to avert aortocaval compression and its potential to lower uterine perfusion (Chap. 4, p. 64). However, the normal laboring woman need not be confined to bed early in labor. A comfortable chair may be beneficial psychologically and perhaps physiologically. Others encourage ambulation.

Proponents of walking report that it shortens labor, lowers rates of oxytocin augmentation, diminishes the need for analgesia, and decreases the frequency of operative vaginal delivery (Flynn, 1978; Read, 1981). In their Cochrane review, Lawrence and associates (2013) reported that labor in ambulant or upright positions shortened first-stage labor by approximately 1 hour and lowered cesarean delivery and epidural analgesia rates. However, they cautioned interpretation given variable study quality. Lupe and Gross (1986) concluded, however, that no conclusive evidence supports assertions that upright maternal posture or ambulation improves labor. They reported that women preferred to lie on their side or sit in bed. Few chose to walk, fewer to squat, and none wanted the knee-chest position. Parturients tended to assume fetal positions in later labor. Most women enthusiastic about ambulation returned to bed when active labor began (Carlson, 1986; Williams, 1980).

Bloom and colleagues (1998) conducted a randomized trial to study the effects of walking during first-stage labor. In 1067 women with uncomplicated term pregnancies delivered at Parkland Hospital, these investigators reported that ambulation did not affect labor duration. Ambulation did not reduce the need for analgesia nor was it harmful to the newborn. Because of these observations, we give women without complications the option to select either recumbency or supervised ambulation during labor.

Pain Management

In general, the needs and desires for pain relief are directed by the parturient. Relaxation techniques may have a role for pain relief and patient satisfaction, although evidence-based data are not robust (Smith, 2018). Discussed in the last section, ambulation is another option. Some women choose to spend part of first-stage labor in a large water tub, if available, for pain relief. With this practice, one Cochrane review found lower rates of regional analgesia use and no greater adverse neonatal or maternal effects compared with traditional labor (Cluett, 2018).

Pharmacologic options include epidural analgesia; intermittent intravenous (IV) or intramuscular (IM) opioids or meperidine (Table 25-2, p. 469), and less often, nitrous oxide. These are discussed in detail in Chapter 25.

Oral Intake

Food and liquids with particulate matter should be withheld during active labor and delivery. Gastric emptying time is remarkably prolonged once labor is established and analgesics are administered. As a consequence, ingested food and most medications remain in the stomach and are poorly absorbed. They may be vomited and aspirated (Chap. 25, p. 482). However, oral intake of moderate amounts of clear liquids is reasonable for women with uncomplicated labor (American Academy of Pediatrics, 2017; American Society of Anesthesiologists, 2016). Water, clear tea, black coffee, carbonated beverages, Popsicles, and pulp-free juices are options. In those with appreciable risks for aspiration or those with significant risks for cesarean delivery, further restriction may be instituted. For example, for those with planned cesarean delivery, liquids are halted 2 hours before and solids are stopped 6 to 8 hours prior to surgery (American College of Obstetricians and Gynecologists, 2019b).

Intravenous Fluids

Although an IV infusion system is often routinely established early in labor, real need for this in the normal pregnant woman is limited. Access allows parenteral analgesia or IV fluid infusion prior to regional analgesia. In the immediate puerperium, a dilute oxytocin solution can be given prophylactically to prevent uterine atony and at times therapeutically to treat it. Moreover, with longer labors, the administration of glucose, sodium, and water to the otherwise fasting woman at the rate of 60 to 120 mL/hr prevents dehydration and acidosis.

Although not mandatory, IV hydration may shorten labor length, and most studies of fluid selection use first-stage labor length as a primary outcome. From these investigations, data support use of fluids containing dextrose compared with fluid without it (Riegel, 2018; Shrivastava, 2009). For administration, rates of 125 or 250 mL/hr are suitable (Dawood, 2013; Ehsanipoor, 2017; Fong, 2017). In our practice, saline with 5-percent dextrose is infused at a rate of 150 mL/hr.

Rupture of Membranes

If the membranes are intact, temptation is great, even during normal labor, to perform amniotomy. Benefits are earlier detection of meconium-stained amnionic fluid and the opportunity to apply an electrode to the fetus or insert a pressure catheter into the uterine cavity for monitoring. In one metaanalysis of 15 studies, normal spontaneous labor was not shortened by amniotomy (Smyth, 2013). Risks include potential uterine infection if performed early and possible cord prolapse. To help prevent prolapse, the fetal head must be well applied to the cervix and not dislodged from the pelvis during amniotomy. The use of amniotomy in the setting of abnormal labor is discussed in Chapter 23 (p. 434).

With prolonged membrane rupture and unknown group B streptococcal (GBS) status, antimicrobial administration for prevention of GBS infections is recommended for intrapartum

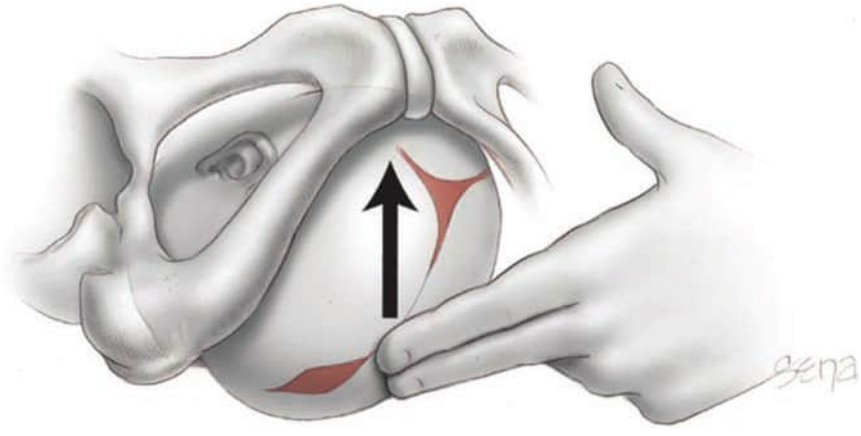

FIGURE 22-10 Locating the sagittal suture by vaginal examination.

risk factors (American College of Obstetricians and Gynecologists, 2020b). These include rupture of membranes greater than 18 hours or intrapartum temperature >38.0°C or >100.4°F (Chap. 67, p. 1194). This practice similarly lowers rates of chorioamnionitis and endometritis (Saccone, 2015).

Urinary Bladder Function

Distention of the bladder can hinder descent of the fetal presenting part and lead to subsequent bladder hypotonia and infection. Periodically, the suprapubic region is palpated to detect distention. If the bladder is readily seen or palpated above the symphysis, the woman should be encouraged to void. Those unable to do so on a bedpan may be able to ambulate with assistance to a toilet. Catheterization is indicated if the bladder is distended and voiding is not possible. Regional analgesia is a common reason. In these cases, continuous or intermittent catheterization is suitable, and both have comparable rates of puerperal urinary tract infection and urinary retention (Li, 2019). Postpartum retention is discussed in Chapter 36 (p. 643).

■ Management of Second-stage Labor

In later first-stage or early second-stage labor, attempts are made to determine head position. The fingers are directed posteriorly and then swept forward over the fetal head toward the maternal symphysis (Fig. 22-10). During this movement, the fingers necessarily cross the sagittal suture, and its lie is delineated. Next, the positions of the two fontanels are ascertained. For this, fingers are passed to the most anterior extension of the sagittal suture, and the fontanel encountered there is examined and identified. The fingers then pass along the sagittal suture to the other end of the head until the other fontanel is felt and differentiated (Fig. 22-11). Last, the station, or extent to which the presenting part has descended into the pelvis, also can be established. Using these maneuvers, the various sutures and fontanels are determined. In unclear cases, sonography can be used as described earlier (p. 420).

With full cervical dilation, which signifies the onset of the second stage, a woman typically begins to bear down. With descent of the presenting part, she develops the urge to defecate. Uterine contractions and the accompanying expulsive forces may now last 1 minute and recur at intervals less than 90 seconds. As discussed earlier, the median duration of the second stage is 50 minutes in nulliparas and 20 minutes in multiparas, although this length can vary. Monitoring intervals of the fetal heart rate were discussed earlier (p. 427), and interpretation of second-stage electronic fetal heart rate patterns is discussed in Chapter 24 (p. 447).

In most cases, bearing down is reflexive and spontaneous during second-stage labor. In those with neuraxial analgesia, this urge may be blunted. To improve spontaneous birth rates, delayed pushing for 60 minutes once the second stage is reached has been suggested to permit passive fetal descent to increase pushing efficiency and minimize maternal exhaustion. One large randomized trial compared immediate and delayed pushing in nulliparas at term with neuraxial analgesia. Routes of delivery were similar. The immediate group actively pushed longer, a mean difference of 9 minutes, but had lower rates of chorioamnionitis (Cahill, 2018). A subsequent metaanalysis noted similar findings (Di Mascio, 2020).

During pushing, a woman may not employ her expulsive forces to good advantage and coaching is desirable. When the next uterine contraction begins, she is instructed to exert downward pressure as though she were straining at stool. A woman is not encouraged to push beyond the completion of each contraction. Instead, she and her fetus are allowed to rest and recover. During this period of active pushing, the fetal heart rate auscultated during the contraction is likely to be slow but should recover to normal range before the next expulsive effort. Fetal and obstetrical outcomes appear to be unaffected whether pushing

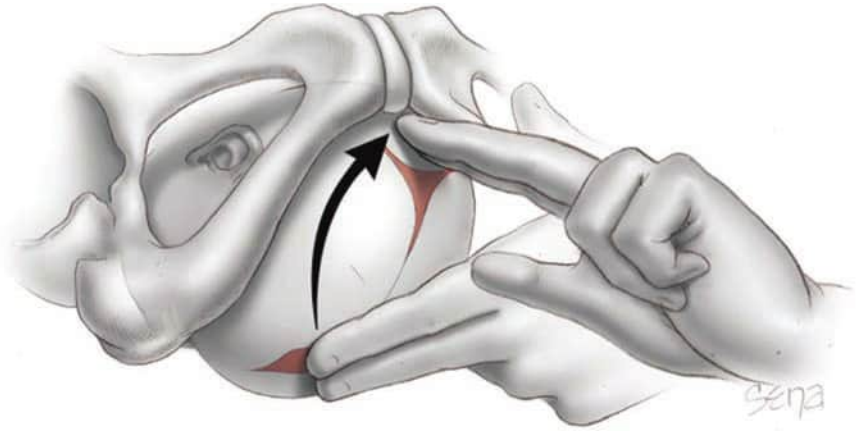

FIGURE 22-11 Differentiating the fontanels by vaginal examination.

is coached or uncoached during second-stage labor (Bloom, 2006; Tuuli, 2012).

Several positions during the second stage have been recommended to augment pushing efforts. The Birth in the Upright Maternal Position with Epidural in Second Stage (BUMPES) trial compared a lateral recumbent position and a supported upright one for nulliparas. Upright positions include standing, sitting out of bed, kneeling, or squatting. The lateral recumbent position required the head of the bed to have an incline ≤30 degrees. When compared, the recumbent group had a spontaneous birth rate of 41 percent, which was significantly higher than the 35-percent spontaneous birth rate experienced by the upright group. Otherwise, rates of operative vaginal delivery (OVD), anal sphincter tear, and neonatal outcome measures were similar (Epidural and Position Trial Collaborative Group, 2017). In a subsequent Cochrane review of studies that included nulliparas and multiparas, upright or recumbent position had little or no affect on rates of "operative birth," which combined OVD and cesarean delivery (Walker, 2018). In those without epidural analgesia, Gupta and coworkers (2017) in their Cochrane review compared upright positions with supine or lithotomy positions during second-stage labor in multiparas and nulliparas. Upright positions offered a marginally shorter interval to delivery and fewer episiotomies and OVDs. However, rates of blood loss >500 mL and perhaps of second-degree lacerations were increased. In sum, no one position is mandated for labor. Repositioning with the goal of maternal comfort and optimal fetal trajectory is suitable as long as appropriate maternal and fetal monitoring can be achieved (American College of Obstetricians and Gynecologists, 2019a). To help avoid femoral or lumbosacral nerve injury from lithotomy positions, hips are not overly flexed, abducted, or externally rotated for extended periods (Chap. 36, p. 644). From early data, transperineal ultrasound assessment of the fetal head's *angle of progression* relative to the symphysis during the second stage may be a tool to predict vaginal birth (Nassr, 2021).

As the head descends through the pelvis, the perineum begins to bulge and the overlying skin becomes stretched. Now the scalp of the fetus may be visible through the vulvar opening. At this time, the woman and her fetus are prepared for delivery, which is described in Chapter 27 (p. 498).

LABOR MANAGEMENT PROTOCOLS

An orderly and systematic approach to labor management results in reproducible beneficial maternal and perinatal outcomes (Althabe, 2008). In Dublin more than 30 years ago, O'Driscoll and associates (1984) pioneered the concept that a disciplined, standardized labor management protocol reduced the number of cesarean deliveries for dystocia. Their overall cesarean delivery rate was 5 percent in the 1970s and 1980s with such management. The approach is now referred to as *active management of labor*. Two of its components—amniotomy and oxytocin—have been widely used, especially in English-speaking countries outside the United States. With this protocol, labor is diagnosed when painful contractions are accompanied by complete cervical effacement, bloody "show," or ruptured membranes. Women with such findings are committed to delivery within 12 hours. Pelvic examination is performed each hour for the next 3 hours, and thereafter at 2-hour intervals. When dilation has not increased by at least 1 cm/hr, amniotomy is performed. Progress is again assessed at 2 hours, and high-dose oxytocin infusion, described in Chapter 26 (p. 493), is started unless dilation of at least 1 cm/hr is attained. Women are constantly attended by midwives. If membranes rupture before admission, oxytocin is begun for no progress at the 1-hour mark.

López-Zeno and colleagues (1992) prospectively compared such active management with their "traditional" approach to labor management at Northwestern Memorial Hospital in Chicago. They randomly assigned 705 nulliparas with uncomplicated pregnancies in spontaneous labor at term. The cesarean delivery rate was significantly lower with active versus traditional management—10.5 versus 14.1 percent, respectively. Subsequent studies did not show this. Wei and associates (2013) in a Cochrane database review found a modest reduction in cesarean delivery rates when active management of labor was compared with standard care. Frigoletto and coworkers (1995) reported another randomized trial with 1934 nulliparous women at Brigham and Women's Hospital in Boston. Although they found that such management somewhat shortened labor, it did not affect the cesarean delivery rate. These observations have since been reported by others (Brown, 2008).

At Parkland Hospital, women are admitted if active labor is diagnosed or if ruptured membranes are confirmed. Labor is defined as cervical dilation of ≥4 cm in the presence of regular uterine contractions. Management guidelines direct that a pelvic examination subsequently be performed approximately every 2 hours. Ineffective labor is suspected when the cervix does not dilate within approximately 2 hours of admission. Amniotomy is then performed, and labor progress determined at the next 2-hour evaluation. In women whose labors do not progress, an intrauterine pressure catheter is placed to assess uterine function. Hypotonic contractions and no cervical dilation after an additional 2 to 3 hours result in stimulation of labor using the high-dose oxytocin regimen described in Chapter 26 (p. 493). The goal is uterine activity of 200 to 250 Montevideo units for 4 hours before dystocia is diagnosed.

In cases in which hypotonic contractions are strongly suspected, internal monitors may be placed with amniotomy and again cervical change and contraction pattern are assessed in 2 hours. Confirmation of deficient Montevideo units at that time may prompt oxytocin augmentation for maternal or fetal indications.

Dilation rates of 1 to 2 cm/hr are accepted as evidence of progress after satisfactory uterine activity has been established with oxytocin. This can require up to 8 hours or more before cesarean delivery is performed for dystocia. The cumulative time required to effect this stepwise management approach permits many women to establish effective labor. This management protocol has been evaluated in >20,000 women with uncomplicated pregnancies. Importantly, these labor interventions and the relatively infrequent use of cesarean delivery did not jeopardize the fetus-newborn.

CHAPTER 23

Abnormal Labor

Labor arrest, abnormal fetal presentation, or fetal jeopardy are indications for a large percentage of primary cesarean deliveries in the United States (Boyle, 2013). Lowering dystocia rates offers the potential to decrease rates of this surgery and associated maternal morbidity.

DYSTOCIA

Dystocia literally means *difficult labor* and is characterized by abnormally slow labor progress. Causes are grouped into three distinct categories. Mechanistically, these simplify into abnormalities of the *powers*—poor uterine contractility and maternal expulsive effort; of the *passenger*—the fetus; and of the *passage*—the pelvis and lower reproductive tract.

These three groups act singly or in combination to produce dysfunctional labor (Table 23-1). For the powers, uterine contractions may be insufficiently strong or inappropriately coordinated to efface and dilate the cervix. This is termed *uterine dysfunction*. Moreover, during second-stage labor, voluntary maternal pushing may be inadequate. For the passenger, fetal

TABLE 23-1. Some Causes of Dystocia in Term Vertex Singletons

Fetal characteristics
Presentation: face, brow, sinciput
Position: OT, OP, asynclitism
Macrosomia
Anomaly: sacrococcygeal teratoma, hydrocephalus, craniofacial tumor, anencephaly
Intrapartum findings
Hydramnios
Chorioamnionitis
Neuraxial analgesia
Higher station at labor onset
Poor maternal pushing: sedation, severe pain, dense regional block, neurologic disease
Maternal characteristics
Nulliparity
Increasing age
Obesity
Large leiomyoma
Uterine müllerian anomaly
Anthropoid, android, or platypelloid pelvis types
Narrow pelvic diameters
Short stature
Pelvic tumor
Prior pelvic fracture

OP = occiput posterior; OT = occiput transverse.

abnormalities of presentation, position, or anatomy may slow progress. Last, for the passage, structural changes can contract the maternal bony pelvis. Or, soft tissue abnormalities of the reproductive tract may block fetal descent.

To describe ineffective labors, two commonly used terms are *cephalopelvic disproportion (CPD)* and *failure to progress*. CPD describes obstructed labor resulting from disparity between the fetal head size and maternal pelvis. The term CPD originated at a time when the main indication for cesarean delivery was overt pelvic contracture from rickets (Olah, 1994). Such absolute disproportion is now rare, and most cases result from malposition of the fetal head within the pelvis (asynclitism). True disproportion is a tenuous diagnosis because 50 to 75 percent of women undergoing cesarean delivery for this reason subsequently deliver even larger newborns vaginally (Lewkowitz, 2015; Place, 2019).

A second phrase, *failure to progress* in either spontaneous or stimulated labor, has become an increasingly popular description of ineffectual labor. This term reflects lack of progressive cervical dilation or halted fetal descent.

ABNORMALITIES OF THE EXPULSIVE FORCES

Types of Uterine Dysfunction

Uterine contractions are needed to dilate the cervix and to expel the fetus. A contraction is initiated by spontaneous action potentials in the membrane of smooth muscle cells. Unlike the heart, a single pacemaker or its site remain unresolved (Young, 2018). Resulting uterine contractions in normal labor show a rising and falling gradient of myometrial activity (Reynolds, 1951). Normal spontaneous contractions can exert pressures approximating 60 mm Hg (Hendricks, 1959). Even so, the lower limit of contraction pressure required to dilate the cervix is 15 mm Hg (Caldeyro-Barcia, 1950).

In abnormal labor, two physiological types of uterine dysfunction may develop. In the more common *hypotonic uterine dysfunction*, basal tone is normal and uterine contractions have a normal gradient pattern (synchronous). However, pressure during a contraction is insufficient to dilate the cervix. In the second type, *hypertonic uterine dysfunction* or *incoordinate uterine dysfunction*, either basal tone is elevated appreciably or the pressure gradient is distorted.

Risk Factors for Uterine Dysfunction

Various factors are implicated in uterine dysfunction. First, neuraxial analgesia can slow labor and has been associated with longer first and second stages of labor (Sharma, 2004). With current anesthesia methods, however, its effect on labor length is blunted (Anim-Somuah, 2018; Myers, 2020). Moreover, cesarean delivery rates are not higher, and supporting studies are presented in Chapter 25 (p. 477).

Chorioamnionitis is associated with prolonged labor. Uterine infection may directly contribute to uterine dysfunction or instead may simply be an associated consequence of prolonged, dysfunctional labor (Mark, 2000; Satin, 1992). Affected gravidas are monitored for labor progress, and augmentation of protracted labor is prudent (American College of Obstetricians and Gynecologists, 2019a).

A higher station at the onset of labor is significantly linked with subsequent dystocia (Friedman, 1965, 1976; Roshanfekr, 1999). Although a risk factor, most nulliparas without fetal head engagement at diagnosis of active labor still deliver vaginally. These observations apply especially for parous women because the head typically descends later in labor.

Dystocia rate rises proportionally with maternal age even after adjusting for maternal and fetal weight and parity (Timofeev, 2013; Waldenström, 2017). Maternal obesity lengthens the first stages of labor by 30 to 60 minutes in nulliparas, even after adjusting for associated diabetes, fetal weight, and parity (Carlhäll, 2013; Kominiarek, 2011). Dystocia-associated cesarean delivery rates are higher in this group (Fyfe, 2011; Kawakita, 2016). Growing evidence suggests a pathologic biological effect of obesity on normal parturition (Azais, 2017; Carlson, 2015).

Labor Disorders

Latent-phase Prolongation

Uterine dysfunction can in turn lead to labor abnormalities (Table 23-2). First, the latent phase may be prolonged, which is defined as >20 hours in the nullipara and >14 hours in the multipara (Friedman, 1961, 1963b). In some, uterine contractions cease, suggesting false labor. In the remainder, an abnormally long latent phase persists and is often treated with amniotomy and oxytocin stimulation (Friedman, 1963a). The diagnosis of uterine dysfunction in the latent phase is difficult and commonly is made retrospectively. Women who are not yet in active labor often are erroneously treated for perceived uterine dysfunction.

Active-phase Disorders

In active labor, disorders are divided into those with slow progress—a *protraction disorder* or those with halted progress—an *arrest disorder*. Terms presented in Table 23-2 and their diagnostic criteria describe abnormal labor. To be diagnosed with either of these, a woman must be in the active phase of labor.

The criteria and management of abnormal labor have undergone modification, and the American College of Obstetricians and Gynecologists and the Society for Maternal–Fetal Medicine (2019b) describe these in their Obstetric Care Consensus titled *Safe Prevention of the Primary Cesarean Delivery*. The Obstetric Care Consensus was a response to the rising cesarean delivery rate because nearly one third of women who give birth each year in the United States undergoes this surgery (Martin, 2019). New recommendations stem from data of normal labor progress in a more contemporary cohort. The World Health Organization (2018) has also revised its recommendations on labor progress. These guidelines have prompted controversy by their significant revision of the preexisting understanding of abnormal labor.

Active-phase Protraction. Of active-phase disorders, protraction disorders are less well described. Previously, protraction has been defined as <1 cm/hr cervical dilation for a minimum of 4 hours. These criteria were adapted from those of Cohen and Friedman (1983) and shown in Table 23-2. For this disorder, observation for further progress is appropriate treatment. In monitoring active labor, if hypotonic contractions are strongly suspected, internal monitors may be placed with amniotomy and again cervical change and contraction pattern are reassessed.

TABLE 23-2. Abnormal Labor Patterns, Diagnostic Criteria, and Methods of Treatment

LABOR PHASE: Labor Disorder	Traditional Criteria and Treatment: Nulliparas		Traditional Criteria and Treatment: Multiparas	Obstetrical Care Consensus Criteria
LATENT PHASE				
Prolongation Disorder				
Prolonged latent phase	>20 hr	>14 hr	Supportive care Oxytocin or amniotomy CD not indicated	Supportive care Oxytocin or amniotomy CD not indicated
ACTIVE PHASE				
Protraction Disorders				
Protracted active-phase dilation	<1.2 cm/hr	1.5 cm/hr	Expectant care CD for CPD	CD not indicated
Protracted descent	<1 cm/hr	<2 cm/hr		
Arrest Disorders				
Prolonged deceleration phase	>3 hr	>1 hr	CD for CPD No CPD: oxytocin	CD indications: Ruptured membranes ***and*** No progress after 4 hr of adequate contractions ***or*** No progress after 6 hr of inadequate contractions despite oxytocin stimulation
Secondary arrest of dilation	>2 hr	>2 hr		
Arrest of descent	>1 hr	>1 hr		
Failure of descent	No descent in deceleration phase or second stage			

CD = cesarean delivery; CPD = cephalopelvic disproportion.
American College of Obstetricians and Gynecologists, 2019b; Cohen, 1983.

Deficient Montevideo units and poor active labor progress typically prompts oxytocin augmentation. In accord with the Consensus Committee (2019b), slow but progressive first-stage labor should not be an indication for cesarean delivery.

Active-phase Arrest. Handa and Laros (1993) diagnosed active-phase arrest, defined as no dilation for ≥2 hours, in 5 percent of term nulliparas. This incidence has not changed since the 1950s (Friedman, 1978). Inadequate uterine contractions, defined as <180 Montevideo units, calculated as shown in Figure 23-1, were diagnosed in 80 percent of women with active-phase arrest. Hauth and coworkers (1986, 1991) reported that when labor is effectively induced or augmented with oxytocin, 90 percent of women achieve 200 to 225 Montevideo

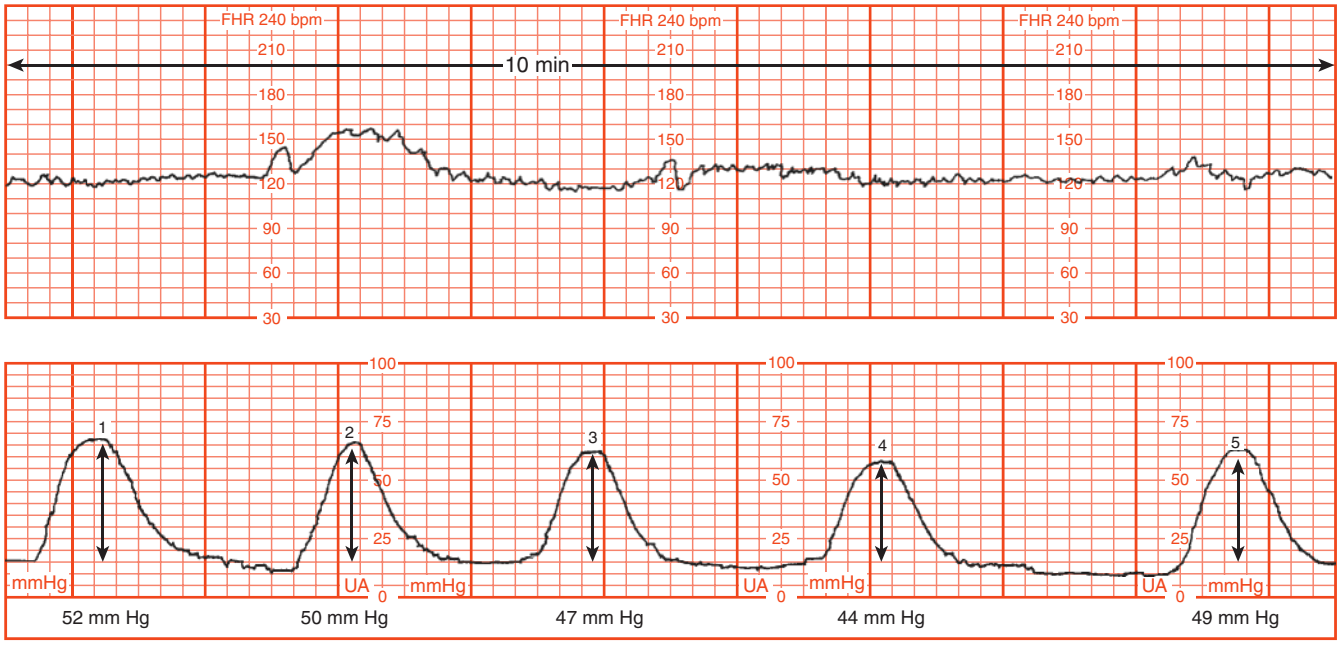

FIGURE 23-1 Montevideo units are calculated by subtracting the baseline uterine pressure from the peak contraction pressure for each contraction in a 10-minute window and adding the pressures generated by each contraction. In the example shown, there were five contractions producing pressure changes of 52, 50, 47, 44, and 49 mm Hg, respectively. The sum of these five contractions is 242 Montevideo units.

units, and 40 percent achieve at least 300 Montevideo units. These results suggest that certain minimums of uterine activity should be achieved before performing cesarean delivery for dystocia. Oxytocin regimens suitable to augment labor mirror those to induce labor. These regimens are outlined in detail in Chapter 26 (p. 493).

Other criteria should also be met. First, the latent phase should be completed, and the cervix is dilated ≥4 cm. Also, a uterine contraction pattern of ≥200 Montevideo units in a 10-minute period has been present for ≥4 hours without cervical change (Rouse, 1999). The Consensus Committee has extended this further, as described next.

Obstetric Care Consensus Committee. Four recommendations of the Consensus Committee apply to management of first-stage labor. The first admonishes against cesarean delivery in the latent phase. Specifically, a prolonged latent phase should not be the sole indication for cesarean delivery. This guideline is not new and is traceable to Friedman's work.

The second directive, too, is conventional practice. It recommends against cesarean delivery if labor is progressive but slow—a *protraction disorder*. This instance is typically managed with observation, assessment of uterine activity, and stimulation of contractions as needed.

A third instruction addresses the cervical dilation threshold that serves to herald active labor. Namely, a cervical dilation of 6 cm—not 4 cm—is now the recommended threshold. Moreover, before this threshold, standards for active-phase progress should not be applied. Of note, the WHO (2018) recognizes 5 cm as the active-labor threshold. Other large studies noted labor acceleration after 5 cm (Ashwal, 2020; Oladapo, 2018).

A fourth stipulation notes that cesarean delivery for active-phase arrest is best reserved for women with cervical dilation ≥6 cm and ruptured membranes who fail to progress despite 4 hours of adequate uterine activity or despite at least 6 hours of oxytocin administration but inadequate contractions.

Of these, the change of thresholds from 4 to 6 cm has prompted the most scrutiny. Described in Chapter 22 (p. 424), original labor curves have been used since first proposed approximately 40 years ago by Friedman (1978). Instead, Zhang and coworkers (2002) proposed a new labor curve derived from a more contemporaneous cohort delivered between 1992 and 1996. The Friedman labor curves reflected women in spontaneous labor with infrequent use of neuraxial labor analgesia or oxytocin augmentation. In contrast, in the later cohort, approximately 50 percent of women had neuraxial analgesia or augmentation. In the later group, the rate of cervical change is slow between 4 and 6 cm but accelerates thereafter. This could reasonably be interpreted as the active phase beginning at 6 cm. In comparing both labor curves, the active phase curve in the Zhang cohort flattens beginning at 3 to 4 cm (Fig. 23-2). Namely, the 6-cm rule for active labor derives from a slowing of the rate or flattening of the slope of cervical change in first-stage labor.

These findings by Zhang and coworkers (2002) are consistent with the labor results obtained in the subsequent Safe Labor Consortium study (Zhang, 2010). However, this study derived its numbers from a retrospective observational dataset built from abstracted labor and delivery information from 19

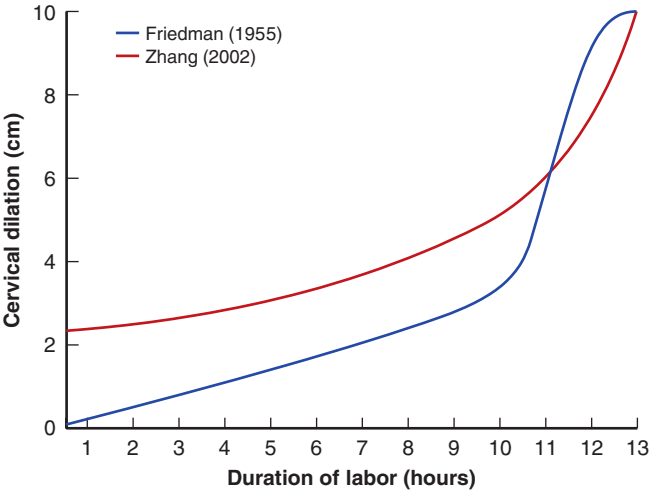

FIGURE 23-2 Cervical dilation curves from Friedman (1955) and Zhang (2002).

hospitals across the United States. Various statistical methods and heavy manipulations of these numbers were used (Cohen, 2015b). Moreover, women were analyzed after excluding all women with cesarean deliveries or asphyxiated newborns. The Consensus Committee (2019b) was explicit that "the Consortium on Safe Labor data, rather than the standards proposed by Friedman, should inform evidence-based labor management."

Critics of the Consensus Committee recommendations note that the Consortium on Safe Labor data were derived from clinical settings with a net cesarean rate of 30 percent. Thus, adherence to the new recommendations may fail to achieve desired cesarean rate reductions. Also, the study lacked a focus on neonatal safety, given that all the asphyxiated neonates were excluded. Supporters note that the study of prolonged first-stage labors by Cheng and coworkers (2010) found higher rates of cesarean delivery and chorioamnionitis but not higher rates of neonatal morbidity. However, Harper and associates (2014) analyzed maternal and neonatal adverse outcomes related to first-stage labor lengths. In 5030 women, first-stage labor durations were divided into those <90th percentile or those ≥90th percentile, with incremental increases thereafter. These authors and those of other large studies similarly found maternal and neonatal composite morbidity scores that were higher in cohorts after adoption of Consensus Committee guidelines compared with groups prior to implementation (Blankenship, 2020; Rosenbloom, 2017). This concern for adverse fetal and maternal effects resulting from the new Consensus Committee guidelines was echoed by Cohen and Friedman (2015a,b).

Another caveat notes that the efficacy of these recommendations to achieve their primary goal is limited. One retrospective cohort study compared 3200 women with uncomplicated term pregnancy undergoing spontaneous or induced labor before guideline changes and 3000 similar gravidas after these changes. The cesarean delivery rate for first-stage labor arrest dropped from 1.8 to 0.9 percent in nulliparas during this time (Thuillier, 2018). Percent changes were not significant in multiparas. Adverse maternal and neonatal outcomes did not significantly differ between epoch groups. In another evaluation of outcomes before and after guideline implementation, cesarean delivery rates were unchanged (Rosenbloom, 2017).

The Consensus Committee suggests that cesarean deliveries for dystocia are being done before 6 cm cervical dilation. However, evidence suggests that all of the Committee's first-stage recommendations are actually already empirically in use but are concurrent with an overall cesarean delivery rate >30 percent. For example, Nelson and associates (2020) analyzed data from nearly 9000 women with primary cesarean deliveries for dystocia at 13 university hospitals between 1999 and 2000. Notably, the median cervical dilation at the time of cesarean for dystocia was 6 cm. As another example, primary cesarean delivery rates for dystocia at Parkland Hospital between 1988 and 2017 did not change significantly. Thus, Consensus Committee guidelines may fail to prevent additional cesareans for dystocia. Logically, further study is needed.

Second-stage Descent Disorders

As discussed in Chapter 22 (p. 425), fetal descent largely follows complete dilation. Moreover, the second stage incorporates many of the cardinal movements necessary for the fetus to negotiate the birth canal. Thus, disproportion of the fetus and pelvis frequently becomes apparent during second-stage labor.

Similar to first-stage labor, time boundaries have been supported to limit second-stage duration to minimize adverse maternal and fetal outcomes. The second stage in nulliparas has been limited to 2 hours and extended to 3 hours when regional analgesia is used. For multiparas, 1 hour has been the limit, extended to 2 hours with regional analgesia. Several studies supported this extension (Cohen, 1977; Menticoglou, 1995a,b; Saunders, 1992). However, of maternal outcomes, higher rates of chorioamnionitis, anal sphincter injury, operative vaginal birth, and postpartum hemorrhage accrue as the second stage lengthens (Allen, 2009; Rouse, 2009).

Newer guidelines have been promoted by the Consensus Committee (2019b) for second-stage labor. These recommend that a nullipara push for at least 3 hours and a multipara push for at least 2 hours before second-stage labor arrest is diagnosed. Importantly, one caveat is that maternal and fetal status should be reassuring. These authors provide options to these times before cesarean delivery is performed. Namely, longer durations may be appropriate as long as progress is documented. Also, a specific maximal length of time spent in second-stage labor beyond which all women should undergo operative delivery has not been identified.

Intuitively, the goal to lower cesarean delivery rates is best balanced with one to ensure neonatal safety. It is problematic that no robust data on neonatal outcomes support the safety of allowing prolonged second-stage labor. Data from many evaluations reveal that serious newborn consequences attend second-stage labors longer than 3 hours (Bleich, 2012; Cahill, 2018; Nelson, 2020; Rosenbloom, 2017). Other data, when adjusted for labor variables, show no difference in adverse neonatal complications for these longer second stages (Cheng, 2004; Le Ray, 2009; Rouse, 2009). Some investigators have argued that the absolute number of such outcomes is small and overall outcomes remain good (Grantz, 2018; Grobman, 2016; Laughon, 2014). That said, some of the adverse outcomes are severe. To fully ascertain specific effect of these guidelines on morbidity rates, randomized controlled trials are needed.

It is possible that prolonged first-stage labor presages that with the second stage. Nelson and coworkers (2013) studied the relationships between the lengths of the first and second stages of labor in 12,523 nulliparas at term delivered at Parkland Hospital. The second stage significantly lengthened concomitantly with increasing first-stage duration. The 95th percentile was 15.6 and 2.9 hours for the first and second stages, respectively. Women with first stages lasting longer than 15.6 hours (>95th percentile) had a 16-percent rate of second-stage labor lasting 3 hours (95th percentile). This compared with a 4.5-percent rate of prolonged second stages in women with first-stage labors lasting <95th percentile.

Maternal Pushing Efforts

With full cervical dilation, most women cannot resist the urge to push with uterine contractions. The combined force created by contractions of the uterus and abdominal musculature propels the fetus downward. However, at times, force created by abdominal musculature is compromised sufficiently to slow or even prevent spontaneous vaginal delivery. Heavy sedation or regional analgesia may reduce the reflex urge to push and may impair the ability to contract abdominal muscles sufficiently. Allowing time for these to abate is reasonable. In other instances, the urge to push is overridden by the intense pain created by bearing down. Depending on fetal station and anticipated second stage, options include emotional support and encouragement, parenteral analgesia, pudendal blockade, or neuraxial analgesia.

PREMATURELY RUPTURED MEMBRANES AT TERM

Membrane rupture at term without spontaneous uterine contractions complicates approximately 8 percent of pregnancies. In the past, labor stimulation was initiated if contractions did not begin after 6 to 12 hours. Practice-changing research included that of Hannah (1996) and Peleg (1999) and their associates, who enrolled a total of 5042 pregnancies with ruptured membranes in a randomized investigation. They measured the effects of induction versus expectant management and also compared induction using intravenous oxytocin with that using prostaglandin E_2 gel. There were approximately 1200 pregnancies in each of the four study arms. They concluded that labor induction with intravenous oxytocin was preferred management. This was based on significantly fewer intrapartum and postpartum infections in women whose labor was induced. There were no significant differences in cesarean delivery rates. Subsequent analysis by Hannah and coworkers (2000) indicated higher rates of adverse outcomes when expectant management at home was compared with in-hospital observation. Mozurkewich and associates (2009) reported lower rates of chorioamnionitis, metritis, and neonatal intensive care unit admissions for women with term ruptured membranes whose labors were induced compared with those managed expectantly. At Parkland Hospital, labor is induced soon after admission when ruptured membranes are confirmed at term. In those with hypotonic contractions or with advanced cervical dilation, oxytocin is selected to lower potential hyperstimulation risk. In those with an unfavorable cervix, no or few contraction, and no significant fetal heart rate decelerations, prostaglandin E_1 (misoprostol) is chosen to promote cervical

ripening and contractions. The benefit of prophylactic antibiotics in women with ruptured membranes before labor at term is unclear (Passos, 2012). However, in those with membranes ruptured longer than 18 hours, antibiotics are instituted for group B streptococcal infection prophylaxis (Chap. 67, p. 1194).

PRECIPITOUS LABOR AND DELIVERY

Labor can be too slow, but it also can be abnormally rapid. *Precipitous labor and delivery* is extremely rapid labor and delivery. It may result from an abnormally low resistance of the soft parts of the birth canal, from abnormally strong uterine and abdominal contractions, or rarely from a lack of pain with contractions to cue advanced labor.

Precipitous labor terminates in expulsion of the fetus in <3 hours. Using this definition, 25,260 live births—3 percent—were complicated by precipitous labor in the United States in 2013 (Martin, 2015). Despite this incidence, little information is published on maternal and perinatal outcomes.

For the mother, complications are few if the cervix is effaced appreciably and compliant, if the vagina has been stretched previously, and if the perineum is relaxed. Conversely, vigorous uterine contractions combined with a long, firm cervix and a noncompliant birth canal may lead to uterine rupture or extensive lacerations of the cervix, vagina, vulva, or perineum (Sheiner, 2004). It is in these latter circumstances that *amniotic-fluid embolism* most likely develops (Chap. 42, p. 743). Precipitous labor is frequently followed by uterine atony. In one report of 99 term pregnancies, short labors were more common in multiparas who typically had contractions at intervals less than 2 minutes. Precipitous labors have been linked to cocaine abuse and associated with placental abruption, meconium, postpartum hemorrhage, and low Apgar scores (Mahon, 1994).

For the neonate, adverse perinatal outcomes from rapid labor may be increased considerably for several reasons. The uterine contractions, often with negligible intervals of relaxation, prevent appropriate uterine blood flow and fetal oxygenation. Related to trauma, resistance of the birth canal rarely may cause intracranial injury. In one review of 22 cases of Erb or Duchenne palsy, precipitous second-stage labor was associated in a third of the cases (Acker, 1988). During unattended birth, the newborn may fall to the floor and be injured. Last, needed resuscitation may not be immediately available due to delivery speed.

As treatment, analgesia is unlikely to modify these forceful contractions significantly. The use of tocolytic agents such as magnesium sulfate or terbutaline is unproven in these circumstances. A single, intramuscular 250-ug terbutaline dose may be reasonable in an attempt to resolve a nonreassuring fetal heart rate pattern. This is balanced against the risk of associated uterine atony if delivery is imminent. Certainly, oxytocin administration should be stopped.

FETOPELVIC DISPROPORTION

Pelvic Capacity

Fetopelvic disproportion arises from diminished pelvic capacity or from abnormal fetal size, structure, presentation, or position. Commonly, both are present. The pelvic inlet, midpelvis, or pelvic outlet may be contracted solely or in combination. Any contraction of the pelvic diameters that diminishes pelvic capacity can create dystocia. Normal pelvic anatomy is also discussed in Chapter 2 (p. 28).

Contracted Inlet

Before labor, the fetal biparietal diameter averages from 9.5 to 9.8 cm. Thus, it might prove difficult or even impossible for some fetuses to pass through a pelvic inlet that has an anteroposterior diameter <10 cm. Mengert (1948) and Kaltreider (1952), employing x-ray pelvimetry, demonstrated that the incidence of difficult deliveries rises when either the anteroposterior diameter of the inlet is <10 cm or the transverse diameter is <12 cm. Either threshold can be used to consider a pelvis contracted. As expected, when both diameters are shortened, dystocia rates are much greater than when only one is diminished.

The anteroposterior diameter of the inlet is also called the *obstetrical conjugate.* It is commonly approximated by manually measuring the *diagonal conjugate*, which is approximately 1.5 cm greater. To measure the diagonal conjugate, a hand with the palm oriented laterally extends its index finger to the promontory. The distance from the fingertip to the point at which the lowest margin of the symphysis strikes the same finger's base is the diagonal conjugate. Inlet contraction usually is defined as a diagonal conjugate <11.5 cm.

A diminutive woman is likely to have a small pelvis, but she is also likely to have a small neonate. Thoms (1937) studied 362 nulliparas and found that the mean birthweight of their offspring was significantly lower—280 g—in women with a small pelvis than in those with a medium or large pelvis.

Normally, cervical dilation is aided by hydrostatic action of the unruptured membranes or by direct application of the presenting part against the cervix after membrane rupture. In contracted pelves, however, because the head is arrested in the pelvic inlet, the entire force exerted by contractions acts directly on the portion of membranes that contact the dilating cervix. Consequently, early spontaneous rupture of the membranes is more likely.

After membrane rupture, absent pressure by the head against the cervix and lower uterine segment predisposes to less effective contractions. Hence, further dilation may proceed very slowly or not at all. Cibils and Hendricks (1965) reported that the mechanical adaptation of the fetal passenger to the bony passage plays an important part in determining the efficiency of contractions. Better adaptation begets more efficient contractions.

A contracted inlet also plays an important part in the production of abnormal presentations. In nulliparas with normal pelvic capacity, the presenting part at term commonly descends into the pelvic cavity before labor onset. If the inlet is contracted considerably or if asynclitism is marked, descent usually does not take place until after labor onset, if at all. Cephalic presentations still predominate, but the head floats over the pelvic inlet or rests more laterally in one of the iliac fossae. Accordingly, very slight influences may cause the fetus to assume other presentations. In women with contracted pelves, face and

shoulder presentations are encountered more frequently, and the cord prolapses more often.

Contracted Midpelvis

This finding is more common than inlet contraction. It frequently causes transverse arrest of the fetal head, which potentially can lead to a difficult midforceps operation or to cesarean delivery.

The obstetrical plane of the midpelvis extends from the inferior margin of the symphysis pubis through the ischial spines and touches the sacrum near the junction of the fourth and fifth vertebrae. A transverse line theoretically connecting the ischial spines divides the midpelvis into anterior and posterior portions (Fig. 2-16, p. 29). The former is bounded anteriorly by the lower border of the symphysis pubis and laterally by the ischiopubic rami. The posterior portion is bounded dorsally by the sacrum and laterally by the sacrospinous ligaments, forming the lower limits of the sacrosciatic notch.

Average midpelvis measurements are as follows: *transverse*, or interischial spinous, 10.5 cm; *anteroposterior*, from the lower border of the symphysis pubis to the junction of S_4 and S_5, 11.5 cm; and *posterior sagittal*, from the midpoint of the interspinous line to the same point on the sacrum, 5 cm. The definition of midpelvic contractions has not been established with the same precision possible for inlet contractions. Even so, the midpelvis is likely contracted when the sum of the interspinous and posterior sagittal diameters of the midpelvis—normally, 10.5 plus 5 cm, or 15.5 cm—falls to 13.5 cm or less. This concept was emphasized by Chen and Huang (1982) in evaluating possible midpelvic contraction. Midpelvic contraction is suspected whenever the interspinous diameter is <10 cm. When it measures <8 cm, the midpelvis is contracted.

Although no precise manual method permits measure of midpelvic dimensions, a suggestion of contraction sometimes can be inferred if the spines are prominent, the pelvic sidewalls converge, or the sacrosciatic notch is narrow. Moreover, Eller and Mengert (1947) noted that the relationship between the intertuberous and interspinous diameters of the ischium is sufficiently constant that narrowing of the interspinous diameter can be anticipated when the intertuberous diameter is narrow. A normal intertuberous diameter, however, does not always exclude a narrow interspinous diameter.

Contracted Outlet

This finding usually is defined as an interischial tuberous diameter of 8 cm or less. The pelvic outlet may be roughly likened to two triangles, with the interischial tuberous diameter constituting the base of both. The sides of the anterior triangle are the pubic rami, and its apex is the inferoposterior surface of the symphysis pubis. The posterior triangle has no bony sides but is limited at its apex by the tip of the last sacral vertebra—not the tip of the coccyx. Diminution of the intertuberous diameter with consequent narrowing of the anterior triangle must inevitably force the fetal head posteriorly. Floberg and associates (1987) reported that outlet contractions were found in almost 1 percent of more than 1400 unselected nulliparas with term pregnancies. A contracted outlet may cause dystocia not so much by itself but by an often-associated midpelvic contraction. *Outlet contraction without concomitant midplane contraction is rare.*

Although the disproportion between the fetal head and the pelvic outlet is not sufficiently great to give rise to severe dystocia, it may play an important part in perineal tears. With increased narrowing of the pubic arch, the occiput cannot emerge directly beneath the symphysis pubis but is forced farther down upon the ischiopubic rami. The perineum, consequently, becomes increasingly distended and thus exposed to risk of laceration.

Pelvic Fractures

Vallier (2012) and Riehl (2014) reviewed experiences with pelvic fractures and pregnancy. Trauma from automobile collisions was the most common cause. Moreover, they note that fracture pattern, minor malalignment, and retained hardware are not absolute indications for cesarean delivery. In determining vaginal delivery candidates, fracture healing requires 8 to 12 weeks and thus recent fracture merits cesarean delivery (Amorosa, 2013). With a healed fracture, care includes review of pelvic radiographs and possible pelvimetry later in pregnancy.

Radiologic Assessment

Current evaluation of pelvic capacity typically uses only digital interrogation of the bony pelvis. Of radiological methods, x-ray pelvimetry with cephalic presentations provides poor predictive value to diagnose CPD (Mengert, 1948; Pattinson, 2017). Similarly, magnetic resonance pelvimetry fails to provide suitable accuracy in predicting cesarean delivery for dystocia (Sporri, 2002; Zaretsky, 2005).

Fetal size alone is seldom the reason for failed labor. Indeed, most cases of CPD arise in fetuses whose weight is well within the range of the general obstetrical population. Figure 23-3 depicts Parkland Hospital data, in which two thirds of neonates who

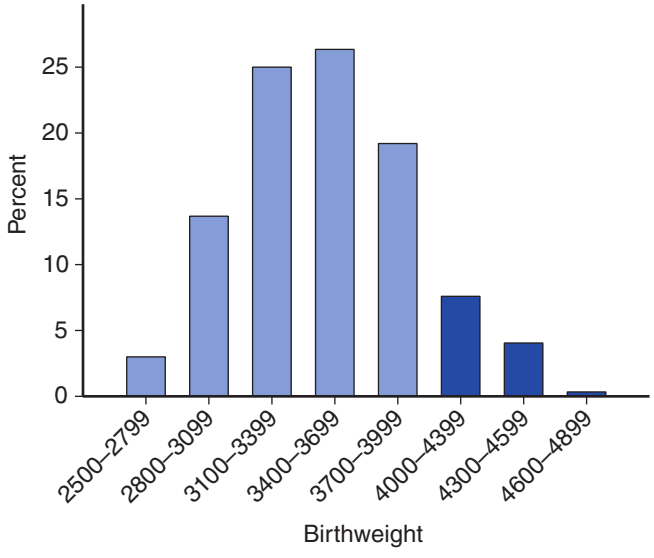

FIGURE 23-3 Birthweight distribution of 362 newborns born by cesarean delivery after a failed forceps attempt at Parkland Hospital from 1989–1999. Only 12 percent (n = 44) of the newborns weighed >4000 g (*dark bars*).

required cesarean delivery after failed forceps delivery weighed <3700 g. Thus, head malposition more likely obstructs fetal passage through the birth canal. These include asynclitism, occiput posterior position, and face, brow, or sinciput presentation.

For fetal head size estimation, clinical and radiographical methods to predict CPD also have proved disappointing. First, Mueller (1885) and Hillis (1930) described a clinical maneuver in which the fetal head is grasped through the abdominal wall, and firm pressure is directed downward along the axis of the inlet. If no disproportion exists, the head readily enters the pelvis, and vaginal delivery can be predicted. However, a prospective evaluation of this *Mueller-Hillis maneuver* found it poorly predicted subsequent labor dystocia (Thorp, 1993).

Measurements of fetal head diameters using plain radiographical techniques are hindered by parallax distortions. The biparietal diameter and head circumference can be measured sonographically, and Thurnau and colleagues (1991) used the *fetal-pelvic index* to identify labor complications. However, the sensitivity of such measurements to predict CPD is poor (Ferguson, 1998; Korhonen, 2015).

Face Presentation

Etiology and Diagnosis

With this presentation, the neck is hyperextended so that the occiput is in contact with the fetal back, and the chin (mentum) is presenting (Fig. 23-4). The rate is approximately 0.1 percent of births (Arsène, 2019; Gardberg, 2011).

Causes of face presentations are numerous and include conditions that favor neck extension or prevent flexion. Preterm fetuses, with their smaller head dimensions, can engage before conversion to occiput presentation, and multifetal gestations carry increased risk (Arsène, 2019; Shaffer, 2006). High parity is another predisposing factor (Fuchs, 1985). In these cases, a pendulous maternal abdomen permits the fetal back to sag forward, which promotes extension of the cervical spine. Fetal malformations and hydramnios are other risk factors for face or brow presentations, and anencephalic fetuses naturally present by the face (Bashiri, 2008). Last, extended neck positions develop more frequently when the pelvis is contracted or the fetus is very large. In a series of 141 face presentations studied by Hellman and coworkers (1950), the incidence of inlet contraction was 40 percent. This high incidence of pelvic contraction should be kept in mind when considering management.

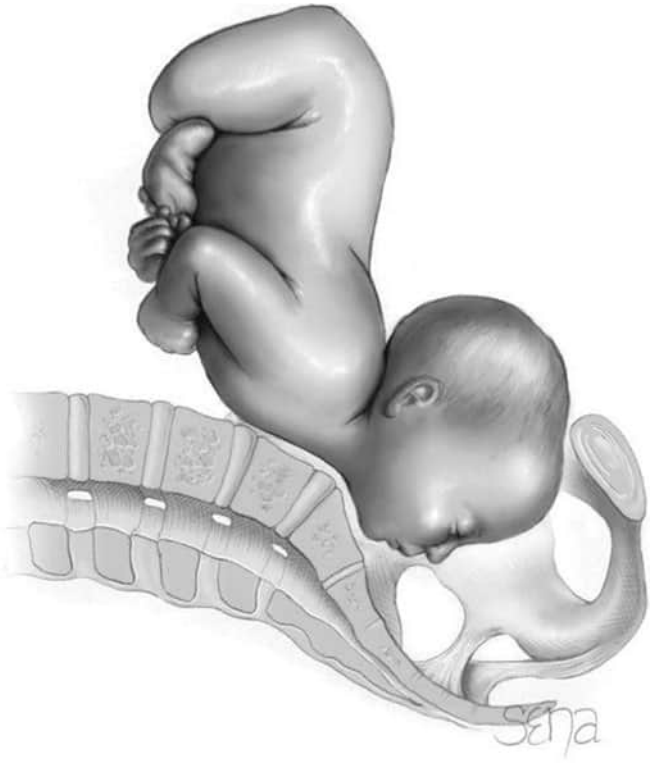

FIGURE 23-4 Face presentation. The chin is directly posterior. Vaginal delivery is impossible unless the chin rotates anteriorly.

Face presentation is diagnosed by vaginal examination and palpation of facial features. Notably, a breech may be mistaken for a face presentation. With careful examination, however, the finger encounters muscular resistance with the anus, whereas the bony, less-yielding jaws and palate are felt through the mouth. The finger, upon removal from the anus, may be stained with meconium. The mouth and malar eminences form a triangular shape, whereas the ischial tuberosities and anus lie in a straight line. Sonography can aid unclear cases (Bellussi, 2017). Used rarely, radiographs demonstrate a hyperextended head with the facial bones at or below the pelvic inlet (Duff, 1981).

Mechanism of Labor

The fetal face may present with the chin (mentum) anteriorly, transversely, or posteriorly, relative to the maternal symphysis pubis (Chap. 22, p. 418). Although some mentum posterior presentations persist, most convert spontaneously to an anterior position, even as late as second-stage labor (Duff, 1981; Sharshiner, 2015).

With the chin anterior, internal rotation of the face brings the chin under the symphysis pubis (Fig. 23-5). Only in this way can the neck traverse the posterior surface of the symphysis pubis. After anterior rotation and descent, the chin and mouth appear at the vulva, and the undersurface of the chin presses against the symphysis. Once the chin clears the symphysis, the neck can flex. The nose, eyes, brow, and occiput then appear in succession over the anterior margin of the perineum. After birth of the head, the occiput sags backward toward the anus. Next, the chin rotates externally to the side toward which it was originally directed, and the shoulders are born as in cephalic presentations. Fortunately temporary, edema and bruising can significantly distort the face.

Instead, if the chin persists posteriorly, the relatively short neck cannot span the anterior surface of the sacrum. Moreover, the fetal brow is pressed against the maternal symphysis pubis. This position precludes the flexion necessary to negotiate the birth canal. Hence, as noted earlier, vaginal birth from a mentum posterior position is impossible unless the shoulders enter the pelvis at the same time, an event that is impossible except for an extremely small or macerated fetus.

Management

During labor, fetal heart rate monitoring is best done with external devices to help avoid face or eye injury. Because face

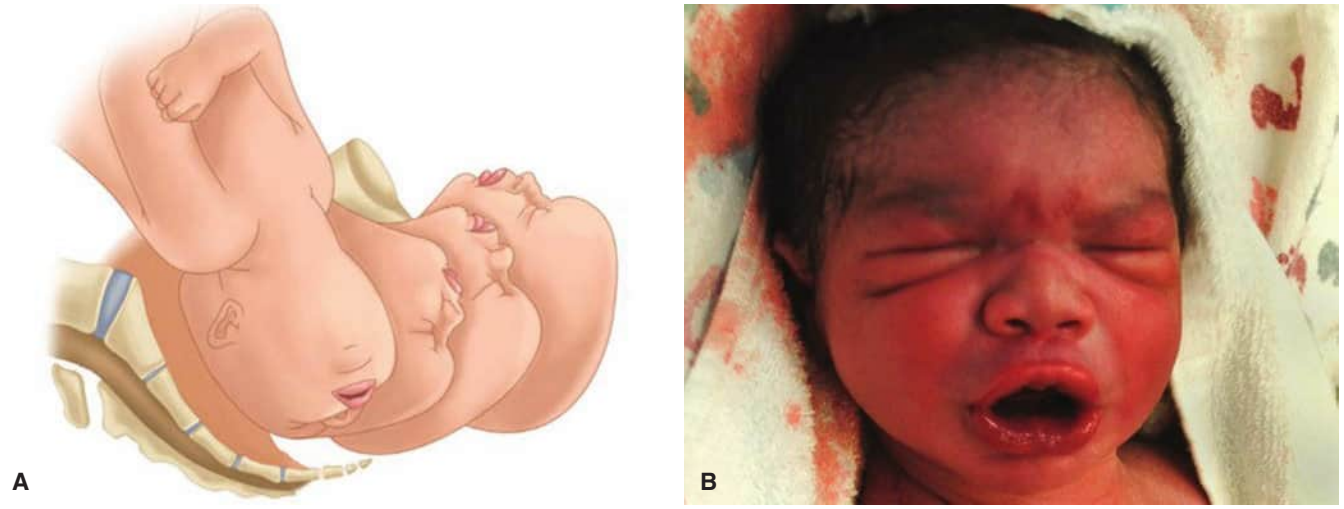

FIGURE 23-5 Face presentation. **A.** Mechanism of labor for right mentoanterior position. **B.** Swollen eyes and lips are common and transient in newborns delivered with face presentation.

presentations among term-size fetuses are more common with some degree of pelvic inlet contraction, cesarean delivery rates are substantially higher than with occiput presentation. If indicated, low or outlet forceps delivery of a mentum anterior face presentation can be completed (Chap. 29, p. 542). Vacuum extraction has been associated with eye trauma and is not recommended (De Bernardo, 2017).

As noted, rotation to a mentum anterior position may occur late in labor. Conversion methods should not be pursued. Namely, attempts to convert a face presentation manually to an occiput one, to rotate a posterior chin to a mentum anterior position, or to complete internal podalic version and extraction are dangerous and not recommended.

Brow Presentation

This uncommon presentation is diagnosed when that portion of the fetal head between the orbital ridge and the anterior fontanel presents at the pelvic inlet. As shown in Figure 23-6, the fetal head thus occupies a position midway between full flexion (occiput) and full extension (face). Rates range from 0.1 to 0.2 percent of births (Gardberg, 2011; Verspyck, 2012).

Risks for persistent brow presentation mirror those for face presentation. A brow presentation is commonly unstable and converts to a face or an occiput presentation (Cruikshank, 1973). The presentation may be recognized by abdominal palpation when both the occiput and chin can be palpated easily, but vaginal examination is usually necessary. The frontal sutures, large anterior fontanel, orbital ridges, eyes, and root of the nose are felt during vaginal examination, but neither the mouth nor the chin is palpable. Sonographic landmarks have been described (Bellussi, 2017).

Except when the fetal head is small or the pelvis is unusually large, engagement of the fetal head and subsequent delivery cannot take place as long as the brow presentation persists. Engagement is impossible until marked molding shortens the occipitomental diameter or, more commonly, until the neck either flexes to an occiput presentation or extends to a face presentation. The considerable molding essential for vaginal delivery of a persistent brow characteristically deforms the head. The caput succedaneum is over the forehead, and it may be so extensive that identification of the brow by palpation is impossible. In these instances, the forehead is prominent and squared, and the occipitomental diameter is diminished. Management principles mirror those for a face presentation.

Transverse Lie

Etiology and Diagnosis

With this, the fetus' long axis lies approximately perpendicular to that of the mother. In a transverse lie, the shoulder is usually

FIGURE 23-6 Brow posterior presentation.

FIGURE 23-7 Transverse lie. Leopold maneuver of a fetus with right acromiodorsoanterior position.

positioned over the pelvic inlet. The head occupies one iliac fossa, and the breech the other. This creates a *shoulder presentation* in which the side of the mother on which the acromion rests determines the designation of the position as right or left acromial. In addition, the back may be directed anteriorly or posteriorly and also superiorly or inferiorly. Thus, it is customary to further distinguish right or left varieties as dorsoanterior and dorsoposterior (Fig. 23-7).

Transverse lie complicates approximately 0.3 percent of births (Cruikshank, 1973; Gemer, 1994). Some of the more common causes include abdominal wall relaxation from high parity, preterm fetus, placenta previa, abnormal uterine anatomy, hydramnios, and contracted maternal pelvis.

A transverse lie is usually recognized easily, often by inspection alone. The abdomen is unusually wide, whereas the uterine fundus extends to only slightly above the umbilicus. No fetal pole is detected in the fundus, and the ballottable head is found on one side and the breech on the other. When the back is anterior, a hard resistance plane extends across the front of the abdomen. When it is posterior, irregular nodules that represent fetal small parts are felt through the mother's abdominal wall. During vaginal examination, in the early stages of labor, if the side of the thorax can be reached, the sequential parallel ribs are felt. With further dilation, the scapula and the clavicle are distinguished on opposite sides of the thorax. The position of the axilla indicates the side of the mother toward which the shoulder is directed.

Mechanism of Labor

Spontaneous delivery of a fully developed newborn is impossible with a persistent transverse lie. After rupture of the membranes, if labor continues, the fetal shoulder is forced into the pelvis, and the corresponding arm frequently prolapses. After some descent, the shoulder is arrested by the margins of the pelvic inlet. As labor continues, the shoulder is impacted firmly in the upper part of the pelvis. The uterus then contracts vigorously in an unsuccessful attempt to overcome the obstacle. With time, a uterine contraction ring rises increasingly higher and becomes more marked. An extreme form is the *Bandl ring*, described in the complication section. With a neglected transverse lie, the uterus will eventually rupture. Even without this complication, maternal and fetal morbidity rates with transverse lie are increased because of the frequent association with placenta previa, umbilical cord prolapse, and fetal manipulations during cesarean delivery.

If the fetus is small—usually <800 g—and the pelvis is large, spontaneous delivery is possible despite persistence of the abnormal lie. The fetus is compressed with the head forced against its abdomen. A portion of the thoracic wall below the shoulder thus becomes the most dependent part, appearing at the vulva. The head and thorax then pass through the pelvic cavity at the same time. The fetus, which is doubled upon itself in a position sometimes referred to as *conduplicato corpore*, is expelled.

Management

Active labor in a woman with a transverse lie typically requires cesarean delivery. With dorsoanterior or back down position, neither the fetal feet nor head occupies the lower uterine segment. A low transverse uterine incision may lead to difficult fetal extraction. Thus, a vertical hysterotomy incision is typically indicated. With dorsoposterior or back up position, one or both feet can be grasped through a low transverse incision and delivered by breech extraction (Chap. 28, p. 527).

Before labor or early in labor, with the membranes intact, attempts at external cephalic version (ECV) are worthwhile. Candidate selection and ECV technique mirror those for the breech fetus and are described in Chapter 28 (p. 528). ECV success rates are high and exceed those for breech fetuses (Correia Costa, 2020; Salzer, 2015).

■ Umbilical Cord Prolapse

Prolapse complicates 0.1 to 0.2 percent of births (Behbehani, 2016; Gibbons, 2014). As noted earlier, umbilical cord prolapse may be more common with pelvis contraction. Most risks stem from an unengaged presenting part and include hydramnios, breech presentation, transverse lie, premature or small fetus with weight <2500 g, preterm rupture of membranes, and multifetal gestation (Hasegawa, 2016). Funic presentation is one in which the umbilical cord is the presenting part. Although rare, it is a potent risk factor for prolapse and merits cesarean delivery prior to labor. Of maternal factors for cord prolapse, grand multiparity, a distorting leiomyoma, or müllerian uterine anomaly are less common reasons (Pagan, 2020).

Umbilical cord prolapse is usually diagnosed clinically. The cord loop is palpated in a position lower in the vaginal canal than the head or beside it. For most cases, prompt manual elevation of the fetal head relieves cord compression. Concurrently,

expeditious transfer to an operating room and preparations for cesarean delivery are completed. Rarely, vaginal or operative vaginal birth is reasonable if it can be completed much more rapidly than emergent cesarean birth (Royal College of Obstetricians and Gynaecologists, 2017).

Compound Presentation

With this, an extremity prolapses alongside the presenting part, and both present simultaneously in the pelvis (Fig. 23-8). Goplerud and Eastman (1953) identified a hand or arm prolapsed alongside the head once in every 700 deliveries. Much less common was prolapse of one or both lower extremities alongside a cephalic presentation or a hand alongside a breech. At Parkland Hospital, compound presentations were identified in only 68 of more than 70,000 singleton fetuses—an incidence of approximately 1 in 1000. Compound presentations form in cases that prevent or delay occlusion of the pelvic inlet and mirror those for other malpresentations.

In most cases, the prolapsed part should be left alone. It typically does not impede labor and often retracts out of the way with descent of the presenting part. If it fails to retract and if it appears to prevent descent of the head, the prolapsed part can be pushed gently upward and the head simultaneously downward by fundal pressure. In cases with a co-presenting hand, the fetus may reflexively retract the hand if pinched by the provider.

In general, rates of perinatal mortality and morbidity are increased, but these mainly stem from effects of associated preterm birth, prolapsed umbilical cord, and traumatic obstetrical procedures. Tebes and coworkers (1999) described a rare case of pressure-induced forearm ischemia and later surgical amputation.

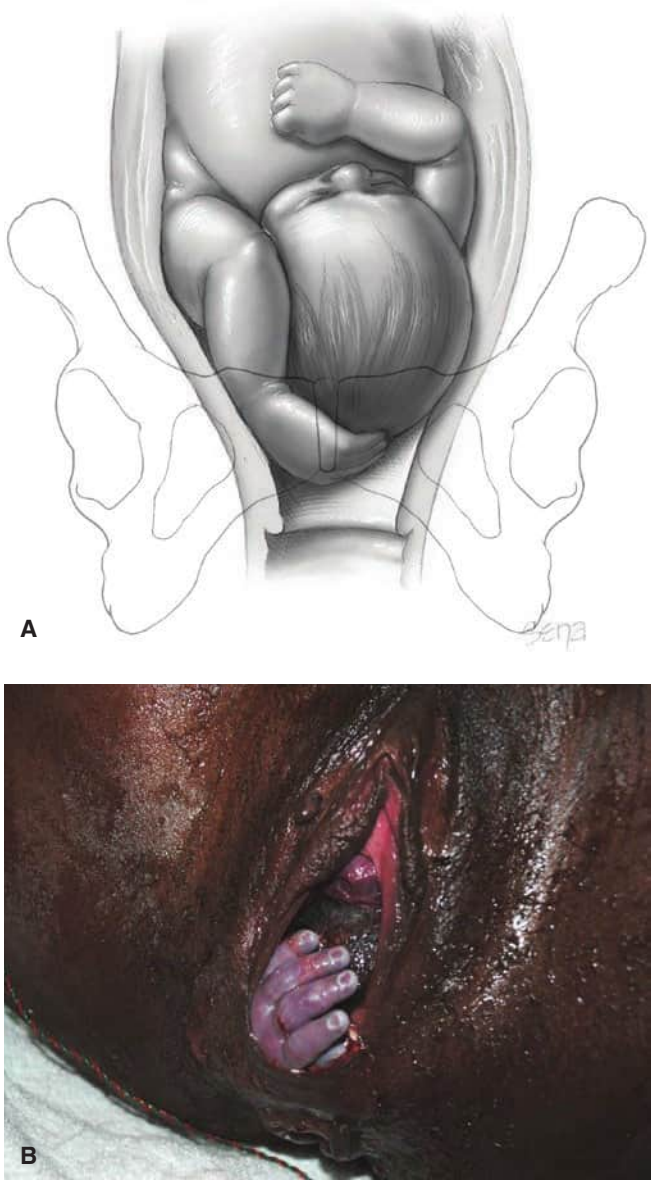

FIGURE 23-8 Compound presentation. **A.** The left hand is lying in front of the vertex. With further labor, the hand and arm may retract from the birth canal, and the head may then descend normally. **B.** Photograph of a small 34-week fetus with a compound presentation that delivered uneventfully with the hand presenting first. Mild bruising resolved uneventfully. (Reproduced with permission from Dr. Elizabeth Mosier.)

COMPLICATIONS WITH DYSTOCIA

Dystocia, especially if labor is prolonged, is associated with a higher incidence of several common obstetrical and neonatal complications. Noted earlier, *maternal infection*, either intrapartum chorioamnionitis or postpartum endomyometritis, is more common with desultory and prolonged labors. *Postpartum hemorrhage* from atony is increased with prolonged and augmented labors. *Uterine tears* at the time of second-stage cesarean delivery also occur at greater incidence if the fetal head is impacted in the pelvis.

Uterine rupture is another risk. Abnormal thinning of the lower uterine segment creates a serious danger during prolonged labor (Delafield, 2018; Ronel, 2012). As described in Chapter 21 (p. 410), the upper segment of the uterus contracts, retracts, and expels the fetus. In response, the softened lower uterine segment and cervix dilate and thereby form a greatly expanded, thinned-out tube through which the fetus can pass. The boundary between these segments is the physiological *retraction ring*. When disproportion is so pronounced that fetal descent arrests, the lower uterine segment becomes increasingly stretched, and the normal *retraction ring* is unusually marked. Seldom encountered today, the *pathological retraction ring of Bandl* is associated with exaggerated thinning of the lower uterine segment. The ring may be seen clearly as a sharp uterine indentation and signifies impending lower segment rupture.

Fistula formation may result from dystocia, in which the presenting part is firmly wedged into the pelvis. Excessive pressure is exerted against tissues lying between the leading part and the pelvic wall. Because of impaired circulation, necrosis may result and become evident several days after delivery as vesicovaginal, vesicocervical, or rectovaginal fistulas (Letchworth, 2018). Most often, pressure necrosis follows a very prolonged second stage. These are rare today except in undeveloped medical systems.

Lower-extremity nerve injury in the mother can follow prolonged second-stage labor. These are discussed in Chapter 36 (p. 644). Fortunately, deficits are mainly sensory, and most resolve within 6 months of delivery in most women.

Similar to the mother, the incidence of peripartum fetal sepsis rises with longer labors. *Caput succedaneum* and *molding* develop commonly and may be impressive (Fig. 22-7, p. 423) (Buchmann, 2008). Mechanical trauma such as nerve injury, fractures, and cephalohematoma also are more frequent and are discussed further in Chapter 33 (p. 608).

CHAPTER 24

Intrapartum Assessment

Electronic fetal monitoring eclipsed periodic fetoscopic auscultation of the fetal heartbeat in the late 1960s (Hon, 1958). It was hoped that the continuous graph-paper portrayal of the fetal heart rate (FHR), termed *cardiotocography*, would reflect pathophysiological events affecting the fetus. Initially, electronic FHR monitoring was used primarily in complicated pregnancies. Now, more than 85 percent of all live births in the United States undergo electronic FHR monitoring (Ananth, 2013).

ELECTRONIC FETAL MONITORING

Internal (Direct) Electronic Monitoring

Direct FHR measurement is accomplished by attaching a bipolar spiral electrode directly to the fetus (Fig. 24-1). The wire electrode penetrates the fetal scalp, and the second pole is a metal wing on the electrode. The P wave, QRS complex, and T wave of the electrical fetal cardiac signal are amplified and fed into a cardiotachometer for heart rate calculation. The peak R-wave voltage is the most reliably detected portion of the fetal electrocardiogram (ECG). Time (t) in milliseconds between fetal R waves is fed into a cardiotachometer, and a new FHR is set with the arrival of each new R wave (Fig. 24-2). The phenomenon of continuous R-to-R wave FHR computation was known as *beat-to-beat variability*, and is now called *baseline variability*. If present, fetal premature atrial contractions (PACs) cause the cardiotachometer to rapidly and erratically seek new heart rates and create the "spiking" shown Figure 24-3.

Electrical cardiac complexes detected by the fetal electrode include those generated by the mother. However, the amplitude of the maternal ECG signal is diminished when recorded through the fetal scalp electrode. Thus, maternal cardiac signals do not appear on the FHR tracing. However, if the fetus is dead, maternal R waves can be still detected by the scalp

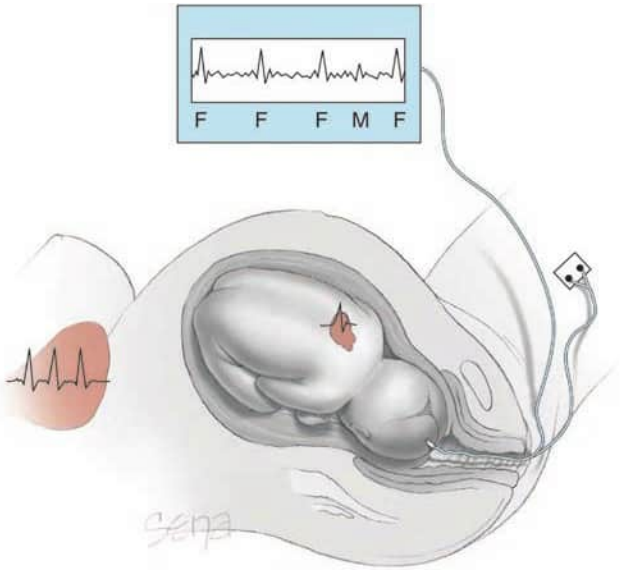

FIGURE 24-1 With internal electronic fetal monitoring a bipolar electrode is attached to the fetal scalp for detection of fetal QRS complexes (F). At times, the maternal heart and its electrical complex (M) also may be detected.

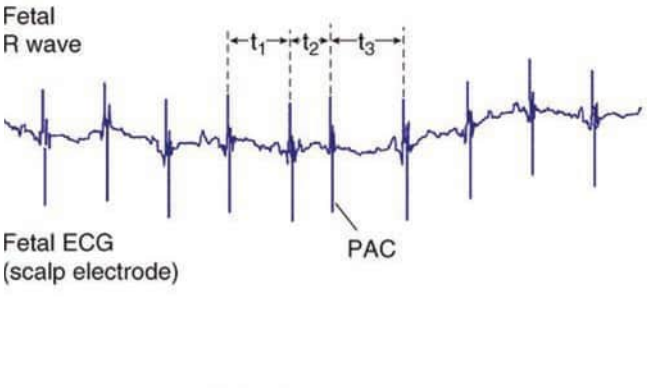

FIGURE 24-2 Fetal electrocardiographic signals from the scalp electrode are used to compute continuous beat-to-beat heart rate. Time intervals (t_1, t_2, t_3) in milliseconds between successive fetal R waves are used by a cardiotachometer to compute instantaneous fetal heart rate. In this example, the t_2 interval has complexes that are close together, which indicates a slighted higher heart rate. This is reflected in the vertical rise on the cardiotachometer graph. ECG = electrocardiogram; PAC = premature atrial contraction.

electrode as the next best signal and are counted by the cardiotachometer (Fig. 24-4).

External (Indirect) Electronic Monitoring

Although it avoids membrane rupture, external monitoring does not provide the precision of internal FHR monitoring (Nunes, 2014). Moreover, in some women, external monitoring may be difficult. For example, fetuses of obese women have a greater amount of unmonitored time compared with those of normal-weight women (Brocato, 2019).

With external monitoring, the FHR is detected through the maternal abdominal wall using the *ultrasound Doppler principle* (Chap. 14, p. 261). The instrument contains a transducer that emits ultrasound and a sensor to detect a shift in frequency of

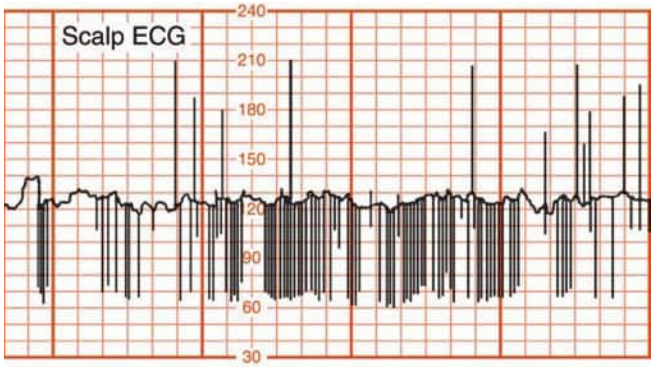

FIGURE 24-3 Standard fetal monitor tracing of heart rate using a fetal scalp electrode. Spiking of the fetal rate reflects premature atrial contractions.

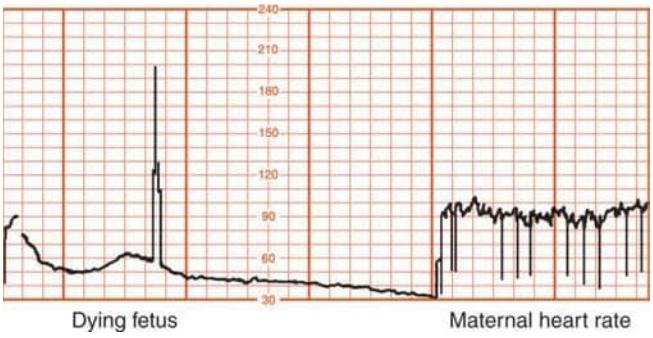

FIGURE 24-4 Placental abruption. The fetal scalp electrode first detects the dying fetus' heart rate. After fetal death, the maternal electrocardiogram complex is detected and recorded.

the reflected sound. The transducer is placed on the maternal abdomen at a site where fetal heart action is best detected. A coupling gel must be applied because air conducts ultrasound waves poorly. The device is held in position by an elastic belt.

Ultrasound Doppler signals are edited electronically before FHR data appear. Reflected ultrasound signals from moving fetal heart valves are analyzed through a microprocessor that compares incoming signals with the most recent previous signal. This process, called *autocorrelation*, is based on the premise that the FHR has regularity, whereas "noise" is random and lacks regularity. Several fetal heart motions must be deemed electronically acceptable by the microprocessor before the FHR is revealed. Such electronic editing has greatly improved tracing quality. Many fetal monitors are capable of interfacing with archival storage systems, which obviates maintaining actual paper tracings.

Other features of current external monitors include the ability to monitor twin fetuses, concurrently assess maternal heart rate, display fetal ECG, and record maternal pulse oximetry values. Wireless, abdominal, dermal-patch, external array systems may improve the interpretability of intrapartum FHR tracings in obese women (Lempersz, 2020; Monson, 2020). Wireless monitors use electrocardiography to accurately measure maternal and fetal heart rates yet allow patient mobility during labor.

Fetal Heart Rate Patterns

The interpretation of FHR patterns can be problematic without definitions and nomenclature. In one study, three Maternal-Fetal Medicine specialists independently interpreted FHR tracings. Agreement was poor for the most ominous tracings and was moderate for less severe patterns (Blackwell, 2011). To help standardize definitions, the National Institute of Child Health and Human Development (NICHD) convened a working group (Table 24-1) (Macones, 2008). The resulting definitions are used in this chapter and have been adopted by the American College of Obstetricians and Gynecologists (2019a). Interobserver agreement improves when these standardized definitions are implemented (Epstein, 2013).

Pattern interpretation derives from the FHR that is portrayed on the monitor or graph paper. Thus, the choice of vertical and horizontal scaling greatly affects patterns. NICHD Workshop scaling parameters recommend that each centimeter

TABLE 24-1. Electronic Fetal Monitoring Definitions

Pattern	Definition
Baseline	• The mean FHR rounded to increments of 5 bpm during a 10-min segment, excluding: —Periodic or episodic changes —Periods of marked FHR variability —Segments of baseline that differ by more than 25 bpm • The baseline must be for a minimum of 2 min in any 10-min segment or the baseline for that time period is indeterminate. In this case, one may refer to the prior 10-min window for determination of baseline. • Normal FHR baseline: 110–160 bpm • Tachycardia: FHR baselines is greater than 160 beats per minute • Bradycardia: FHR baseline is less than 110 beats per minute
Baseline variability	• Fluctuations in the baseline FHR that are irregular in amplitude and frequency • Variability is visually quantified as the amplitude of peak-to-trough in beats per minute —Absent: amplitude range undetectable —Minimal: amplitude range detectable but 5 beats per minutes or fewer —Moderate (normal): amplitude range 6–25 beats per minute —Marked: amplitude range greater than 25 beats per minute
Acceleration	• A visually apparent abrupt increase (onset to peak in less than 30 seconds) in the FHR • At 32 weeks of gestation and beyond, an acceleration has a peak of 15 bpm or more above baseline, with a duration of 15 sec or more but less than 2 minutes from onset to return • Before 32 weeks, an acceleration has a peak of 10 bpm or more above baseline, with a duration of 10 seconds or more but less than 2 minutes from onset to return • Prolonged acceleration lasts 2 minutes or more but less than 10 minutes in duration • If an acceleration lasts 10 minutes or longer, it is a baseline change
Early deceleration	• Visually apparent usually symmetrical gradual decrease and return of the FHR associated with a uterine contraction • A gradual FHR decrease is defined as from the onset to the FHR nadir of 30 seconds or more • The decrease in FHR is calculated from the onset to the nadir of the deceleration • The nadir of the deceleration occurs at the same time as the peak of the contraction • In most cases the onset, nadir, and recovery of the deceleration are coincident with the beginning, peak, and ending of the contraction, respectively
Late deceleration	• Visually apparent usually symmetrical gradual decrease and return of the FHR associated with a uterine contraction • A gradual FHR decrease is defined as from the onset to the FHR nadir of 30 seconds or more • The decrease in FHR is calculated from the onset to the nadir of the deceleration • The deceleration is delayed in timing, with the nadir of the deceleration occurring after the peak of the contraction • In most cases the onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the contraction, respectively
Variable deceleration	• Visually apparent abrupt decrease in FHR • An abrupt FHR decrease is defined as from the onset of the deceleration to the beginning of the FHR nadir of less than 30 seconds • The decrease in FHR is calculated from the onset to the nadir of the deceleration • The decrease in FHR is 15 beats per minute or greater, lasting 15 seconds or greater, and less than 2 minutes in duration • When variable decelerations are associated with uterine contraction, their onset, depth, and duration commonly vary with successive uterine contractions
Prolonged deceleration	• Visually apparent decrease in the FHR below the baseline • Decrease in FHR from the baseline that is 15 beats per minute or more, and less than 2 minutes in duration • If a deceleration last 10 minutes or longer, it is a baseline change
Sinusoidal pattern	• Visually apparent, smooth, sine wave-line undulating pattern in FHR baseline with a cycle frequency of 3–5 per minute which persists for 20 minutes or more

FHR = fetal heart rate.

on the vertical axis represents 30 beats per minute (bpm). Measurement markers on this axis range from 30 to 240 bpm. Along the horizontal axis, the chart recorder moves at a speed of 3 cm/min. The time between each bold vertical line on this axis is 1 minute (see Fig. 24-4).

FHR patterns during labor are dynamic and can interchange rapidly. Although intrapartum evaluation of fetal heart tracings occur every 5 to 30 minutes, tracing interpretation should reflect a longitudinal assessment beyond the current 5- to 30-minute segment (American College of Obstetricians and Gynecologists, 2019b; Robinson, 2008; Vintzileos, 2016). Thus, a full description should include an evaluation of changes or trends over time (Macones, 2008).

Baseline Fetal Heart Activity

This refers to FHR baseline characteristics apart from periodic accelerations or decelerations. Elements include *rate*, *variability*, and distinct FHR patterns such as *sinusoidal* or *saltatory*.

Rate

Beginning at 16 weeks' gestation, the heart rate drops approximately 1 bpm each week (Pillai, 1990; Serra 2009). This continues postnatally such that the average rate is 85 bpm by age 8 years (Tintinalli, 2016). This normal gradual slowing of the FHR is thought to correspond to maturation of parasympathetic (vagal) heart control (Renou, 1969).

The baseline FHR is the approximate mean rate during a 10-minute tracing segment and is rounded to increments of 5 bpm. In any 10-minute window, the minimum interpretable baseline duration must be at least 2 minutes—otherwise the baseline is considered *indeterminate*. For an indeterminate baseline, the previous 10-minute interval is used to determine the baseline heart rate.

If the baseline FHR is <110 bpm, it is termed *bradycardia*. If the baseline rate is >160 bpm, it is called *tachycardia*. The average FHR is considered the result of tonic balance between *accelerator* and *decelerator* influences on cardiac pacemaker cells. In this concept, the sympathetic system is the accelerator influence. The parasympathetic system is the decelerator factor and mediated by vagal slowing of heart rate (Dawes, 1985). Heart rate also is under the control of arterial chemoreceptors such that both hypoxia and hypercapnia can modulate rate. Prolonged hypoxia that is associated with a rising blood lactate level and severe metabolic acidemia induces an extended drop in heart rate (Thakor, 2009).

Bradycardia. In the third trimester, the normal mean baseline FHR ranges between 110 and 160 bpm. But, pragmatically, a rate between 100 and 119 bpm, in the absence of other FHR changes, usually is not representative of fetal compromise. Such mild bradycardias were observed in 2 percent of monitored pregnancies and averaged approximately 50 minutes in duration (Young, 1976). These low baseline heart rates have also been attributed to head compression from occiput posterior or transverse positions, particularly during second-stage labor.

However, fetal bradycardia may stem from congenital heart block or from fetal hypoxia due to maternal or fetal causes (Bravo-Valenzuela, 2018; Lepercq, 2021). For example, Figure 24-4 shows bradycardia in a fetus dying from placental abruption. Less often, sustained maternal hypothermia also can cause fetal bradycardia, but these uniquely involved fetuses apparently are not harmed by several hours of such bradycardia (Spires, 2020).

Tachycardia. This is defined as a baseline FHR >160 bpm. The most common explanation is maternal fever. In some cases, fetal tachycardia may precede overt maternal fever (Gilstrap, 1987). Fetal tachycardia caused by maternal infection typically is not associated with fetal compromise unless it is associated with fetal sepsis or with significant FHR decelerations.

Other causes of fetal tachycardia include fetal compromise, cardiac arrhythmias, and maternal administration of parasympathetic inhibiting (atropine) or sympathomimetic (terbutaline) drugs. Prompt treatment of the compromising event, such as alleviation of maternal fever or volume resuscitation, can result in fetal recovery. The key feature to distinguish fetal compromise in association with tachycardia seems to be concomitant FHR decelerations (Cahill, 2018).

Baseline Variability

This is an important index of cardiovascular function and reflects a sympathetic and parasympathetic "push and pull" mediated by the fetal sinoatrial node. This produces beat-to-beat fluctuations of the baseline FHR (Kozuma, 1997). *Variability* describes these changes during 1 minute, which modify the baseline's waviness (Fig. 24-5). Interpretation of variability is subjective and judges this waviness. The NICHD workshop defined *baseline variability* as irregular fluctuations in the baseline excluding accelerations and decelerations (Macones, 2008). They recommended the criteria shown in Figure 24-5 for quantification of variability. Normal variability shows oscillations that change 6 to 25 bpm. FHR variability increases with advancing gestational age (Serra, 2009; Shuffrey, 2019).

Increased Variability. Several physiological and pathological processes affect variability. Greater variability accompanies fetal breathing and body movements (Dawes, 1981; Zizzo, 2020). Shuffrey and colleagues (2020) showed the FHR had enhanced variation in state 4F (active awake state) compared with 1F (quiet state) and 2F (active state) (Chap. 20, p. 383). However, in one study of 390 fetuses, greater intrapartum variability was associated with abnormal fetal arterial cord blood gas measurements but without increased neonatal morbidity rates (Polnaszek, 2020).

Decreased Variability. *Absent variability* and *minimal variability* are defined as no baseline fluctuation or changes ≤5 bpm. These are shown in Figure 24-5, panels 1 and 2. Of greatest concern, diminished variability can be an ominous sign that indicates a seriously compromised fetus. According to Esplin (2020), metabolic acidemia depresses the fetal brainstem or heart to create the loss of variability. Thus, diminished variability, when it reflects fetal compromise, likely reflects acidemia rather than hypoxia. Severe maternal acidemia also can lower fetal variability, for example, in a mother with diabetic ketoacidosis.

Reduced baseline FHR variability is the single most reliable sign of fetal compromise. Moderate variability is associated with a normal umbilical cord pH in 98 percent of cases (Parer, 2006). Absent or minimal variability is associated with fetal acidemia, but it predicts an umbilical cord pH <7.15 in only 12 to 31 percent of cases (Parer, 2006; Williams, 2003). In a study of 2200 consecutive deliveries, authors concluded that variability by itself could not be used as the only indicator of fetal well-being (Samueloff, 1994). Comorbid fetal tachycardia or FHR decelerations also may help predict fetal acidemia (Esplin, 2020; Vintzileos, 2016).

FIGURE 24-5 Baseline fetal heart rate variability shown in the following five panels. **1.** Undetectable, absent variability. **2.** Minimal variability, ≤5 bpm. **3.** Moderate (normal) variability, 6 to 25 bpm. **4.** Marked variability, >25 bpm. **5.** Sinusoidal pattern. This differs from variability in that it has a smooth, sinelike pattern of regular fluctuation and is excluded in the definition of fetal heart rate variability.

Another common cause of diminished variability is administration of some analgesic drugs during labor (Chap. 25, p. 477). These can depress the central nervous system and include narcotics, barbiturates, phenothiazines, tranquilizers, and general anesthetics. As one specific example, variability regularly diminishes within 5 to 10 minutes following intravenous (IV) meperidine administration, and the effects may last 60 minutes or longer (Hill, 2003; Petrie, 1993). IV butorphanol has similar effects (Schucker, 1996). And, chronically administered buprenorphine suppresses FHR and movement (Jansson, 2017). Corticosteroids also decrease fetal movement and thereby dampen variability (Noben, 2019).

Magnesium sulfate can diminish variability and is widely used in the United States for fetal neuroprotection, tocolysis, and seizure prophylaxis in preeclampsia. In a study of nearly 250 term gestations, its administration led to decreased variability but without evidence of adverse neonatal effects (Duffy, 2012). Others echo these findings (Nensi, 2014; Verdurmen, 2017).

In sum, variability is affected by fetal physiology, and its meaning differs depending on clinical setting. A decrease in variability but without decelerations is unlikely to reflect fetal hypoxia (Parer, 2006). A persistently flat FHR baseline—absent variability—within the normal baseline rate range and without decelerations may reflect a prior fetal insult that has resulted in neurological damage (Freeman, 2003).

Cardiac Arrhythmia

When fetal cardiac arrhythmias are first suspected using electronic monitoring, findings can include baseline bradycardia, tachycardia, or most commonly in our experience, *abrupt baseline spiking* (see Fig. 24-3). An arrhythmia can only be documented, practically speaking, when scalp electrodes are used. Some fetal monitors can be adapted to output the scalp electrode signals into an ECG recorder. Because only a single lead is obtained, analysis and interpretation of rhythm and rate disturbances are severely limited.

In one study, rate and rhythm disturbances in 934 normal pregnancies were evaluated between 30 and 40 weeks' gestation. Arrhythmias, episodes of bradycardia <100 bpm, or tachycardia >180 bpm were encountered in 3 percent (Southall, 1980). Most supraventricular arrhythmias carry little significance during labor unless fetal heart failure, as evidenced by hydrops, is coexistent. Many supraventricular arrhythmias disappear in the immediate neonatal period, although some are associated with structural cardiac defects (Api, 2008). Intermittent baseline bradycardia is frequently due to congenital heart block. Conduction defects, most often complete atrioventricular (AV) block, usually are found in association with maternal connective tissue diseases (Chap. 62, p. 1113). Antepartum evaluation of the fetus with an identified arrhythmia and treatment options are discussed in Chapter 19 (p. 368).

Most fetal arrhythmias without comorbid fetal hydrops are inconsequential during labor, but they may hinder interpretation of FHR tracings and thereby necessitate cesarean delivery. Sonographic evaluation of fetal anatomy and echocardiography can be useful. Generally, without evidence of fetal hydrops, neonatal outcome is not measurably improved by pregnancy intervention. At Parkland Hospital, intrapartum fetal cardiac arrhythmias, especially those associated with clear amnionic fluid, are typically managed conservatively.

Sinusoidal Heart Rate

A sinusoidal baseline is one with a sine wave–like undulating pattern with a frequency of 3 to 5 cycles per minute for at least 20 minutes. A true sinusoidal pattern such as that shown in panel 5 of Figure 24-5 can be observed with fetal intracranial hemorrhage, severe fetal asphyxia, or severe fetal anemia. The last may stem from alloimmunization, fetomaternal hemorrhage, twin-twin transfusion syndrome, fetal parvoviral infection, or vasa previa with bleeding. The pathophysiology of sinusoidal patterns is unclear, in part due to varying definitions. One group proposed that the pattern relates to fetal arterial blood pressure and oscillations in the baroreceptor-chemoreceptor feedback mechanism (Ikeda, 1999). Modanlou (1982, 2004) proposed adoption of a strict definition for true sinusoidal FHR that is most likely ominous. This criteria eliminates the influence of maternal medications.

1. Stable baseline FHR of 120 to 160 bpm with regular oscillations
2. Amplitude of 5 to 15 bpm (rarely greater)
3. 2 to 5 cycles per minute
4. Absent variability and accelerations
5. Oscillation of the sinusoidal waveform above or below a baseline
6. No concurrent drugs such as narcotics

Other investigators classify sinusoidal heart rate patterns into mild—amplitude 5 to 15 bpm; intermediate—16 to 24 bpm; and major—≥25 bpm. Increasing amplitude correlates with advancing fetal risk (Murphy, 1991; Neesham, 1993).

Importantly, insignificant sinusoidal patterns have been reported following administration of meperidine, morphine, alphaprodine, and butorphanol (Angel, 1984; Egley, 1991; Epstein, 1982). When due to narcotics, this pattern has a sine frequency of 6 cycles per minute. A sinusoidal pattern also has been described with chorioamnionitis, fetal distress, and umbilical cord occlusion (Murphy, 1991). Investigators have concluded that intrapartum sinusoidal fetal heart patterns are not generally associated with fetal compromise (Johnson, 1981; Young, 1980a). Thus, management is usually dictated by the clinical setting.

Pseudosinusoidal describes intrapartum sine wave–like baseline variation coupled with periods of acceleration. In one study, this pattern was seen in 15 percent of monitored labors (Murphy, 1991). Mild pseudosinusoidal patterns were associated with use of meperidine and epidural analgesia. Intermediate pseudosinusoidal patterns were linked to fetal sucking or transient episodes of fetal hypoxia caused by umbilical cord compression. In another study, 4 percent of fetuses demonstrated sinusoidal patterns transiently during normal labor (Egley, 1991). These authors noted patterns lasting for 90 minutes in some cases.

Periodic Fetal Heart Rate Changes

These refer to visually apparent deviations from baseline. *Acceleration* refers to a rise in FHR above the baseline, and *deceleration* is a drop below the baseline rate. For the latter, terms used in the United States are *early, late,* or *variable* and refer to the temporal relationship between the deceleration and contractions. Waveform shapes also aid pattern recognition and are described subsequently. The NICHD Workshop (2008) considered decelerations to be *recurrent* if they accompanied ≥50 percent of contractions in any 20-minute period.

Accelerations

These are an abrupt FHR increase above the baseline and are defined by the onset-to-peak rise within 30 seconds (American College of Obstetricians and Gynecologists, 2019a). At ≥32 weeks' gestation, an *acceleration* is one that peaks at a point ≥15 bpm above baseline. Its duration is ≥15 seconds but <2 minutes from onset to baseline return (see Table 24-1). Before 32 weeks, a peak ≥10 bpm and duration lasting 10 seconds to 2 minutes is considered normal. *Prolonged acceleration* is one lasting ≥2 minutes but <10 minutes.

Accelerations occur antepartum and intrapartum. Proposed mechanisms for intrapartum accelerations include fetal movement, stimulation by uterine contractions, umbilical cord occlusion, fetal scalp stimulation, scalp blood sampling, and acoustic stimulation. Accelerations are common during labor. These are virtually always reassuring and almost always confirm that the fetus is not acidemic at that moment (Berkus, 1999).

Accelerations reflect intact neurohormonal cardiovascular control mechanisms linked to fetal behavioral states. In one analysis of FHR tracings in nearly 2000 fetuses, 99.8 percent showed sporadic accelerations during labor. FHR accelerations during the first or last 30 minutes of labor were a favorable sign for fetal well-being (Krebs, 1982). Their absence during labor, however, is not necessarily an unfavorable sign unless coincidental with other nonreassuring changes. The chance of acidemia in the fetus that fails to respond to stimulation despite an otherwise nonreassuring pattern approximates 50 percent (Clark, 1984; Smith, 1986).

Early Deceleration

This physiological response shows a gradual FHR decline and then return to baseline that mirrors the contraction (Fig. 24-6). Etiologically, head compression and dural stimulation probably cause vagal nerve activation, which mediates the FHR deceleration (Paul, 1964). Freeman and associates (2003) defined early decelerations as those generally seen in active labor between 4 and 7 cm cervical dilation. In their definition, the degree of deceleration is generally proportional to the contraction strength and rarely falls below 100 to 110 bpm or 20 to 30 bpm below baseline. These decelerations are common during active labor and not associated with tachycardia, loss of variability, or other FHR changes. Early decelerations are considered benign

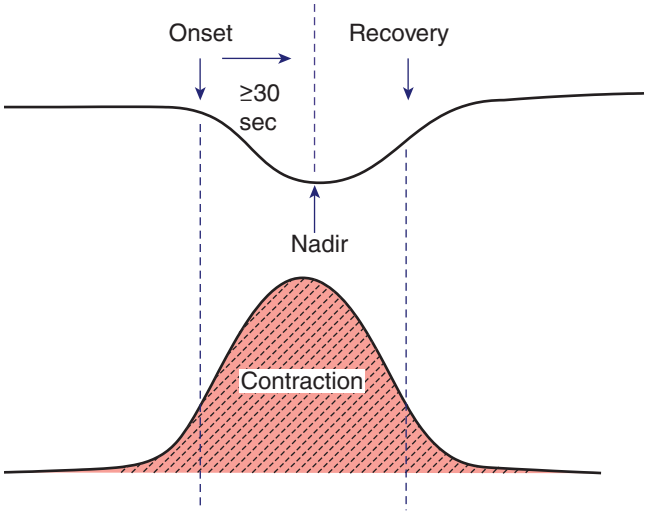

FIGURE 24-6 An early fetal heart rate deceleration characteristically shows a gradual decline and recovery in the heart rate that coincide with the onset and recovery of the contraction. The nadir of the deceleration is ≥30 seconds after the deceleration onset.

and not associated with fetal hypoxia, acidemia, or low Apgar scores.

Late Deceleration

This deceleration is a smooth, gradual, symmetrical decline in the FHR that begins at or after the contraction peak and returns to baseline only after the contraction has ended. It reaches its nadir within 30 seconds of its onset (Fig. 24-7). Typically, a late deceleration's depth is <10 to 20 bpm below baseline. These usually are not accompanied by accelerations.

Late decelerations often reflect poor uterine perfusion or placental dysfunction. In one animal study, uteroplacental perfusion was intentionally compromised, and the lag between contraction onset and late deceleration onset was directly related to basal fetal oxygenation (Myers, 1973). The lower the fetal Po_2 before contractions, the shorter the lag to the late deceleration's onset. This lag reflects the time necessary for the fetal Po_2 to fall below a critical level necessary to stimulate arterial chemoreceptors, which mediate the decelerations.

Late decelerations are the first FHR consequence of uteroplacental-induced hypoxia. Fetal acidemia develops after frequent or prolonged periods of hypoxia. However, late decelerations alone do not predict fetal acidemia (Jia, 2021). Instead, late decelerations plus decreased variability, which itself is an indicator of less activity in the cardioregulatory center of the medulla, are more predictive of fetal acidemia and neonatal morbidity (Cahill, 2018; Holzmann, 2015). Cahill and coworkers (2018) calculated the total area within the below-baseline curves of decelerations. They found that increasing area was more predictive of fetal acidemia than other FHR characteristics.

Generally, any process that produces maternal hypotension, excessive uterine activity, or placental dysfunction can induce late decelerations. The two most common are hypotension from epidural analgesia and uterine hyperactivity from oxytocin stimulation. Maternal hypertension, diabetes, and collagen vascular disorders can cause chronic placental dysfunction. Placental abruption can acutely produce late decelerations.

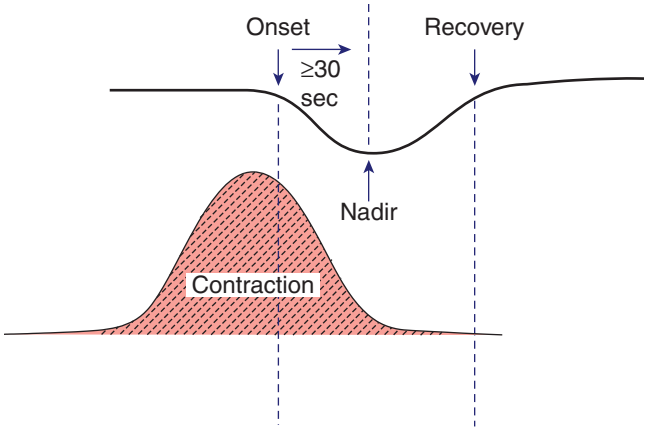

FIGURE 24-7 A late fetal heart rate deceleration characteristically shows a gradual decline in the heart rate that starts at or after the contraction's peak and recovers after the end of the contraction. The deceleration nadir occurs ≥30 seconds after the deceleration's onset.

Variable Deceleration

This is the most frequent deceleration pattern encountered during labor and is attributed to umbilical cord occlusion. In a study of more than 7000 tracings, variable decelerations were identified in 40 percent when labor had progressed to 5 cm dilation and in 83 percent by the end of first-stage labor (Melchior, 1985). The slope of FHR change is abrupt and erratic, giving the waveform its jagged shape (Fig. 24-8). A variable deceleration is defined as a drop in the FHR that begins with the contraction's onset and reaches a nadir in <30 seconds. The deceleration lasts between 15 seconds and 2 minutes, and its depth is ≥15 bpm in amplitude. The onset of deceleration typically varies with successive contractions.

Etiologically, variable deceleration often reflects some degree of umbilical cord occlusion. In one animal study, Hon (1959)

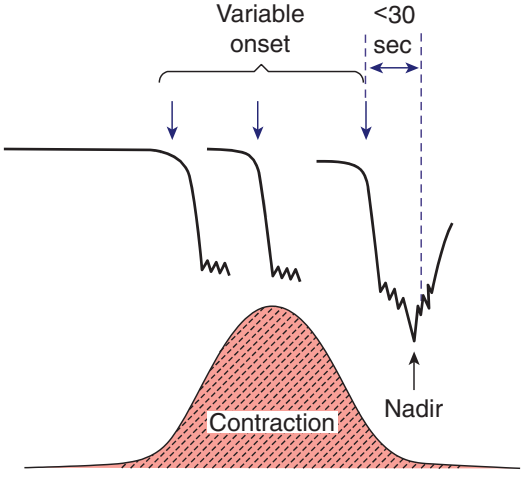

FIGURE 24-8 A variable fetal heart rate deceleration characteristically shows an abrupt drop in the heart rate, and its onset commonly varies with successive contractions. The deceleration depth measures ≥15 bpm, lasts ≥15 seconds, and has an onset-to-nadir phase <30 seconds. Its total duration is <2 minutes.

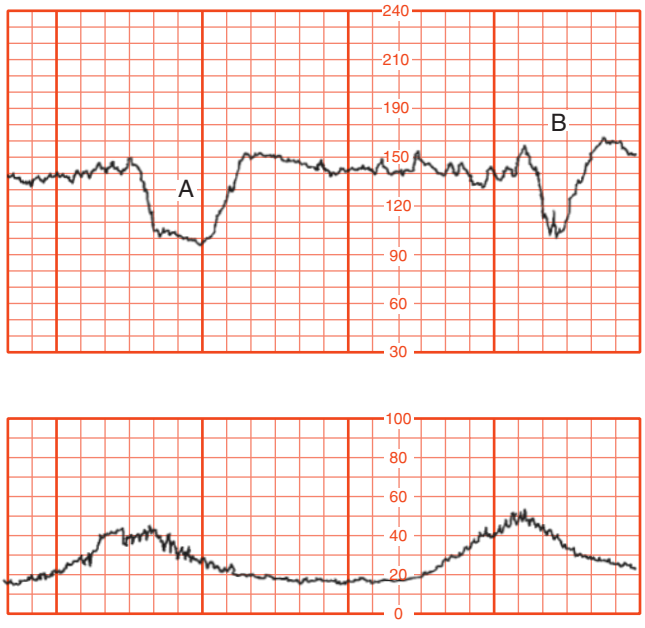

FIGURE 24-9 Variable fetal heart rate decelerations. Deceleration (*B*) exhibits "shoulders" of acceleration compared with deceleration (*A*).

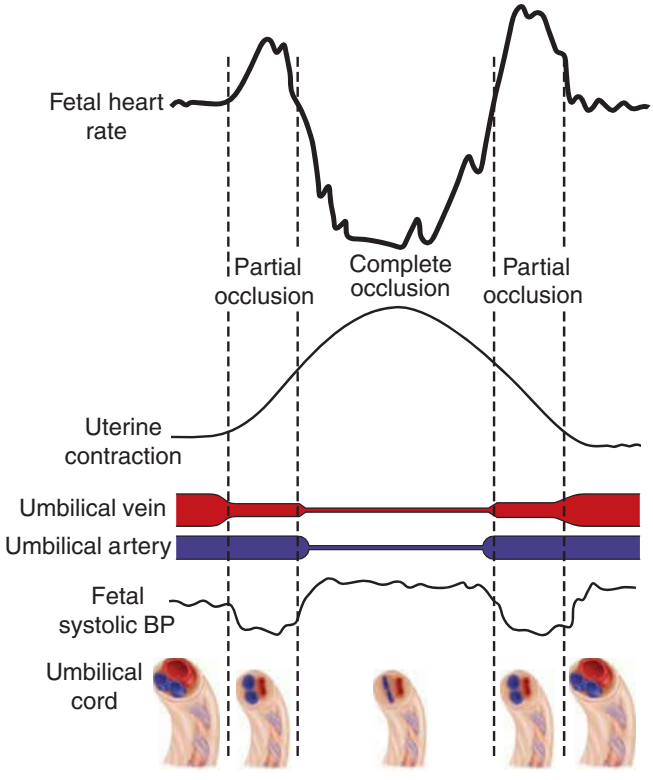

FIGURE 24-10 Schematic representation of the fetal heart rate effects with partial and complete umbilical cord occlusion. Uterine pressures generated early in a contraction cause cord compression predominantly of the thin-walled umbilical vein. The resulting decrease in fetal cardiac output leads to an initial compensatory rise in fetal heart rate. As cord compression intensifies, umbilical arteries are then also compressed. The resulting rise in fetal systolic blood pressure leads to a vagal-mediated fetal heart rate deceleration. As the contraction abates and compression is relieved first on the umbilical arteries, elevated fetal systolic blood pressures drop and the deceleration resolves. A final increase in fetal heart rate is seen as a result of persistent umbilical vein occlusion. With completion of the uterine contraction and cord compression, the fetal heart rate returns to baseline. BP = blood pressure.

assessed the effects of umbilical cord compression on FHR. He found lengthening and deepening of the deceleration curve with longer occlusion times. In another study, variable decelerations in fetal lambs occurred only after umbilical blood flow was reduced by at least 50 percent (Itskovitz, 1983).

Two patterns of variable decelerations are shown in Figure 24-9. The deceleration denoted by "A" is very much like that seen with complete umbilical cord occlusion in experimental animals. However, deceleration "B" differs and displays an acceleration before and after the deceleration component. Lee and coworkers (1975) proposed that this form was caused by differing degrees of cord occlusion. In this scheme, occlusion of only the vein reduces fetal blood return and thereby triggers a baroreceptor-mediated acceleration. With increasing intrauterine pressure and subsequent complete cord occlusion, fetal systemic hypertension develops due to obstructed umbilical artery flow. This stimulates a baroreceptor-mediated deceleration. Presumably, the aftercoming acceleration represents the same events occurring in reverse (Fig. 24-10) (Lee, 1975). Ball and Parer (1992) concluded that variable decelerations are mediated vagally and that the vagal response may be due to chemoreceptor or baroreceptor activity or both. Partial or complete cord occlusion produces an increase in afterload (baroreceptor) and a drop in fetal arterial oxygen content (chemoreceptor). Both result in vagal activity leading to deceleration.

Thus, variable decelerations represent FHR reflexes that reflect either blood pressure changes due to interruption of umbilical flow or changes in oxygenation. It is likely that most fetuses have experienced brief but recurrent periods of hypoxia due to umbilical cord compression during gestation. The great dilemma for the obstetrician in managing variable FHR decelerations is determining when variable decelerations are pathological. According to the American College of Obstetricians and Gynecologists (2019a), recurrent variable decelerations with minimal to moderate variability are *indeterminate*, whereas those with absent variability are *abnormal*.

A *saltatory* FHR baseline is another pattern linked to umbilical cord complications during labor (Fig. 24-11) (Hammacher, 1968). The pattern is rapidly recurring couplets of acceleration and deceleration causing relatively large oscillations of the FHR baseline. We also observed a relationship between cord occlusion and the saltatory pattern in postterm pregnancies (Leveno, 1984). In the absence of other FHR findings, this pattern does not signal fetal compromise.

Prolonged Deceleration

This pattern is defined as an isolated deceleration with a depth >15 bpm and length ≥2 minutes but <10 minutes from onset to return to baseline (Fig. 24-12). Prolonged decelerations are difficult to interpret because they are seen in many different clinical situations. Frequent causes are cervical examination, uterine hyperactivity, cord entanglement, and maternal supine hypotension. Epidural, spinal, or

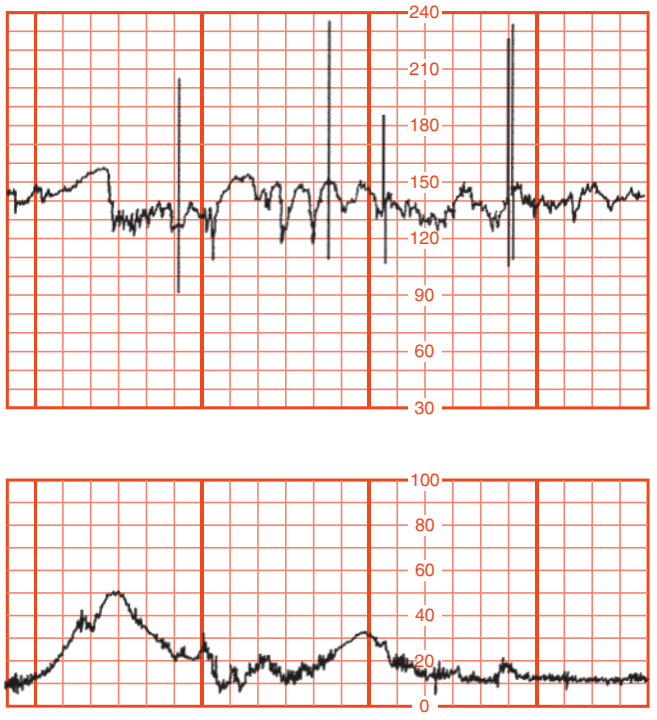

FIGURE 24-11 Saltatory baseline fetal heart rate showing rapidly recurring couplets of acceleration combined with deceleration.

paracervical analgesia may induce a prolonged deceleration (Eberle, 1998). Of women given epidural analgesia during labor in one analysis at Parkland Hospital, prolonged deceleration was noted in 1 percent (Hill, 2003). Other causes include placental abruption, umbilical cord knots or prolapse, maternal hypoperfusion or hypoxia from any cause, maternal seizures, fetal scalp-electrode application, impending birth, or maternal Valsalva maneuver.

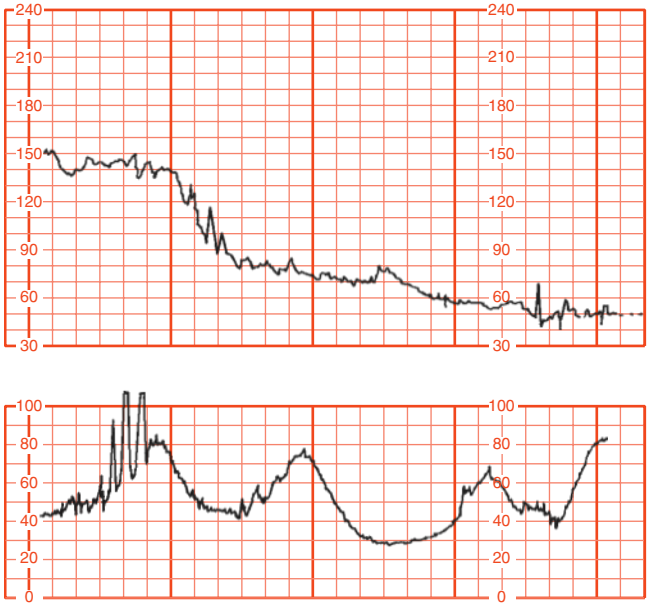

FIGURE 24-12 Prolonged fetal heart rate deceleration due to uterine hyperactivity. Approximately 3 minutes of the tracing are shown, but the fetal heart rate returned to normal after uterine hypertonus resolved. Vaginal delivery later ensued.

The placenta can effectively resuscitate the fetus if the original insult does not recur immediately. Occasionally, such self-limited prolonged decelerations are followed by loss of variability, baseline tachycardia, and even a period of late decelerations. These all resolve as the fetus recovers. Freeman and colleagues (2003) emphasize that the fetus may die during prolonged decelerations. Thus, management of prolonged decelerations can be extremely tenuous. Management of isolated prolonged decelerations is based on bedside clinical judgment, which inevitably will sometimes be imperfect given the unpredictability of these decelerations.

Fetal Heart Rate Patterns During Second-stage Labor

Decelerations are virtually ubiquitous during the second-stage labor. In one study, only 1.4 percent of more than 7000 deliveries lacked decelerations during this stage (Melchior, 1985). Both cord and fetal head compressions are implicated as causes of decelerations and of baseline bradycardia in this stage. In one series, profound, prolonged FHR deceleration in the 10 minutes preceding vaginal delivery was associated with intervention and good fetal outcomes (Boehm, 1975). In a later extension of this series, similarly prolonged second-stage decelerations were also associated with a stillbirth and neonatal death (Herbert, 1981). These experiences attest to the unpredictability of the FHR during second-stage labor.

In the analysis noted earlier by Cahill and associates (2018), an increasing total deceleration area found in the final 120 minutes prior to delivery was most predictive of fetal acidemia. A combination of deceleration area plus a 10-minute period of tachycardia was most predictive of neonatal morbidity. Others have reported similar findings (Krebs, 1981; Picquard, 1988). Gull and colleagues (1996) observed that abrupt FHR decelerations to <100 bpm associated with lost variability for ≥4 minutes predicted fetal acidemia. Thus, second-stage decelerations plus an abnormal FHR baseline (bradycardia or tachycardia and/or absent variability) are associated with greater risk for fetal compromise (Fig. 24-13).

Computerized Interpretation

FHR pattern interpretations are subjective. Thus, the potential for computer assistance to enhance the precision of identifying abnormal patterns appeared promising. The INFANT Collaborative Group (2017) studied whether the addition of computer-based decision-support software for FHR pattern interpretation lowered the number of poor neonatal outcomes. In this large trial, women were randomly assigned to computer-assisted interpretation or to conventional clinical interpretation. Rates of adverse perinatal outcomes that included intrapartum stillbirth, early neonatal death, and neonatal encephalopathy were not improved, and a subset showed no difference in neurological development at 2 years. Cesarean delivery rates were similar in both groups. In a subsequent analysis of 71 adverse outcomes, computer interpretation of FHR tracings was deemed completely valid in only 34 percent of cases. Computer analysis missed a significant portion of decelerations, reduced variability, and tachysystole (Steer, 2019).

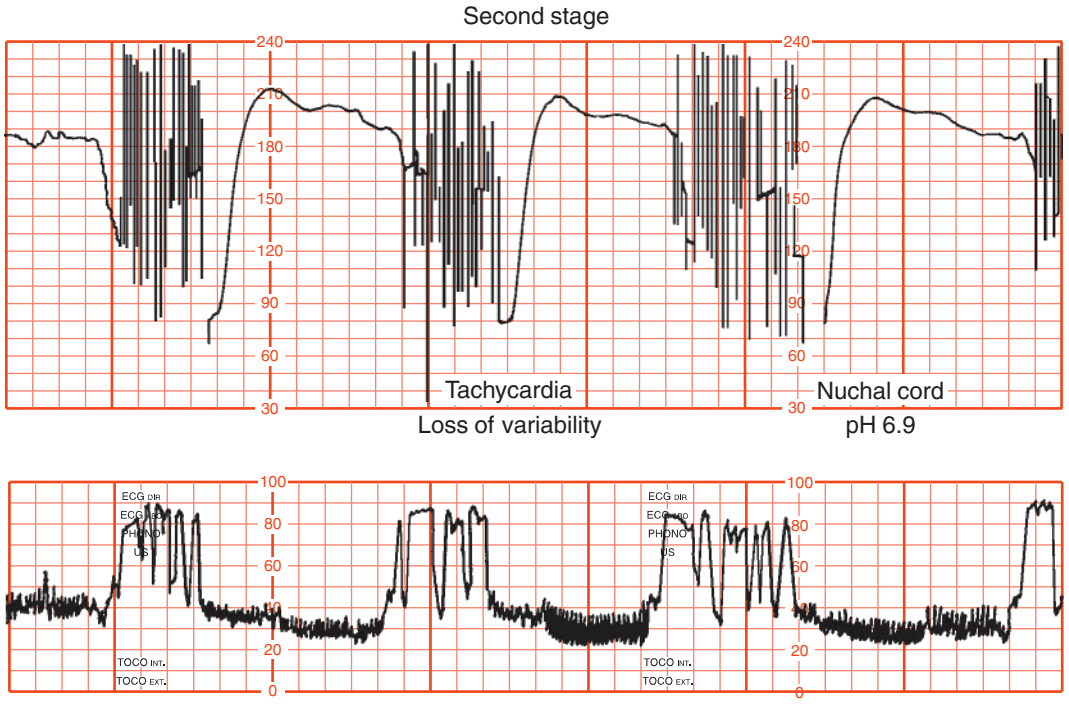

FIGURE 24-13 Cord-compression fetal heart rate decelerations in second-stage labor associated with tachycardia and loss of variability. The umbilical cord arterial pH was 6.9.

OTHER INTRAPARTUM ASSESSMENT TECHNIQUES

Fetal Scalp Blood Sampling

According to the American College of Obstetricians and Gynecologists (2019a), measurements of the pH in capillary scalp blood may help identify the fetus in serious distress. However, this group also emphasizes that neither normal nor abnormal scalp pH results accurately predict neonatal outcome. Although used in other countries, the procedure is not available at most hospitals in the United States.

With sampling, an illuminated endoscope is inserted through the dilated cervix after membrane rupture and is pressed firmly against the fetal scalp. The skin is wiped clean with a cotton swab and coated with a silicone gel, which allows fetal blood to accumulate as discrete globules. An incision is made through the fetal scalp to a depth of 2 mm with a special blade on a long handle. As a drop of blood forms on the surface, it is immediately collected into a heparinized glass capillary tube. The blood pH is measured promptly.

The pH of fetal capillary scalp blood is usually lower than that of umbilical venous blood and approaches that of umbilical arterial blood. In one algorithm, if the pH is ≥7.25, labor is observed, and if between 7.20 and 7.25, the pH measurement is repeated within 30 minutes (Zalar, 1979). If the pH is <7.20, another scalp blood sample is collected immediately, and delivery is performed promptly if the low pH level is confirmed. Otherwise, labor is allowed to continue, and scalp blood samples are repeated periodically.

The only benefits reported for scalp blood pH testing are fewer cesarean deliveries for fetal distress (Young, 1980b). However, Goodwin and coworkers (1994) showed a decrease in the scalp pH sampling rate from approximately 1.8 percent in the mid-1980s to 0.03 percent by 1992. This drop in sampling rate was not associated with a higher cesarean delivery rate for fetal distress. They concluded that scalp blood pH sampling was unnecessary.

Kruger and colleagues (1999) have assessed fetal scalp blood lactate concentration as an adjunct to pH. In one large randomized study, fetuses received scalp blood pH analysis or scalp blood lactate analysis (Wiberg-Itzel, 2008). The authors found either to be equivalent in predicting fetal acidemia. In a secondary analysis, prediction of low Apgar scores or admission to the neonatal intensive care unit did not differ between lactate and pH groups (Stal, 2020). However, cesarean delivery rates were higher in the lactate group.

Scalp Stimulation

Clark and coworkers (1984) have suggested that fetal scalp stimulation is an alternative to scalp blood sampling. This proposal stemmed from the observation that FHR acceleration followed pinching the fetal scalp with an Allis clamp just before obtaining scalp blood and was invariably associated with a normal pH level. However, failure to provoke acceleration was not uniformly predictive of fetal acidemia. In another study of 58 cases in which the FHR accelerated >10 bpm after 15 seconds of digital scalp stroking, 100 percent had a scalp blood pH >7.20 (Elimian, 1997). However, without an acceleration, only 30 percent had a scalp blood pH >7.20. Authors of a recent prospective study concluded that scalp stimulation was a reliable alternative to fetal scalp blood pH determination (Tahir Mahmood, 2018). In our practice, scalp stimulation is

often one element of intrapartum assessment of the fetus with a category II tracing.

Vibroacoustic Stimulation

FHR acceleration in response to vibroacoustic stimulation is another substitute for fetal scalp blood sampling (Edersheim, 1987). The technique uses an electronic artificial larynx placed 1 cm from or directly onto the maternal abdomen (Chap. 20, p. 387). Response to vibroacoustic stimulation is considered normal if the FHR accelerates within 15 seconds after the stimulus and with prolonged fetal movements (Sherer, 1994).

Lin and colleagues (2001) prospectively studied vibroacoustic stimulation in 113 women in labor with either moderate to severe variable or late FHR decelerations. They concluded that this technique effectively predicts fetal acidosis in cases with variable decelerations. In the setting of late decelerations, its prediction of fetal acidosis, however, is limited. Other authors found vibroacoustic stimulation in second-stage labor did not predict neonatal outcome or enhance labor management (Anyaegbunam, 1994).

Skupski and coworkers (2002) performed a metaanalysis of reports on intrapartum fetal stimulation tests. These included fetal scalp puncture for blood pH testing, fetal scalp pinching, vibroacoustic stimulation, and digital stroking of the fetal scalp. Results were similar for all four methods. These authors concluded that intrapartum stimulation tests were useful to exclude fetal acidemia. They cautioned, however, that these tests are "less than perfect."

Fetal Pulse Oximetry

Using technology similar to that of adult pulse oximetry, this tool measures fetal oxyhemoglobin saturation once membranes are ruptured. A unique padlike sensor is inserted through the cervix and positioned against the fetal face. Using fetal pulse oximetry, the lower limit for normal fetal oxygen saturation is generally considered to be 30 percent (Gorenberg, 2003; Stiller, 2002). However, when measured in umbilical arterial blood, fetal oxygen saturation normally varies greatly.

In one large trial of this technology, women with term fetuses that developed abnormal FHR patterns were assigned to conventional FHR monitoring alone or FHR monitoring plus continuous fetal pulse oximetry (Garite, 2000). The use of fetal pulse oximetry significantly reduced the cesarean delivery rate for nonreassuring fetal status from 10.2 to 4.5 percent. No neonatal benefits or adverse effects were associated with fetal pulse oximetry. Based on these observations, the U.S. Food and Drug Administration (FDA) approved marketing of the Nellcor N-400 Fetal Oxygen Monitoring System. However, three subsequent trials compared fetal pulse oximetry with standard care. In each, neonatal outcomes were similar between study arms. In one, the addition of oximetry significantly reduced cesarean delivery rates for fetal indications (East, 2006). However, two studies found no difference in cesarean delivery rates between the two study arms (Bloom, 2006; Klauser, 2005). Because of these findings, in 2005, the manufacturer discontinued device sales in the United States.

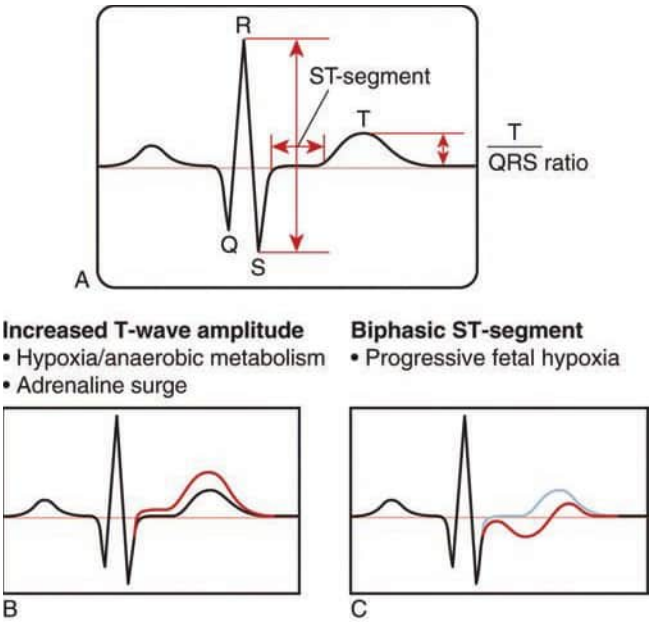

FIGURE 24-14 A. Generation of T:QRS ratio from a normal ST segment. **B.** ST-segment elevation in hypoxic conditions. **C.** Biphasic ST-segment waveform with progressive fetal hypoxia.

Fetal Electrocardiography

As fetal hypoxia worsens, the fetal ECG changes. Namely, the mature fetus with hypoxemia develops an elevated ST segment and a progressive rise in the T-wave height that can be expressed as a T:QRS ratio (Fig. 24-14) (Devoe, 2006). Increasing T:QRS ratios are thought to reflect fetal cardiac ability to adapt to hypoxia and appear before neurological damage. Further worsening of hypoxia then leads to progressively negative ST-segment deflection that creates a biphasic form. It is reasonable to consider that ST-segment abnormalities might occur late in the course of fetal compromise. Indeed, it has been hypothesized that ST-segment changes reflect myocardial tissue hypoxia.

Because of these findings, these parameters have been evaluated as an adjunct to conventional fetal monitoring. The technique requires internal FHR monitoring and special equipment to process the fetal ECG. In 2005, the manufacturer—Neoventa Medical—received FDA approval for their ST-segment analysis program named the *STAN system*.

Several studies have evaluated ST-segment changes with fetal monitoring. In one randomized trial of 2400 pregnancies, neonatal outcomes were not improved compared with those in which conventional FHR monitoring alone was used (Westgate, 1993). However, the cesarean delivery rate for fetal distress declined in those with ST-segment analysis. Subsequent studies revealed conflicting data regarding lower rates of operative delivery, fetal acidemia, and neonatal encephalopathy (Amer-Wåhlin, 2001; Becker, 2012; Doria, 2007).

In a trial by the NICHD, 5532 women were randomly assigned to an ST-segment analysis and 5576 to standard intrapartum management. The primary outcome was a composite of one or more of seven events associated with fetal compromise (Belfort, 2015). In the ST-segment analysis group, clinician

actions were directed by predetermined guidelines. These stipulated that intervention should be withheld, that is, expectant management adopted, for at least 60 minutes despite the presence of minimal variability; variable decelerations lasting ≥60 seconds or dropping to a level ≥60 bpm; recurrent late decelerations; or prolonged decelerations lasting >2 minutes, so long as no ST-segment abnormality was present. These guidelines did not pertain to the standard group. Notably, in the ST-segment analysis group, 55 (20 percent) of the 287 cesarean deliveries performed for fetal indications were done even though trial guidelines indicated that labor could continue. In these cases, physicians likely perceived the FHR patterns to reflect those formerly accepted in their usual practice as nonreassuring. These results showed that STAN system had no effect on neonatal outcome or cesarean delivery rates (Belfort, 2015). A subsequent systematic review reached similar conclusions (Neilson, 2015). These results have essentially eliminated use of ST-segment analysis in the United States, but it is still used in Europe.

NONREASSURING FETAL STATUS

The term *fetal distress* is too broad and vague to be applied with any precision to clinical situations (American College of Obstetricians and Gynecologists, 2019d). Uncertainty regarding the diagnosis based on FHR pattern interpretation has given rise to descriptions such as *reassuring* or *nonreassuring*. The former suggests confidence in the health of the fetus. In contrast, a nonreassuring designation suggests inability to remove doubt. However, these assessments are subjective judgments that are inevitably imperfect and must be recognized as such. The American College of Obstetricians and Gynecologists (2019d) recommends use of these terms followed by a description of the findings.

The difficulty in assigning a nonreassuring label to FHR patterns stems in part from the fact that these patterns reflect fetal physiology more so than pathology. Heart rate control stems from interconnected mechanisms that depend on blood flow and oxygenation. Moreover, these mechanisms are influenced by the preexisting state of fetal oxygenation. Chronic placental insufficiency is one example. Thus, normal labor is a process of repeated fetal hypoxic events and can infrequently lead to significant acidemia (Rogers, 1998).

Diagnosis

Identification of nonreassuring fetal status based on FHR patterns is imprecise. One study of interobserver agreement with FHR pattern interpretation found that consensus varied (Ayres-de-Campos, 1999). Specifically, experts agreed on 62 percent of normal patterns, 42 percent of suspicious patterns, and only 25 percent of pathological patterns. In another study, 17 experts reviewed 50 tracings on two occasions, at least 1 month apart. Approximately 20 percent changed their own interpretations, and approximately 25 percent did not agree with the interpretations of their colleagues (Keith, 1995).

In an attempt to resolve this imprecision, the NICHD recommended a three-tier system for FHR pattern classification (Table 24-2). The American College of Obstetricians and Gynecologists (2019b) has recommended its use. To assess this tiered system, Jackson and associates (2011) studied 48,444 women in labor and found that category I patterns were observed in 99.5 percent of tracings. Category II patterns were found in 84.1 percent, and category III patterns were seen in 0.1 percent

TABLE 24-2. Three-Tier Fetal Heart Rate Interpretation System

Category I—Normal

Include all of the following:

- Baseline rate: 110–160 bpm
- Baseline FHR variability: moderate
- Late or variable decelerations: absent
- Early decelerations: present or absent
- Accelerations: present or absent

Category II—Indeterminate

Include all FHR tracings not categorized as category I or III.

Category II tracings may represent an appreciable fraction of those encountered in clinical care. Examples include any of the following:

Baseline rate

- Bradycardia not accompanied by absent baseline variability
- Tachycardia

Baseline FHR variability

- Minimal baseline variability
- Absent baseline variability not accompanied by recurrent decelerations
- Marked baseline variability

Accelerations

- Absence of induced accelerations after fetal stimulation

Periodic or episodic decelerations

- Recurrent variable decelerations accompanied by minimal or moderate baseline variability
- Prolonged deceleration ≥2 min but <10 min
- Recurrent late decelerations with moderate baseline variability
- Variable decelerations with other characteristics, such as slow return to baseline, "overshoots," or "shoulders"

Category III—Abnormal

Include either:

- Absent baseline FHR variability and any of the following:
  Recurrent late decelerations
  Recurrent variable decelerations
  Bradycardia
- Sinusoidal pattern

bpm = beats per minute; FHR = fetal heart rate.
Reproduced with permission from Macones GA, Hankins GD, Spong CY, et al: The 2008 National Institute of Child Health and Human Development workshop report on electronic fetal monitoring: update on definitions, interpretation, and research guidelines, Obstet Gynecol. 2008 Sep;112(3):661–666.

(54 women). During labor, 84 percent of women had a mix of categories. The American College of Obstetricians and Gynecologists and the American Academy of Pediatrics (2019d) has concluded that a category I or II tracing with a 5-minute Apgar score >7 or with normal arterial blood acid–base values is not consistent with an acute hypoxic-ischemic event.

Other studies have evaluated this three-tiered system. In one, the incidence of umbilical cord acidemia (pH ≤7.10) was correlated retrospectively with FHR characteristics during the 30 minutes preceding delivery. None of the three categories demonstrated a significant association with cord blood acidemia (Cahill, 2012). Sholapurkar (2012) has challenged the validity of the three-tier system because most abnormal FHR patterns fall into the indeterminate category II. It was suggested that this resulted from most FHR decelerations being inappropriately classified as *variable* and attributed to cord compression.

Parer and King (2010) compared this situation in the United States with that of other countries in which a consensus on classification and management has been reached by their professional societies. These authors note that the NICHD three-tier system is inadequate because category II contains a vast heterogenous mixture of patterns that prevents development of a management strategy. Weissbach and associates (2018) found that duration of category II tracings does not predict perinatal asphyxia, but the individual components of diminished variability and fetal tachycardia are predictive.

Parer and Ikeda (2007) had previously proposed a color-coded five-tier system for both FHR interpretation *and* management. Two subsequent reports have compared the five- and three-tier systems. In one, the two systems were similar in FHR interpretations for tracings that were either very normal or very abnormal (Bannerman, 2011). The other study found that the five-tier system had better sensitivity than the three-tier one (Coletta, 2012). It is apparent that despite decades of electronic FHR monitoring, a consensus on FHR pattern interpretation and diagnosis is still lacking (Parer, 2011).

■ Meconium in the Amnionic Fluid

Obstetricians have long realized that meconium during labor is an inaccurate predictor of fetal distress or asphyxia. Indeed, although 12 to 22 percent of labors are complicated by meconium, only a few are linked to neonatal mortality. In an investigation from Parkland Hospital, meconium was found to be a "low-risk" obstetrical hazard because the perinatal mortality rate attributable to meconium was only 1 death per 1000 live births (Nathan, 1994).

Three etiological theories may explain the tenuous association between meconium passage and neonatal mortality. First, fetuses may pass meconium in response to hypoxia, and meconium therefore signals fetal compromise (Walker, 1953). Second, however, in utero passage of meconium may represent normal gastrointestinal tract maturation under neural control (Mathews, 1979). A final theory posits that common but transient umbilical cord entrapment leads to vagal stimulation, increased bowel peristalsis, and meconium passage (Hon, 1961).

Jovanovic and Nguyen (1989) observed that meconium aspirated into fetal lungs during gasping caused aspiration syndrome only in asphyxiated animals. Ramin and associates (1996) studied almost 8000 pregnancies with meconium-stained amnionic fluid delivered at Parkland Hospital. Meconium aspiration syndrome was significantly associated with fetal acidemia at birth. Further analysis of umbilical blood gases suggested that the fetal compromise associated with meconium aspiration syndrome was an acute event. This is because most acidemic fetuses had abnormally elevated P_{CO_2} values rather than a pure metabolic acidemia. Other significant correlates of aspiration included cesarean delivery, forceps to expedite delivery, intrapartum FHR abnormalities, depressed Apgar scores, and need for assisted ventilation at delivery.

Ramin and colleagues (1996) hypothesized that the pathophysiology of meconium aspiration syndrome includes, but is not limited to, fetal hypercarbia, which stimulates fetal respiration leading to aspiration of meconium into the alveoli. Lung parenchymal injury is secondary to acidemia-induced alveolar cell damage. In this pathophysiological scenario, meconium in amnionic fluid is a fetal environmental hazard rather than a marker of preexisting compromise. This proposed pathophysiological sequence is not all-inclusive, because it does not account for approximately half of the cases of meconium aspiration syndrome in which the fetus is not acidemic at birth.

Thus, the high incidence of meconium observed in the amnionic fluid during labor often represents normal physiological fetal passage of gastrointestinal contents. Although normal, such meconium becomes an environmental hazard when fetal acidemia from hypercarbia supervenes. Importantly, such acidemia occurs acutely, and therefore meconium aspiration is unpredictable and likely unpreventable.

Growing evidence indicates that many newborns with meconium aspiration syndrome have suffered chronic hypoxia before birth (Ghidini, 2001). In one study, 60 percent of neonates diagnosed with meconium aspiration syndrome had umbilical artery blood pH ≥7.20, which implies that the syndrome was unrelated to the neonatal condition at delivery (Blackwell, 2001). Similarly, comorbid markers of chronic hypoxia, such as elevated fetal erythropoietin levels and increased nucleated red blood cell counts in newborns, suggest that chronic hypoxia is involved in many meconium aspiration syndrome cases (Dollberg, 2001; Jazayeri, 2000).

Previously, routine obstetrical management of a newborn with meconium-stained amnionic fluid included intrapartum suctioning of the oropharynx and nasopharynx. Current recommendations state that newborns with meconium-stained amnionic fluid, regardless of their vigor, should no longer routinely receive intrapartum suctioning (American College of Obstetricians and Gynecologists, 2021; Wyckoff, 2015). Suctioning is reserved for those with airway obstruction. They also recommend that an appropriately credentialed team with full resuscitation skills be available (Chap. 32, p. 586).

■ Management Options

Initial management of variant FHR patterns aims to correct any fetal insult, if possible. Suggestions are listed in Table 24-3. The woman is moved to a lateral position, and supplemental oxygen is provided by mask. Correcting maternal hypotension

TABLE 24-3. Some Resuscitative Measures for Category II or Category III Tracings

Fetal Heart Rate Abnormality[a]	Interventions[b]
Recurrent late decelerations Minimal or absent FHR variability	Initial actions: lateral decubitus positioning; administer maternal oxygen; intravenous fluid bolus; reduce uterine contraction frequency
Prolonged decelerations or bradycardia Tachysystole with category II or III tracing	Initial actions plus discontinue oxytocin or prostaglandins; consider terbutaline
Recurrent variable decelerations Prolonged decelerations or bradycardia	Initial actions plus consider amnioinfusion; with cord prolapse, manually elevate the presenting part while preparing for immediate delivery

[a]Simultaneous evaluation of the suspected cause(s) is also an important step in management of abnormal FHR tracings.
[b]The combination of multiple interventions simultaneously may be appropriate and potentially more effective than doing them individually or serially.
FHR = fetal heart rate.

caused by regional analgesia and discontinuing oxytocin both serve to improve uteroplacental perfusion. Vaginal examination excludes a prolapsed cord or impending delivery. Simpson and James (2005) assessed the benefits of three maneuvers in 52 women with fetal oxygen saturation sensors already in place. They provided IV hydration with 500 to 1000 mL of lactated Ringer solution given over 20 minutes; lateral versus supine positioning; and administration of supplemental oxygen at 10 L/min using a nonrebreathing mask. Each of these maneuvers significantly raised fetal oxygen saturation levels. A randomized trial comparing oxygen via face mask to room air showed no difference in resolution of recurrent decelerations (75 percent versus 86 percent), time to resolution of recurrent decelerations, and total deceleration area (Raghuraman, 2020b).

Tocolysis

Terbutaline sulfate given to relax the uterus can be a temporizing maneuver in the management of nonreassuring FHR patterns during labor. A single 250-μg IV or subcutaneous injection is used to inhibit uterine contractions and thereby improve fetal oxygenation. One study described 368 pregnancies in which terbutaline was used to relieve contractions in preparation for cesarean delivery that was already planned for nonreassuring fetal status (Cook, 1994). Compared with a group not receiving tocolysis, the treated group had fewer 5-minute Apgar scores <7. Small IV doses of nitroglycerin—60 to 180 μg—also have reported benefit (Mercier, 1997). In one comparator study, both agents resolved tachysystole, but nitroglycerin lowered mean arterial blood pressures (Pullen, 2007). Two systematic reviews both noted that data were limited and reached differing views on tocolysis benefits (Bullens, 2015; Leathersich, 2018). The American College of Obstetricians and Gynecologists (2019b) cites that evidence is insufficient to recommend tocolysis for nonreassuring FHR patterns. We consider terbutaline during labor stimulation to resolve tachysystole-associated prolonged decelerations. However, the chance of success is balanced against terbutaline's side effects should cesarean delivery be needed for unresolved bradycardia. Namely, β agonist–related maternal tachycardia exacerbates the tachycardia associated with surgery itself. We consider maternal cardiopulmonary disease, poorly controlled hyperthyroidism, and maternal or fetal tachycardia with loss of variability to be contraindications.

Amnioinfusion

Early studies infused saline through an intrauterine pressure catheter in laboring women who had either variable or prolonged decelerations attributed to cord compression (Miyazaki, 1983, 1985). Such therapy improved the FHR pattern and decreased cesarean delivery rates for fetal indications. For variable decelerations, other studies also support amnioinfusion to reduce variable deceleration frequency, improve neonatal outcome, and lower cesarean delivery rates (Hofmeyr, 2012; Raghuraman, 2020a). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) conclude that amnioinfusion is a reasonable approach to treat repetitive variable decelerations but not late decelerations. As a prophylactic tool in known cases of oligohydramnios, evidence does not support amnioinfusion to prevent cord compression-related decelerations (Nageotte, 1991; Ogundipe, 1994). Last, attempts to flush out or dilute thick meconium are not recommended (Fraser, 2005; Xu, 2007).

Despite differing amnioinfusion protocols, most provide a 500- to 800-mL bolus of warmed normal saline, which is followed by a continuous infusion of 3 mL/min (Owen, 1990; Pressman, 1996). Rinehart and colleagues (2000) administered a 500-mL bolus of normal saline at room temperature alone or this bolus plus a continuous infusion at 3 mL/min. They included 65 women with variable decelerations and found neither method to be superior. Potential amnioinfusion complications are summarized in Table 24-4 from a U.S. survey of fellowship and residency directors (Wenstrom, 1995).

TABLE 24-4. Complications Associated with Amnioinfusion from a Survey of 186 Obstetrical Units

Complication	Percent
Uterine hypertonus	14
Abnormal fetal heart rate tracing	9
Chorioamnionitis	4
Maternal cardiac or respiratory compromise	2
Uterine rupture	2
Maternal death	1
Other: cord prolapse, abruption	5

Fetal Heart Rate Patterns and Brain Injury

Studies attempting to correlate FHR patterns with brain injury have primarily examined infants identified in medicolegal actions. Phelan and Ahn (1994) reported that among 48 fetuses later found to be neurologically impaired, a persistent nonreactive FHR tracing was already present at the time of admission in 70 percent. They concluded that fetal neurological injury occurred predominantly before arrival to the hospital. When they looked retrospectively at FHR patterns in 209 brain-injured newborns, they concluded that there was not a single unique pattern associated with fetal neurological injury (Ahn, 1996). Others have reported the same conclusion (Nakao, 2020; Phelan, 2000). In a review of literature published between 1966 and 2006 on the effect of FHR monitoring to prevent perinatal brain injury, the summary found no benefit (Graham, 2006).

FHR patterns necessary for perinatal brain damage have been studied in animals. Myers (1972) described the effects of complete and partial asphyxia in rhesus monkeys (Fig. 24-15). Complete asphyxia was produced by total occlusion of umbilical blood flow that led to prolonged deceleration. Fetal arterial pH did not drop to 7.0 until approximately 8 minutes after complete cessation of oxygenation and umbilical flow. At least 10 minutes of such prolonged deceleration were required before surviving fetuses demonstrated brain damage.

The most common FHR pattern during labor—due to umbilical cord occlusion—requires considerable time to significantly affect the fetus in experimental animals. Clapp and colleagues (1988) partially occluded the umbilical cord for 1 minute every 3 minutes in fetal sheep. Rocha and associates (2004) totally occluded the umbilical cord for 90 seconds every 30 minutes for 3 to 5 hours a day for 4 days without producing necrotic brain cell injury. Results from such studies suggest that the effects of umbilical cord entrapment depend on the degree, the duration, and the frequency of such occlusions.

The contribution of intrapartum events to subsequent neurological handicaps has been greatly overestimated, as discussed in Chapter 33 (p. 601). For brain damage, the fetus must be exposed to much more than a brief period of hypoxia. Moreover, the hypoxia must cause profound, just barely sublethal metabolic acidemia. Because of this, the American College of Obstetricians and Gynecologists (2019d) has recommended umbilical cord blood gases be obtained when cesarean delivery is performed for fetal compromise or when a low 5-minute Apgar score, severe fetal-growth restriction, an abnormal FHR tracing, or multifetal gestation is present (Chap. 32, p. 593).

Until recently, the prognosis for moderately affected newborns with hypoxic-ischemic encephalopathy (HIE) was poor. More recently, studies show that brain cooling administered to newborns suffering neonatal HIE could ameliorate the development of subsequent cerebral palsy (Chap. 33, p. 602).

Benefits of Electronic Fetal Heart Rate Monitoring

Several false assumptions underlie the expectation of improved perinatal outcome with electronic FHR monitoring. One is that nonreassuring fetal status is a slowly developing phenomenon and that electronic monitoring permits early detection of the compromised fetus. Another presumption is that all fetal injury develops in the hospital. In reality, most neurologically damaged fetuses suffer insults before arrival at labor units. The very term *fetal monitor* implies that this inanimate technology in some fashion "monitors." The assumption is made that if a dead or damaged fetus is delivered, the tracing strip must provide some clue, because this device was monitoring fetal condition. These assumptions led to expectations that all neonatal deaths or injuries were preventable.

By the end of the 1970s, questions regarding the efficacy, safety, and costs of electronic monitoring were being voiced. Banta and Thacker (2002) reviewed the benefits, or lack thereof, of electronic FHR monitoring. More recently, a review of 13 randomized trials involving more than 37,000 women concluded that electronic FHR monitoring was associated with fewer neonatal seizures but a higher rate of cesarean and operative vaginal deliveries (Alfirevic, 2017). However, rates of perinatal mortality or cerebral palsy did not decline. Grimes and Peipert (2010) concluded that such monitoring has failed as a public health screening program. They noted that the positive-predictive value of electronic FHR monitoring for fetal death in labor or cerebral palsy is near zero and reflects that "almost every positive test result is wrong."

Epidemiologically, two large studies in the United States reported a decline in neonatal mortality rates due to electronic

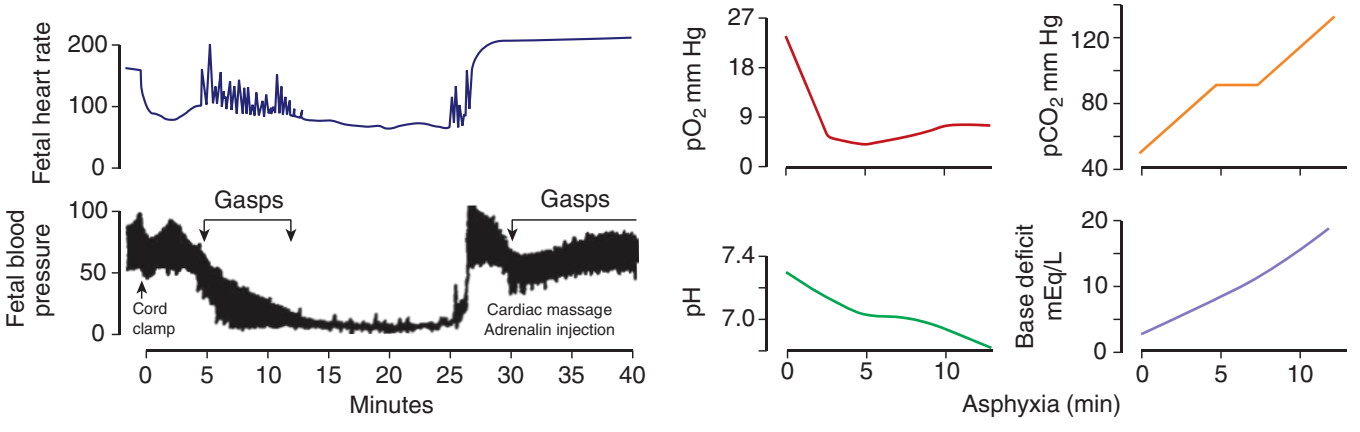

FIGURE 24-15 Prolonged deceleration in a rhesus monkey shown with blood pressure and biochemical changes during total occlusion of umbilical cord blood flow.

FHR monitoring. However, the highest effect was seen in preterm neonates (Ananth, 2013; Chen, 2011). Of note, caution must be used in interpreting these studies, as epidemiological association does not establish causation (Resnik, 2013).

At admission for labor, most women with low-risk pregnancies are monitored for a short time. In one study, 3752 low-risk women in spontaneous labor were randomly assigned at admission to either FHR auscultation or 20 minutes of electronic FHR monitoring (Mires, 2001). Electronic FHR monitoring did not improve neonatal outcome. Moreover, its use resulted in a greater number of interventions, including operative delivery. A similar study echoed these neonatal outcomes (Impey, 2003). Last, admission FHR monitoring for low-risk pregnancy is associated with a higher cesarean delivery rate but not improved neonatal outcomes in one Cochrane review (Devane, 2017).

At Parkland Hospital in July 1982, an investigation began to ascertain whether all women during labor should undergo electronic monitoring (Leveno, 1986). In alternating months, universal electronic FHR monitoring was rotated with selective FHR monitoring, which was the prevailing practice. During the 3-year investigation, more than 17,000 labors were managed using universal electronic FHR monitoring, and these outcomes were compared with a similar-sized cohort of women selectively monitored electronically. No significant differences were found in any perinatal outcome. With universal monitoring, a small but significant increase in the cesarean delivery rate for fetal distress was noted. Thus, greater application of electronic FHR monitoring at Parkland Hospital did not improve perinatal results but did slightly raise the frequency of cesarean delivery for fetal distress. More recently, a Cochrane Database review found that intermittent auscultation was associated with a higher cesarean delivery rate compared with continuous monitoring (Martis, 2017).

Current Recommendations

Methods most commonly used for intrapartum FHR monitoring include intermittent auscultation with a fetal stethoscope or a Doppler ultrasound device, or continuous electronic monitoring of FHR and uterine contractions. Evidence has not identified the most effective method nor the frequency or duration of fetal surveillance that ensures optimum results. That said, Table 24-5 summarizes current guidelines from the American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2017). Intermittent auscultation or continuous electronic monitoring is considered an acceptable method of intrapartum surveillance in both low- and high-risk pregnancies. The recommended interval between checking the heart rate, however, is longer in the uncomplicated pregnancy. When auscultation is used, it is recommended that it be performed after a contraction and for 60 seconds. It also is recommended that a 1-to-1 nurse–patient ratio be used if auscultation is employed. The position taken by the American College of Obstetricians and Gynecologists (2019b) acknowledges that available data do not show a clear benefit to the use of electronic monitoring over intermittent auscultation. At Parkland Hospital, all high-risk labors are continuously monitored electronically. In low-risk pregnancies, both intermittent auscultation and continuous electronic monitoring are used depending on clinical circumstances, including the woman's desire to ambulate.

TABLE 24-5. Guidelines for Methods of Intrapartum Fetal Heart Rate Monitoring

Surveillance	Low-Risk Pregnancies	High-Risk Pregnancies
Acceptable methods		
Intermittent auscultation	Yes	Yes[a]
Continuous electronic monitoring (internal or external)	Yes	Yes[b]
Evaluation intervals		
First-stage labor (active)	30 min	15 min[a,b]
Second-stage labor	15 min	5 min[a,c]

[a]Preferably before, during, and after a uterine contraction.
[b]Includes tracing evaluation and charting at least every 15 min.
[c]Tracing should be evaluated at least every 5 min.

INTRAPARTUM SURVEILLANCE OF UTERINE ACTIVITY

Analysis of electronically measured uterine activity permits some generalities concerning the relationship of certain contraction patterns and labor outcome. However, uterine muscle efficiency to bring about delivery varies greatly. Thus, caution should be exercised before diagnosing true labor or its absence solely from a monitor tracing.

With *internal monitoring* of contractions, amniotic fluid pressure is measured between and during contractions. An intrauterine pressure catheter is placed into the uterus with its distal tip above the presenting part. The catheter tip contains a pressure sensor and allows calculation of intrauterine pressure with each contraction (Fig. 24-16). With *external monitoring*, uterine contractions can be measured by a displacement transducer in which the transducer button, or "plunger," is held against the

FIGURE 24-16 Placement of an intrauterine pressure catheter to monitor contractions and their pressures. The catheter, contained within the light blue introducer, is inserted into the uterus and placed along one side of the fetal head. The catheter is then gently advanced into the uterus, and the introducer is withdrawn.

maternal abdominal wall. As the uterus contracts, the button moves in proportion to the strength of the contraction. This movement is converted into a measurable electrical signal that indicates the *relative* intensity of the contraction. It has generally been accepted that internal monitoring provided a more accurate measure of intensity. That said, in a randomized trial comparing internal versus external monitoring of uterine contractions in 1456 women, the two methods yielded equivalent operative delivery rates and neonatal outcomes (Bakker, 2010).

Patterns of Uterine Activity

Caldeyro-Barcia and Poseiro (1960), from Montevideo, Uruguay, were pioneers in elucidating the patterns of spontaneous uterine activity throughout pregnancy. Waves of uterine activity were usually measured using intraamnionic pressure catheters. But early in their studies, as many as four simultaneous intramyometrial microballoons also were used to record uterine pressure. Contraction intensity was defined as the rise in this pressure above a resting pressure baseline. These investigators also introduced the concept of *Montevideo units* to define uterine activity (Chap. 23, p. 435). With this definition, uterine performance is the product of contraction intensity in mm Hg multiplied by the number of contractions in a 10-minute span. For example, three contractions in 10 minutes, each with 50-mm Hg intensity, would equal 150 Montevideo units.

According to Caldeyro-Barcia and Poseiro (1960), clinical labor usually commences when uterine activity reaches values between 80 and 120 Montevideo units. This translates into approximately three contractions of 40 mm Hg every 10 minutes. Importantly, no clear-cut division marks labor onset, which is a gradual and progressive transition.

In first-stage labor, uterine contractions progressively grow in intensity from approximately 25 mm Hg at labor commencement to 50 mm Hg at its end. At the same time, the frequency advances from three to five contractions per 10 minutes, and uterine baseline tone rises from 8 to 12 mm Hg. Uterine activity is further enhanced during second-stage labor, aided by maternal pushing. Contraction intensity of 80 to 100 mm Hg is typical, and the uterus contracts as frequently as five to six times each 10 minutes. Hauth and coworkers (1986) quantified uterine contraction pressures in 109 women at term who received oxytocin for labor induction or augmentation. Most of these women achieved 200 to 225 Montevideo units, and 40 percent had up to 300 units to effect delivery. The authors suggested that these levels of uterine activity should be sought before consideration of cesarean delivery for presumed dystocia (Chap. 23, p. 436).

Interestingly, the duration of uterine contractions—60 to 80 seconds—does not lengthen appreciably from early active labor through the second stage (Bakker, 2007; Pontonnier, 1975). Presumably, this duration constancy serves fetal respiratory gas exchange. During a uterine contraction, as the intrauterine pressure exceeds that of the intervillous space, respiratory gas exchange is halted. This leads to functional fetal "breath holding," which has a 60- to 80-second limit that remains relatively constant.

Caldeyro-Barcia and Poseiro (1960) also observed empirically that uterine contractions are clinically palpable only after their intensity exceeds 10 mm Hg. Moreover, until the intensity of contractions reaches 40 mm Hg, the uterine wall can readily be depressed by the finger. At greater intensities, the uterine wall then becomes so hard that it resists easy depression. Uterine contractions usually are not associated with pain until their strength exceeds 15 mm Hg. Presumably, this is the minimum pressure required to distend the lower uterine segment and cervix.

Hendricks (1968) observed that "the clinician makes great demands upon the uterus." The uterus is expected to remain well relaxed during pregnancy, to contract effectively but intermittently during labor, and then to remain in a state of almost constant contraction for several hours postpartum. Figure 24-17 demonstrates an example of normal uterine

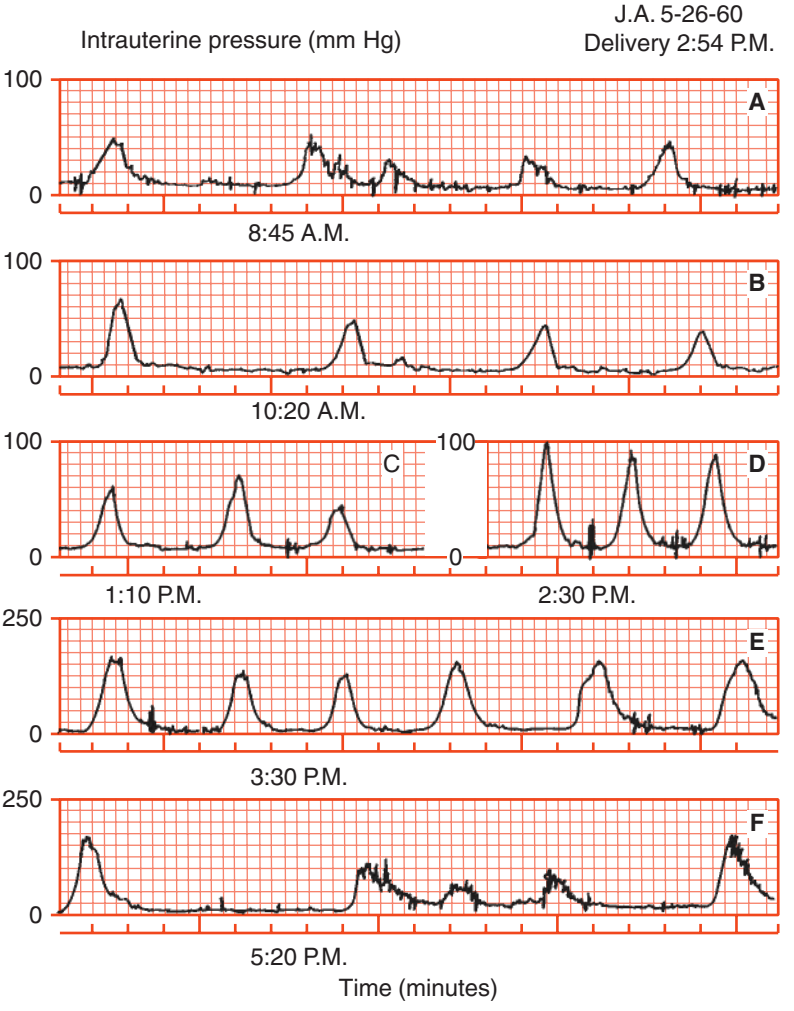

FIGURE 24-17 Intrauterine pressure recorded through a single catheter. **A.** Prelabor. **B.** Early labor. **C.** Active labor. **D.** Late labor. **E.** Spontaneous activity ½ hour postpartum. **F.** Spontaneous activity 2½ hours postpartum. (Redrawn from Hendricks CH: Uterine contractility changes in the early puerperium. Clin Obstet Gynecol 1968 Mar;11(1):125–144.)

activity during labor. Uterine activity progressively and gradually rises from early through late labor. Interestingly, uterine contractions after birth are identical to those resulting in delivery of the newborn. Logically, the uterus that performs poorly before delivery is also prone to atony and puerperal hemorrhage.

Uterine Contraction Terminology

Terms to describe uterine contractions have been recommended by the American College of Obstetricians and Gynecologists (2019b). *Normal uterine activity* is defined as five or fewer contractions in 10 minutes, averaged during a 30-minute span. *Tachysystole* is more than five contractions in 10 minutes, averaged over 30 minutes. Tachysystole can be applied to spontaneous or induced labor. The term *hyperstimulation* was abandoned.

Stewart and associates (2012) prospectively studied uterine tachysystole in 584 women undergoing labor induction with misoprostol at Parkland Hospital. A higher rate of adverse neonatal outcomes was not associated with an increasing number of contractions per 10 minutes or per 30 minutes. Counts of six or more contractions in 10 minutes, however, were significantly associated with FHR decelerations.

Electronic Fetal Monitoring Complications

Electrodes for FHR evaluation and catheters for uterine contraction measurement are both associated with infrequent but potentially serious complications. Rarely, an intrauterine pressure catheter may lacerate a fetal vessel in the placenta during placement. Also with insertion, placental and possibly uterine perforation can cause hemorrhage, abruption, and spurious recordings that have resulted in inappropriate management. Severe cord compression has been described from entanglement with the pressure catheter. Injury to the fetal scalp or breech by a FHR electrode is rarely severe. However, face presentations pose risk for eye or mouth trauma.

Both the fetus and the mother may be at greater risk of infection from internal monitoring (Faro, 1990). Scalp wounds from the electrode may become infected, but subsequent cranial osteomyelitis is rare (Brook, 2005; Eggink, 2004; McGregor, 1989). Certain maternal infections that include human immunodeficiency virus (HIV), herpes simplex virus, and hepatitis B and C virus are relative contraindications to internal FHR monitoring (American Academy of Pediatrics, 2017).

CHAPTER 25

Obstetrical Analgesia and Anesthesia

Obstetrical anesthesia presents unique challenges. Labor begins without warning, and anesthesia may be required within minutes of a full meal. Vomiting with aspiration of gastric contents is a constant threat. The usual physiological adaptations of pregnancy require special consideration, especially with disorders such as preeclampsia, placental abruption, or sepsis.

Obstetrical analgesia and anesthesia have become extraordinarily safe over the past 40 years (Hawkins, 2011). Anesthetic-related maternal mortality rates decreased more than 60 percent during this time, and from 2007 to 2017, only 0.4 percent of 6765 maternal deaths were due to anesthesia complications (Petersen, 2019). Creanga and colleagues (2017) reported the contribution of anesthetics to pregnancy-associated deaths has declined markedly in the United States (Fig. 25-1). Approximately two thirds of deaths associated with general anesthesia were caused by induction problems or intubation failures during cesarean delivery. Deaths associated with regional analgesia were caused by spinal or epidural blocks reaching higher than planned spinal levels—26 percent; respiratory failure—19 percent; and drug reaction—19 percent.

Of factors contributing to improved obstetrical anesthesia safety, the increased use of regional analgesia for labor and delivery is the most significant. For general anesthesia, the improved case-fatality rate is especially notable considering that this method is now used for the highest-risk patients and for emergencies with decision-incision intervals <15 minutes (Bloom, 2005). In addition, the incidence of aspiration, hypoxia, or other respiratory events has declined during the past three decades. This is likely due to use of difficult-airway algorithms, advanced airway equipment, and increased in-house anesthesia staffing (Davies, 2017; Lim, 2018). Despite these encouraging results with general anesthesia, rising complications with regional analgesia techniques are now reported (Davies, 2017).

GENERAL PRINCIPLES

Obstetrical Anesthesia Services

Every obstetrician should be proficient in local and pudendal analgesia for select circumstances. However, it is preferable for

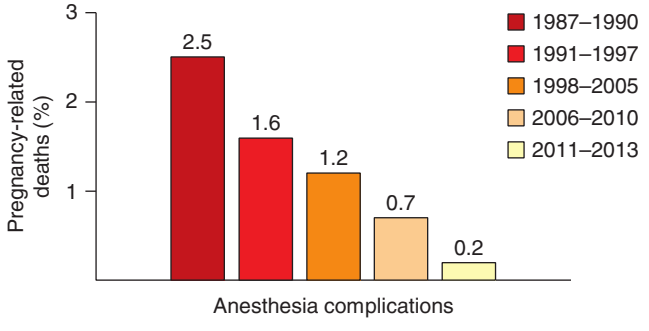

FIGURE 25-1 Contribution of anesthetic complications to pregnancy-associated deaths—United States, 1987–2013.

TABLE 25-1. Maternal Factors That May Prompt Anesthetic Consultation

Anatomical abnormalities of the face, neck, or spine
Thyromegaly
Cardiac, pulmonary, renal, hepatic, or neurological disease
Bleeding disorders
Prior anesthetic complications
Class III obesity (BMI ≥40 kg/m^2)
Obstetrical complications likely to lead to operative delivery
Severe pregnancy-associated hypertension
Obstetrical hemorrhage

BMI = body mass index.

an anesthesiologist or anesthetist to provide rapid and reliable pain relief to allow the obstetrician to focus attention on the laboring woman and her fetus.

The American College of Obstetricians and Gynecologists (2019b) and the American Society of Anesthesiologists (2016) have reaffirmed prior directives that a woman's request for labor pain relief is sufficient indication for its provision. Identification of any of the risk factors shown in Table 25-1 should prompt consultation and collaboration with anesthesia personnel. The resulting plan should ideally minimize the need for emergency anesthesia in this high-risk group.

Goals for optimizing obstetrical anesthesia services have been established by the American College of Obstetricians and Gynecologists (2019b) and the American Society of Anesthesiologists (2016). To achieve these goals, the following is a partial list of requisites:

1. Availability of a licensed practitioner credentialed to administer an appropriate anesthetic whenever necessary and to maintain support of vital functions in an obstetrical emergency
2. Availability of anesthesia personnel to permit the start of cesarean delivery within 30 minutes of the decision to perform the procedure (decision–incision time)
3. Anesthesia personnel immediately available to support an emergency cesarean delivery during the active labor of a woman attempting vaginal birth after prior cesarean (Chap. 31, p. 578)
4. Appointment of a qualified anesthesiologist to be responsible for all anesthetics administered
5. Availability of a qualified physician with obstetrical privileges to perform operative vaginal or cesarean delivery during anesthesia administration
6. Availability of equipment, facilities, and support personnel equal to that provided in a surgical suite
7. Immediate availability of personnel, other than the surgical team, to assume responsibility for resuscitation of a depressed newborn (Chap. 32, p. 586).

To meet these goals, 24-hour in-house anesthesia staffing is usually necessary. Providing such service in smaller facilities is more challenging. This is underscored by the fact that approximately 40 percent of all hospitals providing obstetrical care have fewer than 500 deliveries per year (American Academy of Pediatrics, 2017). Bell and coworkers (2000) calculated the financial burden that may be incurred to provide 24/7 obstetrical anesthesia coverage. They concluded that such coverage could not operate profitably at their tertiary referral institution, given the average indemnity and Medicaid reimbursement for labor epidural analgesia. Compounding this burden, some third-party payers have denied reimbursement for epidural analgesia in the absence of a specific medical indication—an approach repudiated by the American College of Obstetricians and Gynecologists (2019b).

■ Principles of Pain Relief

Labor pain caused by uterine contractions and cervical dilation is transmitted through visceral afferent sympathetic nerves entering the spinal cord from T_{10} through L_1. Later, perineal stretching transmits painful stimuli through the pudendal nerve and sacral nerves from S_2 through S_4. Cortical responses to pain and anxiety are complex and may be influenced by multiple factors.

Labor pain is a highly individual response to variable stimuli that are uniquely received and interpreted (Hawkins, 2010). These stimuli are modified by emotional, motivational, cognitive, social, and cultural circumstances. Specific modifiers are maternal expectations for her childbirth experience, age, antepartum labor education, and quality of emotional support. Major causes of dissatisfaction with pain relief are perceived labor pain and delay in ameliorating the pain (Yurashevich, 2019).

A mother's physiological responses to labor pain may influence maternal and fetal well-being and labor progress. First, a higher metabolic rate leads to more oxygen consumption and the resultant hyperventilation may induce hypocarbia. Second, the sympathetic nervous system response to pain leads to elevated circulating catecholamine levels. These in turn raise cardiac output and vascular resistance, which may raise maternal blood pressure. Catecholamines also directly can adversely affect uterine activity and uteroplacental blood flow. Last, pain, stress, and anxiety cause release of stress hormones such as cortisol and endorphins. Effective analgesia attenuates or eliminates these responses.

ANALGESIA AND SEDATION DURING LABOR

If uterine contractions cause discomfort, pain relief with a narcotic such as meperidine, plus an antiemetic tranquilizer such as promethazine, is appropriate. With a successful program of analgesia and sedation, discomfort usually is felt at the acme of a uterine contraction, and the mother can rest quietly between contractions. Appropriate drug selection and administration from the medications shown in Table 25-2 safely accomplishes these objectives.

■ Parenteral Agents

Meperidine and Promethazine

Meperidine, 50 to 100 mg, with promethazine, 25 mg, may be administered intramuscularly (IM) at intervals of 2 to

TABLE 25-2. Typical Parenteral Analgesic Agents for Labor Pain

Agent	Usual Dose	Frequency	Onset	Neonatal Half-Life
Meperidine	25–50 mg (IV) 50–100 mg (IM)	Every 1–2 hr Every 2–4 hr	5 min 30–45 min	~18–20 hr ~60 hr
Fentanyl	50–100 µg (IV)	Every 1 hr	1 min	~5 hr
Remifentanil	0.15–0.5 µg/kg (PCA)	Every 2 min	<1 min	10 min
Butorphanol	1–2 mg (IV or IM)	Every 4 hr	1–2 min (IV) 10–30 min (IM)	~5 hr
Morphine	2–5 mg (IV) 10 mg (IM)	Every 4 hr	5 min 30–40 min	~7 hr

IV = intravenously; IM = intramuscularly; PCA = patient-controlled analgesia.

4 hours. Analgesia is maximal 30 to 45 minutes after an IM injection. An almost immediate effect is achieved by giving meperidine intravenously (IV) in doses of 25 to 50 mg every 1 to 2 hours. In an earlier study, meperidine was found to be the most common opioid used worldwide for pain relief in labor (Bricker, 2002). Tsui and associates (2004) found meperidine to be superior to placebo for pain relief in the first stage of labor. In a randomized investigation at Parkland Hospital, IV patient-controlled analgesia (PCA) with meperidine was found to be an inexpensive and reasonably effective method for labor analgesia (Sharma, 1997). Women received 50-mg meperidine with 25-mg promethazine IV as an initial bolus. Thereafter, an infusion pump was set to deliver 15 mg of meperidine every 10 minutes as needed until delivery. Neonatal sedation, as measured by need for naloxone treatment in the delivery room, was identified in 3 percent of newborns.

Meperidine readily crosses the placenta, and its depressant effect in the fetus closely follows peak maternal analgesia. The active metabolite of meperidine, normeperidine, has a half-life of approximately 72 hours in the neonate. Therefore, other opioids discussed below are favored for labor analgesia. (American College of Obstetricians and Gynecologists, 2019b).

Butorphanol

This synthetic opioid-receptor agonist-antagonist narcotic, given in 1- to 2-mg IV doses every 4 hours as needed, compares favorably with meperidine for labor analgesia. Its major side effects are somnolence, dizziness, and dysphoria. Neonatal respiratory depression is less than with meperidine. Importantly, the two drugs are not given contiguously because butorphanol antagonizes the narcotic effects of meperidine. Hatjis and Meis (1986) described a transient sinusoidal fetal heart rate pattern following butorphanol administration, but no short-term maternal or neonatal adverse sequelae were noted (Chap. 24, p. 451).

Fentanyl

This short-acting and potent synthetic opioid may be given in doses of 50 to 100 µg IV every hour. Its main disadvantage is a short duration of action, which requires frequent dosing or use of a PCA pump. Atkinson and coworkers (1994) reported that butorphanol provided better initial analgesia than fentanyl and was associated with fewer requests for additional medication or for epidural analgesia.

Remifentanil

This ultrashort-acting opioid can be given using a PCA pump (see Table 25-2). Remifentanil is administered through a dedicated IV cannula to avoid bolus dosing, which can lead to apnea. Both respiratory monitoring and 1:1 nursing-to-patient ratio help watch for apneic spells, which occur in 25 percent of treated women (Stocki, 2014). In the RemiPCA SAFE Network Study, moderate maternal hypoxia (SaO_2 <94 percent) was documented in a fourth of women (Melber, 2019). A multicenter randomized study showed PCA-administered remifentanil halved the proportion of women subsequently requesting epidural analgesia compared with IM meperidine (Wilson, 2018).

Parenteral Agent Safety

Parenteral sedation is not without risks. Hawkins and colleagues (1997) reported that 4 of 129 maternal anesthetic-related deaths were from such sedation. One was from aspiration, two from inadequate ventilation, and one from overdosage.

Narcotics used during labor may cause newborn respiratory depression. Naloxone is a narcotic antagonist capable of reversing respiratory depression induced by opioid narcotics. It acts by displacing the narcotic from specific receptors in the central nervous system. After adequate ventilation has been established, naloxone may be given to a newborn whose mother received narcotics. Naloxone is contraindicated in a newborn of a narcotic-addicted mother because withdrawal symptoms may be precipitated (American Academy of Pediatrics, 2017).

■ Nitrous Oxide

A self-administered mixture of 50-percent nitrous oxide (N_2O) and oxygen may provide satisfactory analgesia during labor (Zafirova, 2018). Some preparations are premixed in a single cylinder (Entonox), and in others, a blender mixes the two gases from separate tanks (Nitronox). The gases are connected to a breathing circuit through a valve that opens only when the patient inspires. The use of intermittent nitrous oxide did not alter the rate of epidural analgesia but did improve birth experience satisfaction rates (Bobb, 2016; Lim, 2018). Maternal side effects include nausea, vomiting, dizziness, and drowsiness. Neonatal Apgar scores or umbilical cord blood gas results did not differ in women using

TABLE 25-3. Commonly Used Local Anesthetic Agents in Obstetrics

Anesthetic Agent[a]	Usual Concentration (%)	Usual Volume (mL)	Onset	Average Duration (min)	Maximum Dose (mg)	Clinical Use
Aminoesters[b]						
2-Chloroprocaine	2	10–20	Rapid	30–60	800	Local infiltration or pudendal block
	3	10–20		30–60		Epidural for cesarean or forceps delivery
Aminoamides[b]						
Bupivacaine	0.0625–0.125	5–10	Slow	60–90	175	Epidural for labor
	0.5	10–20		90–150		Epidural for cesarean
	0.75	1.5–2		60–120		Spinal for cesarean
Lidocaine	1–1.5	10–20	Rapid	30–60	300	Local infiltration or pudendal block
	1.5–2	5–20		60–90		Epidural for cesarean
	5	1.5–2		45–60		Spinal for D & C or puerperal tubal
Ropivacaine	0.08–0.2	5–10	Slow	60–90	200	Epidural for labor
	0.5–1	10–30		90–150	250	Epidural for cesarean

nitrous oxide compared with those selecting other pain management methods or no analgesia in labor (Likis, 2014).

NERVE BLOCKS

Various nerve blocks provide pain relief during labor and/or delivery. These include pudendal, paracervical, and neuraxial blocks such as spinal, epidural, dural-puncture epidural, and combined spinal-epidural techniques.

Anesthetic Agents

Commonly used nerve block anesthetics are summarized in Table 25-3. The dose of each agent varies widely and is dependent on the particular nerve block and physical status of the woman. The onset, duration, and quality of analgesia can be enhanced by increasing the anesthetic agent's dose, concentration, and volume or by altering its delivery mode. With their use, safety tenets include incremental boluses of the agent and carefully monitoring for early warning signs of adverse effects. Appropriate equipment and personnel to manage these reactions must be immediately available.

Local analgesic agents are manufactured in more than one concentration and ampule size, and this raises the potential for dosing errors. Most often, serious toxicity follows inadvertent intravenous, subarachnoid, or subdural injection. Systemic toxicity from local anesthetics typically manifests in the central nervous and cardiovascular systems. For this reason, before epidural analgesia is initiated, a mixture of a small amount of local anesthetic drug and epinephrine is given as a test dose. Epinephrine with its associated tachycardia is used as a marker to help identify incorrect placement if it occurs. A sudden significant elevation in the maternal heart rate or blood pressure within 1 to 2 minutes after administration suggests intravenous catheter placement. A block extending over wider than expected spinal levels and/or dense motor blockade indicate inadvertent catheter placement into the subarachnoid or into the subdural space.

Central Nervous System Toxicity

Early symptoms are those of *stimulation*, but as serum levels rise, *depression* follows. Symptoms may include lightheadedness, dizziness, tinnitus, metallic taste, and numbness of the tongue and mouth. Patients may also show bizarre behavior, slurred speech, and muscle fasciculation and excitation. Ultimately, generalized convulsions and loss of consciousness could result.

For neural and cardiac toxicity treatment, a rapid IV infusion of 20-percent intralipids effectively disassociates anesthetic drugs from neural and myocardial cell membranes. For patients weighing >70 kg, a 100-mL bolus dose of lipid emulsion is given. Boluses can be repeated once or twice every 5 minutes for persistent cardiac instability. The initial bolus is followed by a 200-mL infusion over 15 minutes (Neal, 2018).

For convulsions, an airway is established, and oxygen delivered. To halt seizures, lorazepam, 4 mg IV slowly, is administered and may be repeated once after 10 to 15 minutes. Alternatively, diazepam, 5 to 10 mg IV every 10 to 15 minutes up to a total dose of 30 mg, can be used. Succinylcholine abolishes the peripheral manifestations of the convulsions and allows tracheal intubation. Magnesium sulfate, administered according to the regimen for eclampsia, also controls convulsions (Chap. 41, p. 719).

Abnormal fetal heart rate patterns such as late decelerations or persistent bradycardia may develop from maternal hypoxia and lactic acidosis. With arrest of convulsions, oxygen administration, and other supportive measures, the fetus usually

recovers more quickly in utero than following immediate cesarean delivery. Moreover, the mother is better served if delivery is delayed until the intensity of hypoxia and metabolic acidosis has diminished.

Cardiovascular Toxicity

These manifestations generally develop later than those from cerebral toxicity, and they may not develop at all because they are induced by higher serum drug levels. The exception is bupivacaine, which is associated with the development of neurotoxicity and cardiotoxicity at virtually identical levels (Catterall, 2018). Fortunately, bupivacaine is mostly used in dilute epidural solutions, and use of 0.75-percent solution is limited to a small dose for spinal analgesia. Similar to neurotoxicity, cardiovascular toxicity is characterized first by stimulation and then by depression. Accordingly, hypertension and tachycardia are soon followed by hypotension, cardiac arrhythmias, and impaired uteroplacental perfusion. As before, 20-percent intralipids serve as the rescue.

Hypotension is managed initially by turning the woman onto either side to avoid aortocaval compression. A crystalloid solution is infused rapidly along with vasopressors. Emergency bedside cesarean delivery is considered if maternal vital signs have not been restored within 4 minutes of cardiac arrest, and the goal is delivery within 5 minutes (Chap. 50, p. 897). However, as with convulsions, the fetus is likely to recover more quickly in utero once maternal cardiac output is reestablished.

■ Pudendal Block

Pain with vaginal delivery arises from stimuli from the lower genital tract. These are transmitted primarily through the pudendal nerve, the peripheral branches of which provide sensory innervation to the perineum, anus, vulva, and clitoris (Chap. 2, p. 21). The pudendal nerve passes beneath the posterior surface of the sacrospinous ligament just as the ligament attaches to the ischial spine. Sensory nerve fibers of the pudendal nerve are derived from ventral branches of the S_2 through S_4 nerves.

The pudendal nerve block is a relatively safe, simple method of analgesia for vaginal delivery (Sultan, 2021). As shown in Figure 25-2, a tubular introducer is used to sheath and guide a 15-cm, 22-gauge needle into position near the pudendal nerve. The end of the introducer is placed against the vaginal mucosa just beneath the tip of the ischial spine. The introducer allows 1.0 to 1.5 cm of needle to protrude beyond its tip, and the needle is pushed beyond the introducer tip into the mucosa. A mucosal wheal is made with 1 mL of 1-percent lidocaine solution or an equivalent dose of another local anesthetic (see Table 25-3). To guard against intravascular infusion, aspiration is attempted before this and all subsequent injections. The needle is then advanced until it touches the sacrospinous ligament, which is infiltrated with 3 mL of lidocaine. The procedure is repeated on the other side.

Within 3 to 4 minutes of injection, the successful pudendal block will allow pinching of the lower vagina and posterior vulva without pain. If delivery occurs before the pudendal block becomes effective and an episiotomy is indicated, the fourchette, perineum, and adjacent vagina can be infiltrated with 5 to 10 mL of 1-percent lidocaine solution directly at the planned episiotomy site. The pudendal block usually has become effective by the time of repair.

The maximum recommended total dose of lidocaine is 4.5 mg/kg and not to exceed 300 mg (see Table 25-3). For a 50-kg woman, this would equal 225 mg (4.5 mg/kg × 50 kg). Thus, if 1-percent lidocaine is used, the calculated allowed amount would be: 225 mg ÷ 10 mg/mL = 22.5 mL. Of note, for any drug solution, 1 percent = 10 mg/mL.

Pudendal block usually does not provide adequate analgesia when delivery requires extensive obstetrical manipulation. Parenteral or neuraxial anesthesia is usually necessary when complete visualization of the cervix and upper vagina or manual exploration of the uterine cavity is indicated.

Infrequently, complications may follow this block. As previously described, intravascular injection of a local anesthetic agent may cause serious systemic toxicity. Hematoma formation from perforation of a blood vessel is most likely when there is a coagulopathy (Lee, 2004). The addition of a corticosteroid injected along with the local anesthetic did not decrease the incidence of pudendal neuralgia at 3 months (Labat, 2017). Rarely, severe infection may originate at the injection site. The infection may spread posteriorly to the hip joint, into the gluteal musculature, or into the retropsoas space (Svancarek, 1977).

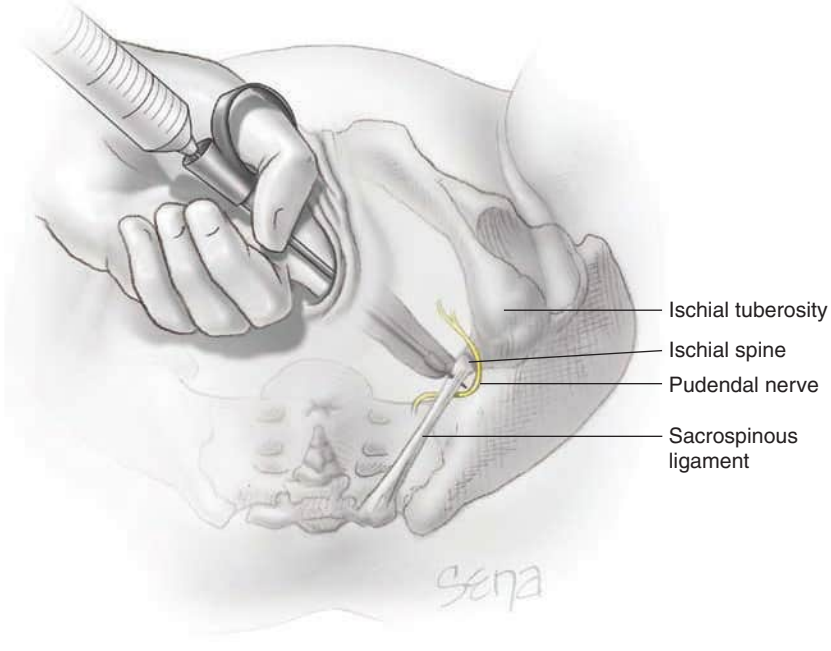

FIGURE 25-2 Local infiltration of the pudendal nerve. Transvaginal technique showing the needle extended beyond the needle guard and passing through the sacrospinous ligament to reach the pudendal nerve.

Paracervical Block

The cervix, vagina, and uterus are richly supplied by nerves of the uterovaginal plexus (Fig. 2-12, p. 25). This plexus lies within the connective tissue lateral to the uterosacral ligaments. Thus, injections are most effective if placed immediately lateral to the insertion of the uterosacral ligaments into the uterus (Rogers, 1998). For paracervical blockade, usually 1-percent lidocaine or 3-percent chloroprocaine, 5 to 10 mL, is injected into the cervix laterally at 4 and 8 o'clock positions. This block usually provides satisfactory pain relief during first-stage labor. However, because the pudendal nerves are not blocked, additional analgesia is required for delivery. The block may have to be repeated during labor because these anesthetics are relatively short acting.

Fetal bradycardia is a worrisome complication that develops in approximately 15 percent of these blocks (Rosen, 2002). Bradycardia usually develops within 10 minutes and may last up to 30 minutes. Doppler studies have shown an increase in the pulsatility index of the uterine arteries following paracervical blockade (Chap. 14, p. 262). These observations support the hypothesis of drug-induced arterial vasospasm as a cause of fetal bradycardia (Manninen, 2000). Thus, paracervical block should not be used in situations of potential fetal compromise. For all of these reasons, we do not use this block at Parkland Hospital.

NEURAXIAL ANALGESIA

Neuraxial Regional Blocks

Epidural, spinal, dural-puncture epidural, or combined spinal-epidural techniques are the most common methods used for relief of pain during labor and/or delivery in the United States. Nearly 75 percent of mothers receive neuraxial anesthesia for pain relief (Butwick, 2018a). Among first births, 68 percent of women who delivered vaginally received neuraxial pain relief compared with 57 percent of women delivering their second or higher number child. Antepartum education programs improve the understanding of labor analgesia and increase its use by 30 percent in Hispanic women who traditionally choose labor epidural analgesia less often (Togioka, 2019). Butwick and associates (2018b) showed women are more likely to receive neuraxial analgesia with higher class of obesity—class I, 72 percent; class II, 73 percent; and class III, 76 percent.

As a brief review, the epidural space lies just outside the dural sac. The dura mater encases the subarachnoid space, which contains the cauda equina of the spinal cord and cerebrospinal fluid (CSF) (Fig. 25-3). Spinal and intrathecal anesthesia are synonymous, and agents are injected into the subarachnoid space.

Epidural analgesia via a catheter in the epidural space is typically used for relief of labor pain, although it can also be used for *anesthesia* during operative vaginal and cesarean delivery. *Spinal analgesia* is typically given as a single intrathecal injection of a local anesthetic at the time of operative vaginal or cesarean delivery. Variations of these two basic approaches are described in the subsequent sections.

Spinal (Subarachnoid) Block

Introduction of a local anesthetic into the subarachnoid space to effect analgesia offers a short procedural time, rapid blockade onset, and high success rate of inducing analgesia. The subarachnoid space is smaller during pregnancy likely because of internal vertebral venous plexus engorgement (see Fig. 25-3A). As a result, compared with nonpregnant women, the same amount of anesthetic agent in the same volume of solution produces a higher-level blockade in parturients.

Vaginal Delivery

Spinal analgesia involving only lower spinal levels can be used for operative vaginal delivery. The level of analgesia should extend to the T_{10} dermatome, which corresponds to the level of the umbilicus. Blockade to this level provides excellent relief from the pain of uterine contractions. The spinal block provides also excellent analgesia to the lower uterine segment, vagina, and perineum.

Several local anesthetic agents have been used for spinal analgesia (see Table 25-3). Addition of dextrose to any of these agents creates a hyperbaric solution, which is heavier and denser than CSF. A sitting position causes a hyperbaric solution to settle caudally, whereas a lateral position will have a greater effect on the dependent side. Lidocaine given in a hyperbaric solution produces excellent analgesia and has the advantage of a rapid onset and relatively short duration. Isobaric bupivacaine provides satisfactory analgesia for more than 1 hour. Single-dose spinal analgesia is usually administered when the cervix is fully dilated, and all other criteria for safe operative vaginal delivery have been fulfilled (Chap. 29, p. 533). Preanalgesic IV hydration with 1 L of crystalloid solution will prevent or minimize hypotension in many cases.

Cesarean Delivery

A level of sensory blockade extending to the T_4 dermatome is desired for cesarean delivery. A dose of 10 to 12 mg of bupivacaine in a hyperbaric solution is administered. The addition of 20 to 25 μg of fentanyl improves the quality and prolongs the duration of the spinal block, reduces shivering, and minimizes referred pain. In addition, 0.1 to 0.2 mg of intrathecal morphine can be added for pain control postoperatively.

With intrathecal morphine, the risk for respiratory depression should be considered. The Society of Obstetric Anesthesia and Perinatology recommends postoperative respiratory monitoring based on dose, patient risk factors, and perioperative risk factors. A low-dose regimen, defined as >50 μg and ≤ 150 μg, in women with no risk factors requires respiratory rate and sedation checks postoperatively for the first 12 hours. In women with additional risk factors, these safeguards are conducted postoperatively for the first 24 hours, and additional monitoring with pulse oximetry or capnography is considered. Last, this monitoring method is also recommended in all women receiving doses >150 μg (Bauchat, 2019).

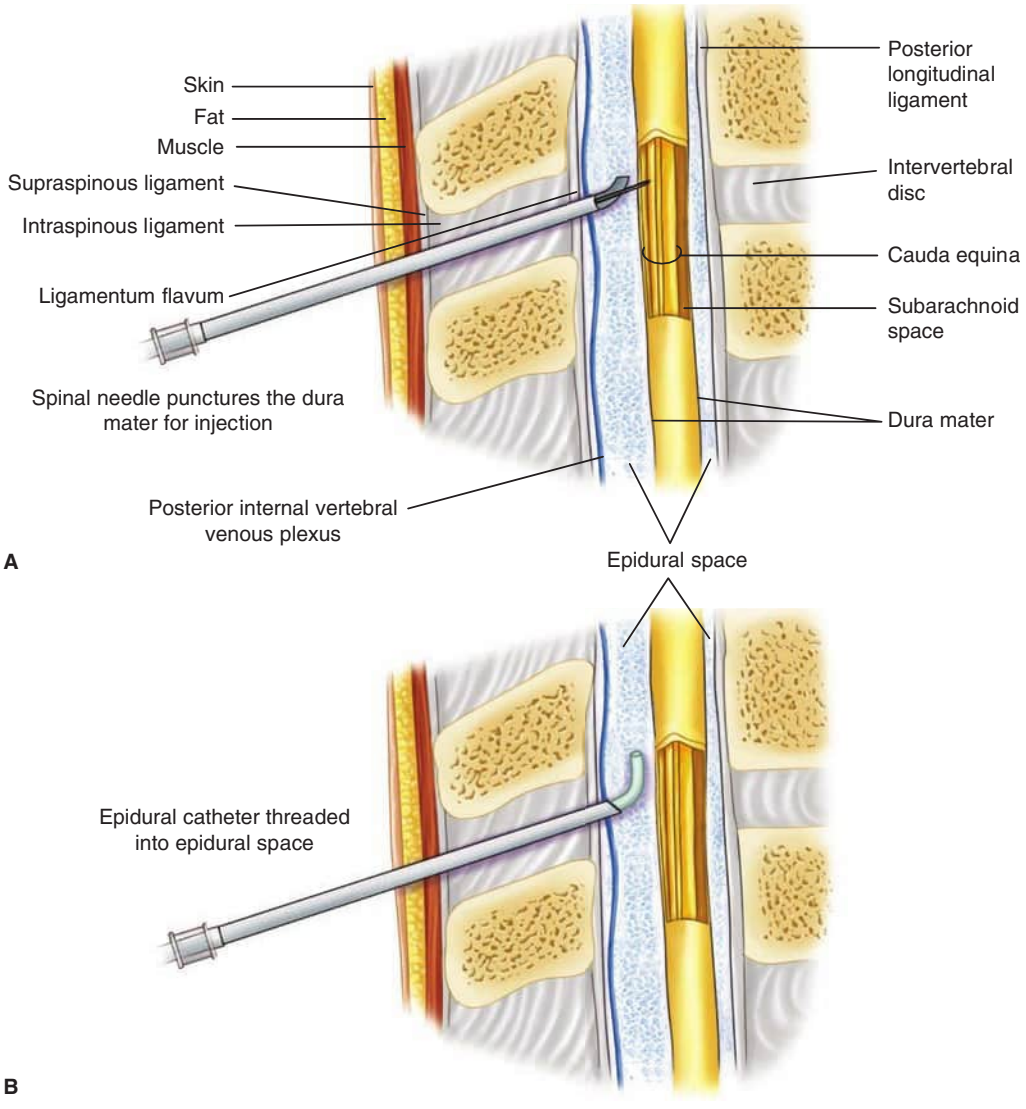

FIGURE 25-3 Neuraxial analgesia. **A.** Combined spinal-epidural analgesia. **B.** Epidural analgesia.

Complications

Shown in Table 25-4 are some of the more common complications associated with neuraxial analgesia.

Hypotension. This common complication may develop soon after injection of the local anesthetic agent. It stems from vasodilation caused by sympathetic blockade and is compounded by obstructed venous return due to uterine compression of the vena cava. In the supine position, even in the absence of maternal hypotension, placental blood flow may still be significantly diminished. Treatment includes uterine displacement by left lateral patient positioning, rapid IV crystalloid infusion, and IV vasopressors.

One systematic review concluded that vasopressors should be given only in the setting of hypotension (Fitzgerald, 2020). For treatment, phenylephrine is now the preferred drug to treat hypotension from neuraxial analgesia. It is a pure alpha agonist and raises blood pressure solely through vasoconstriction. Maternal bradycardia develops more frequently with

TABLE 25-4. Complications of Neuraxial Analgesia

Fever >38°C
Hypotension—highest with spinal analgesia (~50%)
Fetal heart rate abnormalities
High spinal level
Increased QT interval—with spinal analgesia in postterm pregnancies
Inadequate analgesia (~10%)
Postdural puncture headache (1–3%)
Nerve injury—arachnoiditis
Pruritus—with addition of opioids

From American College of Obstetricians and Gynecologists, 2019b; American Society of Anesthesiologists, 2016; D'Angelo, 2014; Karahan, 2020; Maronge, 2018.

phenylephrine than with ephedrine or norepinephrine (Sharkey, 2019; Veeser, 2012). Although ephedrine was believed to correct hypotension without reducing blood flow, phenylephrine is associated with better umbilical cord blood gases (Ngan Kee, 2017). A metaanalysis of 36 randomized trials also suggests that both agents have comparable efficacy but that phenylephrine yields a lower rate of fetal acidosis (Xu, 2018). For administration, prophylactic infusions of phenylephrine are effective and may require less physician intervention compared with intermittent boluses (Ngan Kee, 2004). As another potential agent, norepinephrine may improve cardiac output with its beta-adrenergic effects but also is associated with a lower cord arterial pH compared with phenylephrine (Chen, 2021; Mohta, 2019).

High Spinal Blockade. Most often, complete spinal blockade follows administration of an excessive dose of local anesthetic. However, it can also develop with inadvertent delivery of a small amount of local anesthetic drugs into the subdural space. This small potential space lies between the dura mater and arachnoid mater and outside the subarachnoid space. Because of its limited capacity, even small volumes will reach higher spinal levels. Hypotension and apnea develop quickly and must be immediately treated to prevent cardiac arrest. In the undelivered woman: (1) the uterus is immediately displaced laterally to minimize aortocaval compression, (2) effective ventilation is established, preferably with tracheal intubation, and (3) IV fluids and vasopressors are given to correct hypotension.

Postdural Puncture Headache. Leakage of CSF from the dural puncture site can lead to postdural puncture headache. Presumably, when the woman sits or stands, the diminished CSF volume creates traction on pain-sensitive central nervous system structures. An alternative mechanism is compensatory cerebral vasodilation in response to CSF loss—the *Monro-Kellie hypothesis* (Mokri, 2001).

The incidence of obstetrical postdural puncture headache in women undergoing spinal analgesia ranges from 0.2 to 1 percent (Maronge, 2012; Sprigge, 2008). This rate is similar to the overall occurrence of postdural puncture headaches, which approximates 1 headache per 200 blocks. A study of 567 postpartum hospital encounters showed that 40 percent of presentations for headache are due to neuraxial anesthesia, and these visits most often occur within 7 days of delivery (Rodriguez, 2020).

Procedural preventive steps include using a small-gauge spinal needle and avoiding multiple punctures. In a prospective, randomized study of five different spinal needles, Sprotte and Whitacre needles had the lowest risks of associated postdural puncture headaches (Vallejo 2000). Rates are high with inadvertent dural puncture during epidural analgesia and approximate 0.2 to 1 percent (Introna, 2012; Maronge, 2018). No strong evidence supports placing a woman flat on her back or providing vigorous hydration to prevent headache (Arevalo-Rodriguez, 2016). A prophylactic blood patch performed within 24 hours of dural puncture does not diminish either the incidence of postdural puncture headache or the need for a subsequent therapeutic blood patch (Scavone, 2004).

If a headache develops, administration of caffeine, which is a cerebral vasoconstrictor, has limited efficacy (Katz, 2017). With severe headache, an *epidural blood patch* is most effective and preferred treatment. Autologous blood is obtained aseptically by venipuncture, and 10 to 20 mL is injected into the epidural space at or below the site of dural puncture. This site is selected because the blood will spread more readily in the cephalad direction. Further CSF leakage is halted by either mass effect or clot formation. Relief is immediate, and complications are uncommon.

If a headache does not have the pathognomonic postural characteristics or persists despite treatment with a repeat blood patch, other diagnoses should be considered. Chisholm and Campbell (2001) described a case of superior sagittal sinus thrombosis that manifested as a postural headache. Chan and Paech (2004) reported persistent CSF leak in three women. Smarkusky and colleagues (2006) described pneumocephalus, which caused immediate cephalgia. Last, intracranial and intraspinal subarachnoid hematomas have developed after spinal analgesia (Bi, 2021; Maronge, 2018; Moore, 2019).

Convulsions. Rarely, postdural puncture cephalgia is associated with temporary blindness and convulsions. Shearer and associates (1995) described eight such cases in 19,000 regional analgesia procedures done at Parkland Hospital. It is presumed that these also are caused by hypotension from CSF leak. Immediate treatment of seizures and epidural blood patch were usually effective.

Bladder Dysfunction. With neuraxial analgesia, bladder sensation is likely to be obtunded and bladder emptying impaired for several hours after delivery. As a consequence, bladder distention is a frequent postpartum complication, especially if appreciable volumes of IV fluid are given. Millet (2012) randomized 146 women with neuraxial analgesia to either intermittent or continuous bladder catheterizations and found that the intermittent method was associated with significantly greater rates of bacteriuria.

Arachnoiditis and Meningitis. Local anesthetics used for neuraxial blocks are required to be free of methylparaben or other preservatives. This practice, coupled with aseptic technique and disposable equipment, has made meningitis and arachnoiditis rare (Centers for Disease Control and Prevention, 2010; Maronge, 2018).

Contraindications to Spinal Analgesia

Shown in Table 25-5 are absolute contraindications to spinal analgesia. Obstetrical complications that are associated with maternal hypovolemia and hypotension—for example, severe hemorrhage—are contraindications to spinal blockade. The additive deleterious cardiovascular effects of spinal blockade plus acute blood loss in nonpregnant patients have been documented (Kennedy, 1968).

Severe preeclampsia is another obstetrical complication in which decreased blood pressure can be encountered when neuraxial analgesia is used (Wallace, 1995). These effects are mitigated by judicial dosing of anesthetic solutions. Perhaps related, Ulubaşoğlu and colleagues (2018) reported that preeclamptic

TABLE 25-5. Absolute Contraindications to Spinal Analgesia

Refractory hypotension
Maternal coagulopathy
Thrombocytopenia <70,000/μL
Untreated maternal bacteremia
Skin infection at site of needle placement
Increased intracranial pressure
Prophylactic low-molecular-weight heparin within 12 hours

women undergoing general anesthesia required more antihypertensive medication than those with spinal analgesia.

Disorders of coagulation that result in poor hemostasis also preclude the use of neuraxial analgesia. Women with a bleeding diathesis such as von Willebrand disease or hemophilias carry an increased risk for subarachnoid hematoma formation (Chap. 59, p. 1062). Rare subdural hematomas may mimic postdural puncture headaches (Lim, 2016). However, neuraxial analgesia can be safely performed in these patients following factor replacement and normalization of levels (Choi, 2009; Katz, 2015). As discussed earlier, these patients should receive consultation with an anesthesiologist prior to labor.

The use of anticoagulation to prevent or treat venous thromboembolism is frequently encountered during the peripartum period. No randomized studies guide the management of anticoagulation at the time of delivery, but consensus opinion is provided by the Society for Anesthesia and Perinatology (Leffert, 2018). Briefly, women receiving >10,000 units/d of unfractionated heparin are individually assessed regarding timing and dose of last injection. Thromboprophylaxis with low-molecular-weight heparin (LMWH) should have a 12-hour delay. Therapeutic doses of LMWH merit a 24-hour delay. This is discussed further in Chapter 55 (p. 985). Spinal analgesia is also contraindicated if there is infection at the needle entry site.

Other maternal conditions may pose relative contraindications to neuraxial analgesia. Many women with neurological disorders such as Chiari malformation or pseudotumor cerebri may be candidates for neuraxial analgesia after consultation with an anesthesiologist and neurologist. Women with severe aortic stenosis or pulmonary hypertension also have a relative contraindication to spinal analgesia due to the deleterious effects of hypotension and diminished preload and afterload (Chap. 52, p. 926).

■ Epidural Analgesia

Relief of labor and childbirth pain, including cesarean delivery, can be accomplished by injection of a local anesthetic agent into the epidural space (see Fig. 25-3B). This potential space contains areolar tissue, fat, lymphatics, and the internal vertebral venous plexus. Entry for obstetrical analgesia is usually through a lumbar intervertebral space. Although only one injection may be given, usually an indwelling catheter is placed for subsequent bolus administration or continuous infusion (Billingham, 2018). Infusions use a volumetric pump controlled either by the patient or by a caregiver. Under appropriate physician supervision, labor and delivery nursing personnel with specific training in the management of epidural infusions should be able to adjust dosage and also discontinue infusions.

■ Continuous Lumbar Epidural Analgesia

Complete analgesia for the pain of labor and vaginal delivery necessitates a block from the T_{10} to the S_4 dermatomes. For cesarean delivery, a block extending from the T_4 to the S_1 dermatomes is desired. The effective spread of anesthetic depends upon the catheter tip location and the dose, concentration, and volume of anesthetic agent used. Individual variations in anatomy or synechiae or septa in the epidural space may preclude a completely satisfactory block. Last, the catheter tip may migrate from its original location during labor.

Technique

One example of the sequential steps and techniques for performance of epidural analgesia is detailed in Table 25-6. Before injection of the local anesthetic therapeutic dose, a test dose is given containing small amounts of lidocaine and epinephrine. The woman is observed for features of toxicity from intravascular injection and for signs of either subarachnoid or subdural injection. If these are absent, analgesia is initiated with a full dose of the anesthetic alone. Analgesia is maintained by a continuous infusion or by programmed intermittent boluses delivered by infusion pump (Billingham, 2018). The addition of a short-acting, lipid-soluble narcotic—fentanyl or sufentanil—lowers the required amount of local anesthetic drug needed to achieve analgesia. This helps preserve motor function (Lyons, 1997). One popular regimen is 0.0625- to 0.125-percent bupivacaine with 2-μg/mL fentanyl.

As with spinal blockade, close monitoring, including the level of analgesia, must be performed by trained personnel. Appropriate resuscitation equipment, drugs, and personnel must be available during administration of epidural analgesia.

Complications

As shown in Table 25-4, certain problems are inherent to epidural analgesia.

High Spinal Blockade. Dural puncture with inadvertent and unrecognized either subarachnoid or subdural injection may cause total spinal blockade. In a study of more than 18,000 women, the incidence of recognized accidental dural puncture at the time of epidural analgesia was 0.91 percent (Sprigge, 2008). Management of this complication is described earlier (p. 474).

Ineffective Analgesia. Using currently popular continuous or intermittent epidural infusion regimens, 90 percent of women rate their pain relief as good to excellent (Sharma, 1997). In a study of almost 2000 parturients, Hess and associates (2001) found that 12 percent complained of three or more episodes of

TABLE 25-6. Technique for Labor Epidural Analgesia

Obtain informed consent and consult the obstetrician
Monitoring includes the following:
Blood pressure every 1–2 minutes for 15 minutes after giving a bolus of local anesthetic
Continuous maternal heart rate monitoring during analgesia induction
Continuous fetal heart rate monitoring
Continual verbal communication
Hydration with 500–1000 mL of Ringer lactate solution
The woman assumes a lateral decubitus or sitting position
The epidural space is identified by the needle's loss of resistance during insertion
The epidural catheter is threaded 3–5 cm into the epidural space
After a negative aspiration, a test dose of 3 mL of 1.5% lidocaine with 1:200,000 epinephrine is injected between contractions. Epinephrine is injected after careful aspiration to avert intravascular injection and after a uterine contraction. This minimizes the chance of confusing tachycardia that results from labor pain with that of tachycardia from intravenous injection of the test dose.
A positive test dose manifests as symptoms of an intravascular injection of lidocaine and epinephrine, which are tinnitus, circumoral numbness, dizziness, heart rate increase >20 bpm in 1 minute. Another potential symptom is an inability to raise the lower extremities against gravity in 4 min, which reflects the effects of a subarachnoid space injection.
If the test dose is negative, 10–15 mL of 0.0625–0.125% bupivacaine are injected to achieve a sensory T_{10} level
After 15–20 minutes, the block is assessed using loss of sensation to cold or pinprick. If no block is evident, the catheter is replaced. If the block is asymmetrical, the epidural catheter is withdrawn 0.5–1.0 cm and an additional 3–5 mL of 0.25% bupivacaine is injected. If the block remains inadequate, the catheter is replaced.
The woman is positioned in the lateral or semilateral position to avoid aortocaval compression
Subsequently, maternal blood pressure is recorded every 5–15 minutes. The fetal heart rate is monitored continuously
The level of analgesia and intensity of motor blockade are assessed at least hourly

pain or pressure. Its efficacy was more likely to decrease with rising body mass index (Dresner, 2006). Inadequate analgesia may result in patient dissatisfaction. Catheter replacement should be considered.

Moreover, a poorly functioning epidural catheter cannot be used for additional dosing of local anesthetic drugs for intrapartum cesarean delivery. Such conversion of labor epidural analgesia to cesarean delivery anesthesia has an approximately 20 percent failure rate. This necessitates placement of a new regional block or general anesthesia (Mankowitz, 2016). In a Maternal Fetal Medicine Units (MFMU) Network study, 4 percent of women initially given epidural analgesia required a general anesthetic for cesarean delivery (Bloom, 2005).

Also at times, perineal analgesia for vaginal delivery is difficult to obtain, especially when lower volumes of epidural local anesthetic drugs are used. With this situation, additional doses can be given, or a pudendal block may be added.

Hypotension. Sympathetic blockade from epidurally injected analgesic agents may cause peripheral vasodilation with resulting hypotension and diminished cardiac output. Hypotension is more common—20 percent—in women with an admission pulse pressure <45 mm Hg compared with 6 percent in those whose pulse pressure is >45 mm Hg (Miller, 2013). Pulse pressure is calculated by subtracting diastolic from systolic blood pressure measurements. Obese women also have significantly higher rates of hypotension (Vricella, 2011). In normal gravidas, hypotension induced by epidural analgesia usually can be prevented by rapid IV infusion of 500 to 1000 mL of crystalloid solution as described for spinal analgesia. Maintaining a lateral position also minimizes hypotension. Despite these precautions, hypotension is the most frequent side effect and is severe enough to require treatment in a third of women (Sharma, 1997).

Central Nervous Stimulation. Convulsions are an uncommon but serious complication. Described earlier, the immediate management involves infusion of 20-percent intralipids and treatment with lorazepam or diazepam (p. 470).

Fever. Some women develop intrapartum fever following epidural analgesia. Many studies are limited by the inability to control for other risk factors, such as labor length, duration of ruptured membranes, and number of vaginal examinations. With this in mind, the frequency of intrapartum fever associated with epidural analgesia is 10 to 15 percent above the baseline rate (Lieberman, 2002).

The two general theories concerning the etiology of maternal hyperthermia are *maternal-fetal infection* or *dysregulation of body temperature* (American College of Obstetricians and Gynecologists, 2019b). A study of placental histopathology in women given epidural analgesia identified intrapartum fever only when there was placental inflammation (Dashe, 1999). This suggests that fever is due to infection. Sharma (2014) randomized 400 nulliparas with labor epidural analgesia to receive 2 g cefoxitin prophylactically versus placebo. It was hypoth-

esized that epidural-related fever was due to infection and that prophylactic antimicrobials should significantly reduce the rate of fever. Approximately equal proportions—40 percent—of women developed fever ≥38°C during labor. This result suggests that infection is unlikely to cause the fever associated with epidural analgesia during labor. Whatever the mechanism, women with persistent fever are usually treated with antimicrobials for presumed chorioamnionitis.

The other proposed mechanisms include alteration of the hypothalamic thermoregulatory set point, impaired peripheral thermoreceptor input to the central nervous system with selective blockade of warm stimuli, or imbalance between heat production and heat loss. Del Arroyo and colleagues (2019) suggested that bupivacaine blocks release of antipyretic interleukins.

Back Pain. An association between epidural analgesia and back pain has been reported by some. In a prospective cohort study, Butler and Fuller (1998) reported that back pain after delivery was common with epidural analgesia, however, persistent pain was infrequent. Based on their systematic review, Lieberman and O'Donoghue (2002) concluded that available data do not support an association between epidural analgesia and development of de novo, long-term backache.

Miscellaneous Complications. A spinal or epidural hematoma is a rare complication of an epidural catheter (Grant, 2007). These are considered neurological emergencies, and treatment is usually surgical. Epidural abscesses are rare, and the most common pathogen is *Staphylococcus aureus* (McQuaid, 2018). These may be managed conservatively with IV antibiotics, but surgical intervention may be necessary. For both conditions, timely neurosurgical consultation is important. Uncommonly, the plastic epidural catheter is sheared off (Noblett, 2007). Computed tomography can localize the retained fragment. For a tip left in the epidural space, surveillance is reasonable in the absence of symptoms. With neurological changes or with fragments in the subarachnoid space, neurosurgical consultation is recommended (Mitra, 2007). Last, an association of epidural analgesia and autism spectrum disorder seems unlikely (Mikkelsen, 2021).

Effect on Labor

Most studies, including five combined randomized trials from Parkland Hospital shown in Table 25-7, report that epidural analgesia prolongs labor and increases the use of oxytocin stimulation (Sharma, 2004). Alexander and associates (2002) examined the effects of epidural analgesia on the Friedman (1955) labor curve (Chap. 22, p. 424). There were 459 nulliparas randomly assigned to receive patient-controlled epidural analgesia or patient-controlled IV meperidine. Compared with original Friedman criteria, epidural analgesia prolonged the active phase of labor by 1 hour. In a cohort study, similar labor durations were observed for both spinal-epidural and epidural analgesia (Poma, 2019).

The effect of labor epidural on the second stage is unclear. Prolongation of the second stage was particularly true in earlier studies, at a time when higher concentrations of local anesthetic drugs were used. This association has been attributed to local-anesthetic-induced motor blockade and resultant impaired maternal expulsive efforts. Chestnut and associates (1999) reported that, with epidural analgesia, operative vaginal delivery occurred more frequently because of prolonged second-stage labor. In a systematic review, Anim-Somuah and colleagues (2018) reported that epidural analgesia prolongs the first stage by 32 minutes and the second stage by 15 minutes. Craig and coworkers (2015) randomly assigned 310 nulliparous women with labor epidural analgesia to receive 0.125-percent bupivacaine plus fentanyl or epidural fentanyl alone during second-stage labor. Epidural bupivacaine analgesia did cause motor blockade during the second stage, however, the duration of the second stage was not longer. Neither obstetrical nor neonatal outcomes were different between the two groups. Patient satisfaction was high with both methods.

TABLE 25-7. Selected Labor Events in 2703 Nulliparous Women Randomized to Epidural Analgesia or Intravenous Meperidine Analgesia

Event[a]	Epidural Analgesia n = 1339	Intravenous Meperidine n = 1364	*p* value
Labor outcomes			
First-stage duration (hr)[b]	8.1 ± 5	7.5 ± 5	0.011
Second-stage duration (min)	60 ± 56	47 ± 57	<0.001
Oxytocin after analgesia	641 (48)	546 (40)	<0.001
Type of delivery			
SVD	1027 (77)	1122 (82)	<0.001
Forceps	172 (13)	101 (7)	<0.001
Cesarean	140 (10.5)	141 (10.3)	0.92

[a]Data are presented as n (%) or mean ± SD.
[b]First stage = initiation of analgesia to complete cervical dilation.
SVD = spontaneous vaginal delivery.

Fetal Heart Rate. Hill and associates (2003) examined the effects of epidural analgesia with 0.25-percent bupivacaine on fetal heart rate patterns. Compared with IV meperidine, no worrisome effects were identified. Reduced beat-to-beat variability and fewer accelerations were more common in fetuses whose mothers received meperidine (Chap. 24, p. 450). Based on their systematic review, Reynolds and coworkers (2002) reported that epidural analgesia was associated with improved neonatal acid-base status compared with meperidine.

Cesarean Delivery Rates. A contentious issue in the past was whether epidural analgesia increased the risk for cesarean delivery. Early evidence that it did was from an era when dense motor blockade resulted from high concentrations of local

TABLE 25-8. Cesarean Delivery (CD) Rates in Laboring Women Receiving Epidural Analgesia or Intravenous Meperidine

Study	Odds Ratio[a]	CD Incidence Higher with
Ramin (1995)	1.20 (0.73–1.97)	Epidural
Sharma (1997)	0.77 (0.31–1.91)	Meperidine
Gambling (1998)	1.13 (0.65–1.97)	Epidural
Lucas (2001)	1.05 (0.68–1.63)	Epidural
Sharma (2002)	0.81 (0.41–1.61)	Meperidine
Adjusted	1.04 (0.81–1.34)	

[a]Shown with 95-percent confidence intervals.

anesthetic agents. Now however, with the administration of *dilute* anesthetic solutions, the risk for cesarean delivery is not increased.

Several studies conducted at Parkland Hospital were designed to answer this and related questions. From 1995 to 2002, a total of 2703 nulliparas at term and in spontaneous labor were enrolled in five trials to evaluate epidural analgesia techniques compared with IV meperidine. The results from these are summarized in Table 25-8 and show that epidural analgesia does not significantly raise cesarean delivery rates (Sharma, 2004). The American College of Obstetricians and Gynecologists (2019b) and the American Society of Anesthesiologists (2016) also conclude that epidural analgesia is not associated with a greater cesarean delivery rate.

Timing of Epidural Placement. Earlier studies indicated that epidural placement in early labor was linked to a higher risk of cesarean delivery (Lieberman, 1996; Rogers, 1999; Seyb, 1999). These observations prompted at least five randomized trials, which showed that the timing of epidural placement has no effect on the risk of cesarean birth, forceps delivery, or fetal malposition (Chestnut, 1994a,b; Luxman, 1998; Ohel, 2006; Wong, 2005, 2009). Thus, withholding epidural placement until some arbitrary cervical dilation has been attained serves only to deny women maximal labor pain relief.

Safety

Among nearly 20,000 women who received epidural analgesia in the MFMU Network study cited earlier, no anesthesia-related maternal deaths were reported (Bloom, 2005). Ruppen and colleagues (2006) reviewed data from 27 studies involving 1.4 million pregnant women who received epidural analgesia. Their calculated adverse-event rates were 1:145,000 for deep epidural infection, 1:168,000 for epidural hematoma, and 1:240,000 for persistent neurological injury. More recently, the Society for Obstetric Anesthesia and Perinatology established the Serious Complication Repository Project (D'Angelo, 2014). During a 5-year period, more than 228,000 women had neuraxial analgesia. There were no maternal deaths related to anesthesia, but two each were attributed to cardiac arrest and myocardial infarction. There were four cases of epidural abscess or meningitis, 58 high-spinal-level neuraxial blocks (1 in 4000), 27 neurological injuries, and 16 respiratory arrests (1 in 10,000).

Contraindications

As with spinal analgesia, contraindications are listed in Table 25-5.

Thrombocytopenia. Although low platelet counts are intuitively worrisome, the level at which epidural bleeding *might* develop is unknown. Epidural hematomas are rare, and their incidence was estimated to be 0 to 0.6 percent in women whose platelet count is <70,000/μL (Goodier, 2015; Lee, 2017). The American College of Obstetricians and Gynecologists (2019b) and Society for Obstetric Anesthesia and Perinatalogy (Bauer, 2021) have concluded that women with a platelet count of ≥70,000/μL may be candidates for neuraxial analgesia.

Anticoagulation. Women receiving anticoagulation therapy who are given regional analgesia are at increased risk for spinal cord hematoma and compression (Chap. 55, p. 985). The American College of Obstetricians and Gynecologists (2019b) has concluded the following:

1. With prophylactic unfractionated heparin (UFH) in a dose of 5000 units twice daily, regional analgesia is not contraindicated.
2. With an intermediate dose of UFH (7500 to 10,000 units), it is likely low risk to proceed with neuraxial analgesia at a point more than 12 hours after the last dose.
3. With a high dose of UFH (>20,000 units), it is likely low risk to use regional analgesia at a point more than 24 hours after the last dose if the activate partial thromboplastin time (aPTT) is within normal range or the anti-Xa level is undetectable.
4. With thromboprophylaxis with LMWH, needle or catheter placement or removal should be delayed 12 hours or more.
5. With treatment doses of LMWH, placement or removal of a neuraxial catheter should be delayed for 24 hours.

Severe Preeclampsia-Eclampsia. Concerns with neuraxial analgesia in women with severe preeclampsia include hypotension as well as hypertension from pressor agents given to correct hypotension. Additionally, pulmonary edema may follow infusion of large volumes of crystalloid. These risks are outweighed by the disadvantages of general anesthesia (American College of Obstetricians and Gynecologist, 2020). Of these, tracheal intubation may be difficult because of upper airway edema. Also, general anesthesia can lead to severe, sudden hypertension that can cause pulmonary or cerebral edema or intracranial hemorrhage.

With improved techniques for infusion of dilute local anesthetics into the epidural space, most have come to favor epidural blockade for labor and delivery in women with severe preeclampsia. In a study from Parkland Hospital, Lucas and associates (2001) randomly assigned 738 women with hypertension to epidural analgesia or patient-controlled IV analgesia during labor. A standardized protocol for prehydration,

incremental epidural administration, and ephedrine use was employed. They concluded that labor epidural analgesia was safe in women with hypertensive disorders.

Thrombocytopenia is seen with severe preeclampsia complicated by hemolysis, elevated liver enzyme levels, low platelet count—HELLP syndrome (Chap. 40, p. 689). Discussed earlier and in general, it seems safe to use neuraxial techniques if the platelet count is ≥70,000/μL (American College of Obstetricians and Gynecologists, 2019b, 2020).

Women with severe preeclampsia can have remarkably diminished intravascular volume compared with normal pregnancy (Zeeman, 2009). Conversely, total body water volume is increased because of the capillary leak caused by endothelial cell activation (Chap. 40, p. 693). This imbalance is manifested as pathological peripheral edema, proteinuria, ascites, and total lung water. For all of these reasons, aggressive volume replacement raises the risk for pulmonary edema, especially in the first 72 hours postpartum (American College of Obstetricians and Gynecologists, 2019b). In one study, 3.5 percent of women with severe preeclampsia developed pulmonary edema when preloaded without a protocol limit to the volume infused (Hogg, 1999).

The risk of pulmonary edema can be reduced or obviated with judicious prehydration—usually with 500 to 1000 mL of crystalloid solution. Specifically, in the study by Lucas and colleagues (2001) cited earlier, no instances of pulmonary edema developed among the women in whom the infused crystalloid preload volume was limited to 500 mL. Moreover, vasodilation produced by epidural blockade is less abrupt if the analgesia level is achieved slowly with dilute solutions of local anesthetic agents.

With vigorous IV crystalloid therapy, cerebral edema also may develop (Chap. 40, p. 701. Last, most cases of pharyngolaryngeal edema are related to aggressive volume therapy (Heller, 1983).

Epidural Opioid Analgesia

Opioids alone usually will not provide adequate analgesia, and they are often used as an adjunct to a local anesthetic agent such as bupivacaine (Wang, 2020). This combination lowers the local anesthetic drug concentration needed to achieve analgesia, which in turn creates a less dense motor blockade. Other benefits are rapid onset of pain relief and a decrease in shivering. Common side effects include pruritus and urinary retention. Nalbuphine, a mixed opioid agonist/antagonist, will abolish these symptoms without affecting the analgesic action. When neuraxial morphine is given for postoperative pain, monitoring for respiratory depression is necessary as discussed earlier (p. 472) (Bauchat, 2019).

Combined Spinal–Epidural Techniques

The combination of spinal and epidural techniques (CSE) has risen in popularity and may provide rapid and effective analgesia for labor and then for cesarean delivery. An epidural needle is first placed in the epidural space. A small-gauge spinal needle is then introduced through the epidural needle into the subarachnoid space—this is called the *needle-through-needle technique* (see Fig. 25-3A). A single bolus of an opioid, a local anesthetic, or sometimes a combination is injected into the subarachnoid space. A subarachnoid opioid bolus results in the rapid onset of profound pain relief with virtually no motor blockade (Poma, 2019). The spinal needle is withdrawn, and an epidural catheter is then placed into the epidural space. The epidural catheter remains and permits repeated analgesia dosing.

Miro and associates (2008) compared epidural analgesia with CSE analgesia for labor in 6497 women and found the overall outcomes and complications to be similar. Poma and coworkers (2019) also found comparable analgesia results with epidural or CSE techniques. They noted that subarachnoid sufentanil was associated with lower uterine contractility, but labor duration was not affected. A greater incidence of fetal heart rate abnormalities related to uterine hypertonus has been reported with CSE analgesia (Abrão, 2009; Beamon, 2014). The analgesia failure rate is 11.6 percent for traditional labor epidural and 6.6 percent for CSE (Booth, 2016). Although CSE provides a faster onset of labor analgesia, the intrathecal injection of local anesthetic drugs and/or narcotic may cause hypotension and pruritus.

Continuous Spinal Analgesia During Labor

The technique of continuous spinal analgesia for relief of labor pain is seldom used because of postdural puncture headaches (American College of Obstetricians and Gynecologists, 2019b). With redesigned needles and catheters, Arkoosh (2008) randomized 429 women to either continuous spinal or conventional epidural analgesia during labor. Complication rates between these two neuraxial techniques did not differ.

Dural-Puncture Epidural Analgesia

Gaining popularity, this technique is similar to CSE, but initial steps differ. First, a single dural puncture is made using a 25-gauge spinal needle placed through the epidural needle shaft (see Fig. 25-3A). No anesthetic is injected, but the needle can help confirm correct subarachnoid space placement by the drip of CSF from its distal hub. After removal of the spinal needle, the epidural catheter is threaded into the epidural space (see Fig. 25-3B). The dural puncture allows for a small amount of local anesthetic drugs to be translocated from the epidural space to the subarachnoid space. This aids a faster onset of pain relief than traditional epidural analgesia. Without the intrathecal injection, dural-puncture epidural analgesia is associated with fewer side effects than CSE analgesia and provides better block quality than an epidural (Chau, 2017). A review of five studies with 581 patients showed dural puncture epidural technique was associated with a faster onset of analgesic effects, a reduction in provider-initiated boluses "top-ups," and better sacral coverage. The incidence of post-dural puncture headache was not significantly increased (Heesen, 2019). A study confirmed fewer top-ups and a greater local anesthetic drug sparing effect evaluating the combined use of this technique and the intermittent bolus drug delivery mode (Song, 2021).

Local Infiltration Analgesia

A local block is occasionally useful to augment an inadequate or "patchy" regional block that was given emergently. Rarely, local infiltration may be needed to perform an emergency cesarean delivery to save the life of a fetus in the absence of anesthesia support. Two methods are described here.

In one technique, the skin is infiltrated along the proposed incision, and the subcutaneous, muscle, and rectus sheath layers are injected as the abdomen is opened. Injection of large volumes into the fatty layers, which are relatively devoid of nerve supply, is avoided to limit the total dose of local anesthetic needed.

Cooper and coworkers described using 52 mL of 0.5-percent lidocaine with 1:200,000 epinephrine. This delivered 260 mg of lidocaine. Related to lidocaine toxicity, higher lidocaine volumes can be used when paired with epinephrine, because vasoconstriction lowers the intravascular transfer of anesthetic. The maximum dose is 7 mg/kg. Others have used 1-percent procaine with or without epinephrine (Larsen, 1971; Ranney, 1975).

A second technique involves a field block of the major branches supplying the abdominal wall, to include the 10th, 11th, and 12th intercostal nerves and the ilioinguinal and genitofemoral nerves (Nandagopal, 2001). As shown in Figure 25-4, the former group of nerves is located at a point midway between the costal margin and iliac crest in the midaxillary line. The latter group is found at the level of the external inguinal ring. A total of four skin punctures, two on each side, are made. First, at the intercostal block site, the needle is directed medially, and injection is carried down to the transversalis fascia, avoiding injection of the subcutaneous fat. Five mL of 0.5-percent lidocaine with epinephrine are injected. The needle is redirected but not removed, and similar dosing is delivered to sites located at a 45-degree angle cephalad and caudad. The other side is then injected. Second, at the ilioinguinal and genitofemoral sites, the injection is started at a spot 2 to 3 cm lateral from the pubic tubercle at a 45-degree angle. Last, the skin overlying the planned incision is injected.

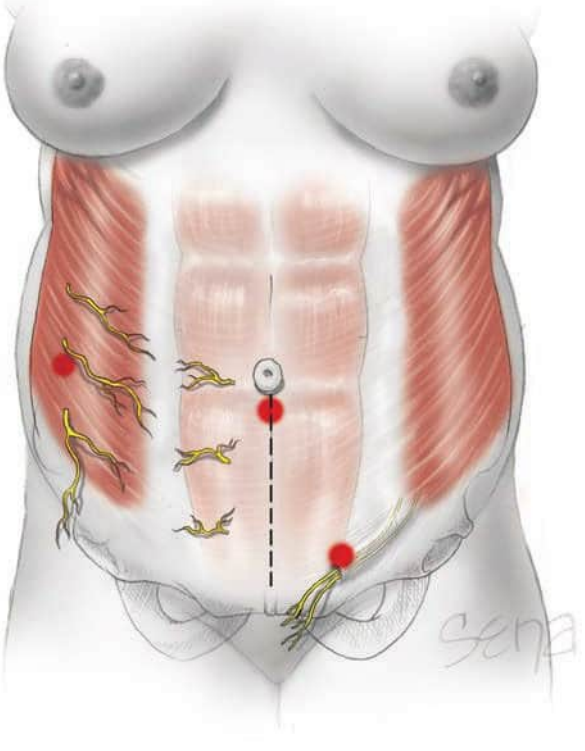

FIGURE 25-4 Local anesthetic block for cesarean delivery. The first injection site is halfway between the costal margin and iliac crest in the midaxillary line to block the 10th, 11th, and 12th intercostal nerves. A second injection at the external inguinal ring blocks branches of the genitofemoral and ilioinguinal nerves. Although not shown, both sites are infiltrated bilaterally. The final site is along the line of proposed skin incision.

Transversus Abdominis Plane Block

This block may be used for those with suitable training (Young, 2012). It is usually performed under ultrasound guidance and involves injection of a local anesthetic into the transversus abdominis plane (TAP) between the internal oblique and transversus abdominis muscles (Fig. 2-2, p. 14). The nerves lying in this plane supply the anterior abdominal wall at the T_6 to L_1 dermatomes. Ng and colleagues (2018) concluded that high- versus low-dose local anesthetics performed comparably.

Local infiltration or TAP blocks can be used also for postoperative pain control. The TAP block in one trial was not superior to local wound infiltration (Tawfik, 2017). Gao and associates (2019) demonstrated that pain relief with the TAP block was comparable with that from patient-controlled IV analgesia. Another study found that the TAP block was equivalent to intrathecal morphine for postoperative pain (Kwikiriza, 2019). Last, Prabhu and coworkers (2018) reported that a liposomal bupivacaine incisional block was not superior to placebo.

GENERAL ANESTHESIA

Trained personnel and specialized equipment—including fiberoptic intubation—are mandatory for the safe use of general anesthesia. A common cause of death cited is failed intubation. The latter occurs in approximately 1 of every 390 general anesthetics administered to pregnant women (Kinsella, 2015).

This relatively higher mortality rate suggests that neuraxial analgesia is the preferred method of pain control and should be used unless contraindicated (American College of Obstetricians and Gynecologists, 2019b; American Society of Anesthesiologists, 2016). In two reports from the MFMU Network, 93 percent of more than 54,000 cesarean deliveries were performed using neuraxial analgesia (Bloom, 2005; Brookfield, 2013). Racial and ethnic disparities exist, and a higher incidence of general anesthesia use is seen among non-white women (Butwick, 2014; Lange, 2017). It is often used for emergent cesarean delivery for acute fetal distress (Metogo, 2021). In contrast, with obstetrical anesthesiologist subspecialists, the overall likelihood that neuraxial analgesia will be used is higher (Cobb, 2019).

Patient Preparation

Before anesthesia induction, several steps should be taken to help minimize complication risks. First, antacid administration shortly before anesthesia induction has probably decreased mortality rates from general anesthesia more than any other

single practice. The American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2016) recommends timely administration of a nonparticulate antacid, an H_2-receptor antagonist, or metoclopramide. For many years, we have recommended administration of 30 mL of Bicitra—sodium citrate with citric acid—a few minutes before anesthesia induction by either general or major neuraxial block. If more than 1 hour has passed after the first dose was given and anesthesia has not yet been induced, a second dose is given.

Lateral uterine displacement also is provided as the uterus may compress the inferior vena cava and aorta when the mother is supine. With uterine displacement, the duration of general anesthesia has less effect on neonatal condition than if the woman remains supine (Crawford, 1972).

Last, because functional reserve lung capacity is diminished, and oxygen consumption is increased, the pregnant woman becomes hypoxemic more rapidly during periods of apnea than do nonpregnant patients. Obesity exacerbates this tendency. To minimize hypoxia between the time of muscle relaxant injection and intubation, nitrogen is replaced by oxygen in the lungs. This preoxygenation is accomplished by administering 100-percent oxygen via face mask for 2 to 3 minutes before anesthesia induction. In an emergency, four vital capacity breaths of 100-percent oxygen via a tight breathing circuit will provide similar benefit (Norris, 1985). High-flow nasal oxygen was found to be inferior to administration by face mask (Shippam, 2019; Tan, 2019).

Induction of Anesthesia

Drugs used to induce general anesthesia include propofol, etomidate, and ketamine. Propofol has the undesirable side effect of hypotension. Etomidate is associated with fewer hemodynamic changes. Ketamine also may be used for induction of general anesthesia in hemodynamically unstable women.

Intubation

Immediately after a patient is rendered unconscious, a muscle relaxant is given to aid intubation. *Succinylcholine,* a rapid-onset and short-acting agent, is used. Cricoid pressure—the *Sellick maneuver*—is applied by a trained assistant to occlude the esophagus from the onset of induction until intubation is completed. Before the operation begins, proper placement of the endotracheal tube must be confirmed.

As discussed, and although uncommon, failed intubation is a major cause of anesthesia-related maternal mortality. A history of prior difficult intubation and a careful anatomical assessment of the neck and the maxillofacial, pharyngeal, and laryngeal structures may help predict intubation complications. Even in cases in which the initial airway assessment was unremarkable, edema may develop intrapartum and present considerable challenges. Morbid obesity is a major risk factor for failed or difficult intubation.

The American Society of Anesthesiologists Task Force on Obstetric Anesthesia (2016) stresses the importance of appropriate preoperative preparation. This includes the immediate availability of specialized equipment such as different-shaped laryngoscopes, laryngeal mask airways, and video laryngoscopes, as well as equipment for transtracheal ventilation and awake oral intubation with a fiberoptic bronchoscope.

Following failed intubation, the woman is ventilated by mask and cricoid pressure is applied to reduce the aspiration risk. Surgery may proceed with mask ventilation, or the woman may be allowed to awaken. In those cases in which the woman has been paralyzed and in which ventilation cannot be reestablished by insertion of an oral airway, by laryngeal mask airway, or by use of a fiberoptic laryngoscope, then a life-threatening emergency exists (Eskander, 2019). To restore ventilation, percutaneous or even open cricothyrotomy is performed, and jet ventilation begun. Failed intubation drills have been recommended to optimize response to such an emergency.

Inhalational Anesthetics

Once the endotracheal tube is secured, a volatile halogenated agent is given to provide amnesia and analgesia. The most commonly used volatile anesthetics in the United States include *desflurane* and *sevoflurane.* These gases can also produce uterine relaxation when given in high concentrations. These are used when relaxation is a requisite, such as for internal podalic version of the second twin, breech decomposition, ex utero intrapartum treatment (EXIT) procedures, and replacement of the acutely inverted uterus.

Extubation

The endotracheal tube may be safely removed only if the woman is conscious to a degree that enables her to follow commands and is capable of maintaining oxygen saturation with spontaneous respiration. Consideration should be given to emptying the stomach via a nasogastric tube before extubation. As induction has now become safer, extubation may be relatively more perilous. Of 15 anesthesia-related deaths of pregnant women from 1985 to 2003 in Michigan, none occurred during induction, whereas five resulted from hypoventilation or airway obstruction during emergence, extubation, or recovery (Mhyre, 2007).

Fasting

Data are insufficient regarding fasting times for clear liquids and the risk of pulmonary aspiration during labor. The American Society of Anesthesiologists Task Force on Obstetrical Anesthesia (2016) and the American College of Obstetricians and Gynecologists (2017) recommend that modest amounts of clear liquids such as water, clear tea, black coffee, carbonated beverages, and pulp-free fruit juices be allowed in uncomplicated laboring women. As discussed in Chapter 30 (p. 550), enhanced recovery after surgery (ERAS) protocols provide consumption of these same liquids up to 2 hours before scheduled surgery (Wilson, 2018b). Obvious solid foods should be avoided. A fasting period of 6 to 8 hours, depending on the type of food ingested, is recommended for uncomplicated parturients undergoing elective cesarean delivery or puerperal tubal ligation. The amount of gastric fluid—2 mL/kg—in nonlaboring women is almost the same as that in nonpregnant

women (Van de Putte, 2019). However, pregnancy is associated with horizontal shift of the stomach and a reduced esophageal sphincter tone. Our policy at Parkland Hospital is to allow clear liquids in low-risk uncomplicated laboring women in whom vaginal delivery is anticipated.

Aspiration

Massive gastric acidic inhalation may cause pulmonary insufficiency from aspiration pneumonitis (Mandell, 2019). Such pneumonitis has in the past been the most common cause of anesthetic deaths in obstetrics and therefore deserves special attention. To minimize this risk, antacids should be given routinely, intubation should be accompanied by cricoid pressure, and regional analgesia should be employed when possible.

Pathophysiology

In 1952, Teabeaut demonstrated experimentally that if the pH of aspirated fluid was below 2.5, severe chemical pneumonitis developed. It was later demonstrated that the gastric fluid pH of nearly half of women tested intrapartum was <2.5 (Taylor, 1966). The right mainstem bronchus usually offers the simplest pathway for aspirated material to reach the lung parenchyma, and therefore, the right lower lobe is most often involved. In severe cases, involvement is bilateral and widespread.

The woman who aspirates may develop evidence of respiratory distress immediately or several hours after aspiration, depending in part on the material aspirated and the severity of the response. Aspiration of a large amount of solid material causes obvious signs of airway obstruction. Smaller particles without acidic liquid may lead to patchy atelectasis and later to bronchopneumonia.

When highly acidic liquid is inspired, decreased oxygen saturation along with tachypnea, bronchospasm, rhonchi, rales, atelectasis, cyanosis, tachycardia, and hypotension are likely to develop. At the injury sites, there is pulmonary capillary leakage and exudation of protein-rich fluid containing numerous erythrocytes into the lung interstitium and alveoli. This causes decreased pulmonary compliance, shunting of blood, and severe hypoxemia.

Suspicion of aspiration demands close monitoring for evidence of pulmonary damage. Respiratory rate and oxygen saturation as measured by pulse oximetry are the most sensitive and earliest indicators of injury. Radiographic changes may not appear immediately and may be variable. Therefore, chest radiographs alone should not be used to exclude aspiration.

Treatment

Inhaled fluid should be immediately and thoroughly wiped from the mouth and removed from the pharynx and trachea by suction. Saline lavage may further disseminate the acid throughout the lung and is not recommended. If large particulate matter is inspired, bronchoscopy may be indicated to relieve airway obstruction. Use of corticosteroid therapy or prophylactic antimicrobial administration are not supported by clinical or experimental evidence (Mandell, 2019). If infection develops, however, vigorous treatment is given. Etiological agents have shifted from anaerobic or mixed infections to bacteria causing community- or hospital-acquired pneumonitis (Metlay, 2019). These infections are discussed in Chapter 54 (p. 962). If acute respiratory distress syndrome develops, mechanical ventilation with positive end-expiratory pressure may prove lifesaving (Chap. 50, p. 885).

CHAPTER 26

Induction and Augmentation of Labor

Today, several pharmacological agents permit labor to be induced or augmented. *Induction* implies stimulation of contractions before the spontaneous onset of labor, with or without ruptured membranes. When the cervix is closed and uneffaced, labor induction is often preceded by *cervical ripening*, a process to soften and open the cervix. This is somewhat of a misnomer in that cervical ripening, per se, may also be a means of labor induction. *Augmentation* refers to enhancement of spontaneous contractions that are considered inadequate because of failed cervical dilation and poor fetal descent. This chapter presents indications and methods for labor induction or augmentation and for cervical ripening.

LABOR INDUCTION

Indications

In the United States, the incidence of labor induction rose from 9.5 percent in 1991 to 27 percent in 2019 (Martin, 2019). Induction is indicated when the benefits to either mother or fetus outweigh those of pregnancy continuation. The more common indications include membrane rupture without labor, gestational hypertension, oligohydramnios, nonreassuring fetal status, postterm pregnancy, and various maternal medical conditions such as chronic hypertension and diabetes (American College of Obstetricians and Gynecologists, 2019a).

Methods to induce or augment labor are contraindicated by most conditions that preclude spontaneous labor or delivery. Maternal contraindications are an abnormally implanted placenta or a prior uterine incision type that is associated with a high rupture risk. Uncommon conditions are active genital herpes infection, contracted or distorted pelvic anatomy, or cervical cancer. Fetal factors include appreciable macrosomia, severe hydrocephalus, malpresentation, or nonreassuring fetal status.

Risks

Some maternal complications associated with labor induction are chorioamnionitis, uterine rupture, and postpartum hemorrhage from uterine atony. Earlier nonrandomized studies suggested a particularly higher risk for cesarean delivery in nulliparas undergoing labor induction (Luthy, 2004; Yeast, 1999). More recent ones, however, cite comparable or even lower rates of cesarean delivery when induced labor is compared with spontaneous labor (Middleton, 2020; Souter, 2019).

These studies used spontaneous labor as the comparator, which may be less suitable than using expectant management as the comparator. In the ARRIVE trial—A Randomized Trial of Induction Versus Expectant Management-more than 6000 low-risk nulliparas at 39 weeks' gestation were randomly assigned to labor induction or expectant management groups (Table 26-1) (Grobman, 2018; Tita, 2021). Primary outcome, which was the rate of severe neonatal morbidity or death, did not differ between cohorts. However, the cesarean delivery rate in the induction arm was significantly lower than that in the expectantly managed cohort—18.6 versus 22.2 percent, respectively. Rates

TABLE 26-1. Selected Maternal and Perinatal Outcomes with Labor Induction Versus Expectant Management in Low-Risk Nulliparous Women—the ARRIVE Trial

Factor	Induction (%) (n = 3059)	Expectant (%) (n = 3037)	*p* value
Maternal outcome[a]			
Cesarean delivery	18.6	22.2	<0.001
Operative vaginal delivery	7.3	8.5	0.07
Hypertensive disorder	9.1	14.1	<0.001
Chorioamnionitis	13.3	14.1	0.35
Postpartum hemorrhage	4.6	4.5	0.81
Perinatal outcome[b]	4.3	5.4	0.049
Respiratory support	3.0	4.2	
Apgar score ≤3 at 5 min	0.4	0.6	
Seizure	0.4	0.1	
Meconium aspiration	0.6	0.9	
Birth trauma	0.5	0.6	
Perinatal death	0.1	0.1

of chorioamnionitis, postpartum hemorrhage, and peripartum infection were not significantly different. In a metaanalysis of six cohort studies, elective induction at 39 weeks' gestation had a significantly lower risk of cesarean delivery and these other morbidities compared with expectant management (Grobman, 2019).

With induction, the overall associated risk of uterine rupture is low but is highest with a prior uterine scar (Landon, 2004). The American College of Obstetricians and Gynecologists (2019c) recommends against the use of prostaglandins for preinduction cervical ripening or for labor induction in women with a prior uterine incision. It recognizes labor induction with oxytocin as an option but also notes the higher potential rupture rate and lower VBAC rate. Oxytocin augmentation may be used in those undergoing TOLAC, although evidence for higher rupture rates are conflicting.

Amniotomy is often selected to augment labor (p. 494). Of other potential risks, women whose labor is managed with amniotomy have a higher incidence of chorioamnionitis compared with those in spontaneous labor (American College of Obstetricians and Gynecologists, 2019a).

In some, but not all studies, uterine atony and associated postpartum hemorrhage are more common in women undergoing induction or augmentation (Grobman, 2018; Widmer, 2020). And as discussed in Chapter 42 (p. 733), atony with intractable hemorrhage, especially following cesarean delivery, is a frequent indication for peripartum hysterectomy. In a study from Parkland Hospital, labor induction was associated with 17 percent of 553 unanticipated peripartum hysterectomies (Hernandez, 2013).

■ Elective Labor Induction

Until recently, the American College of Obstetricians and Gynecologists (2019a) did not recommend elective labor induction at term for convenience. Occasional exceptions are risk of rapid labor, psychosocial indications, or logistics that factor family support availability and distance from the hospital. Importantly, several studies have shown that elective delivery before 39 completed weeks' gestation is associated with significant adverse neonatal morbidity (Chiossi, 2013; Salemi, 2016; Tita, 2009).

This proscription against elective induction at term was reconsidered following publication of the previously cited ARRIVE trial. Because of the results from that trial, the American College of Obstetricians and Gynecologists (2018) and the Society for Maternal-Fetal Medicine (2019) conclude that offering elective induction to low-risk, well-dated nulliparas at 39 weeks' gestation is reasonable. These women must meet the criteria for the ARRIVE trial, and it is recommended to combine shared decision-making with consideration of available resources.

■ Factors Affecting Induction Success

Several factors affect the ability of labor induction to achieve vaginal delivery. Favorable factors include younger age, multiparity, body mass index (BMI) <30, favorable cervix, and birthweight <3500 g (Freret, 2021; Sievert, 2017). In many cases, the uterus is simply poorly prepared for labor. One example is an "unripe" or "unfavorable" cervix. Indeed, investigators with the *Consortium on Safe Labor* reported that elective induction resulted in vaginal delivery in 97 percent of multiparas and 76 percent of nulliparas. Induction was more often successful with a "ripe cervix" (Laughon, 2012).

Failure of induction is likely strongly influenced by the induction duration, especially with an unfavorable cervix (Spong, 2012). In one study, labor duration to reach the active phase and to complete dilation was adversely affected by a higher BMI (Kominiarek, 2011). Similar findings were

TABLE 26-2. Some Commonly Used Regimens Compared with Oxytocin Infusion for Preinduction Cervical Ripening and/or Labor Induction

Techniques	Agent	Route/Dose	Compared with Oxytocin
Pharmacological			
Prostaglandin E_2	Dinoprostone gel, 0.5 mg (Prepidil) Dinoprostone insert, 10 mg (Cervidil)	Cervical 0.5 mg; repeat in 6 hr; permit 3 doses total Posterior fornix, 10 mg	1. Shorter I-D times with oxytocin infusion than oxytocin alone 1. Insert has shorter I-D times than gel 2. 6–12 hr interval from last insert to oxytocin infusion
Prostaglandin E_1[a]	Misoprostol tablet, 100 or 200 μg (Cytotec)[b]	Vaginal, 25 μg; repeat 3–6 hr prn Oral, 50–100 μg; repeat 3–6 hr prn	1. Contractions within 30–60 min 2. Success comparable to oxytocin for ruptured membranes at term and/or favorable cervix 3. Tachysystole common with vaginal doses >25 μg
Mechanical			
Transcervical 36F Foley catheter	30-mL balloon	Transcervical	1. Improves Bishop scores rapidly 2. 80-mL balloon more effective 3. Combined with oxytocin infusion is superior to PGE_1 vaginally 4. With EASI, results improved and possible decreased infection rate
Hygroscopic dilators	Laminaria, hydrogel	Intracervical	1. Rapidly improves Bishop score 2. May not shorten I-D times with oxytocin 3. Uncomfortable, requires speculum and placement on an examination table

[a]Off-label use.
[b]Tablets must be divided for 25- and 50-μg dose, but drug is evenly dispersed.
EASI = extraamnionic saline infusion at 30–40 mL/hr; I-D = induction-to-delivery.

reported for women with diabetes (Hawkins, 2017). Simon and Grobman (2005) concluded that a latent phase as long as 18 hours allowed most women undergoing labor induction to achieve a vaginal delivery without a significantly increased risk of maternal or neonatal morbidity. Rouse and associates (2000) recommend a minimum of 12 hours of uterine stimulation with oxytocin after membrane rupture, whereas Kawakita and coworkers (2016) recommend up to 15 hours for multiparas.

PREINDUCTION CERVICAL RIPENING

As noted, a soft cervix—described as "ripe" or "favorable"—is important to successful labor induction. However, some estimates of favorability are highly subjective (Feltovich, 2017). Still, pharmacological and mechanical methods can enhance cervical qualities in a process of *preinduction cervical ripening*.

Some of the techniques may have benefits compared with oxytocin induction alone (Table 26-2). Namely, some are able to initiate labor and may effect delivery when used alone. However, few data support the premise that any of these methods lower cesarean delivery rates or lessen maternal or neonatal morbidity compared with women in whom these methods are not used.

■ Cervical "Favorability"

One quantifiable method to predict labor induction outcomes is the score described by Bishop (1964) and presented in Table 26-3. As favorability or Bishop score rises, the rate of induction to effect vaginal delivery also increases. A *Bishop score* >8 conveys a high likelihood for a successful induction, and a score ≤6 is considered unfavorable (American College of Obstetricians and Gynecologists, 2019a).

TABLE 26-3. Bishop Scoring System Used for Assessment of Inducibility

	Cervical Factor				
Score	Dilatation (cm)	Effacement (%)	Station (–3 to +2)	Consistency	Position
0	Closed	0–30	–3	Firm	Posterior
1	1–2	40–50	–2	Medium	Midposition
2	3–4	60–70	–1	Soft	Anterior
3	≥5	≥80	+1, +2	—	—

Laughon and coworkers (2011) attempted to simplify the Bishop score by performing a regression analysis on 5610 nulliparas with term singletons at 38 to 42 weeks' gestation. Cervical dilation, station, and effacement were significantly associated with successful vaginal delivery. Thus, a simplified Bishop score had a similar or improved positive- or negative-predictive value compared with that of the original Bishop score. Others have reported similar findings when consistency and position are omitted (Ivars, 2016; Raghuraman, 2016).

Transvaginal sonographic measurement of cervical length has been evaluated as a Bishop score alternative (Feltovich, 2017). However, data from a metaanalysis of 31 trials showed overall low sensitivity and specificity and limited predictive utility to forecast successful induction (Verhoeven, 2013).

Pharmacological Agents

Prostaglandin analogues make up available options. These can also stimulate contractions and thereby aid subsequent labor induction or augmentation. Importantly, in most studies of preinduction cervical ripening, oxytocin infusion either is initiated with the ripening agent or follows cervical change.

Prostaglandin E_2

Dinoprostone is a synthetic analogue of prostaglandin E_2 (PGE_2). It is commercially available in three forms: a gel, a time-release vaginal insert, and a 20-mg suppository (see Table 26-2). The gel and time-release vaginal insert formulations are indicated only for cervical ripening before labor induction. *Importantly, the 20-mg suppository is not indicated for cervical ripening.* It instead is used for pregnancy termination between 12 and 20 weeks' gestation and for evacuation of the uterus after fetal demise up to 28 weeks.

Local application of the PGE_2 gel form—*Prepidil*—is available in a 2.5-mL syringe for an intracervical application of 0.5 mg of dinoprostone. With the woman supine, the tip of a prefilled syringe is placed intracervically, and the gel is deposited just below the internal cervical os. After application, the woman remains reclined for 30 minutes. Doses may be repeated every 6 hours, with a maximum of three doses recommended in 24 hours.

A 10-mg dinoprostone vaginal insert—*Cervidil*—also is approved for cervical ripening. This is a thin, flat, rectangular polymeric wafer held within a small, white, mesh polyester sac (Fig. 26-1). The sac has a long attached tail to allow easy removal from the vagina. The insert provides slower release of medication—0.3 mg/hr—than the gel form. Cervidil is used as a single dose placed transversely in the posterior vaginal fornix. Lubricant is used sparingly, if at all, because it can coat the device and hinder dinoprostone release. Following insertion, the woman remains recumbent for at least 2 hours. The insert is removed after 12 hours or with labor onset and at least 30 minutes before the administration of oxytocin. Since the active drug is encased in a mesh sac, one benefit is the ability for removal if fetal heart rate abnormalities or tachysystole develop.

Most metaanalyses of dinoprostone efficacy report a reduced time to delivery within 24 hours. However, they do not consistently show a reduction in the cesarean delivery rate.

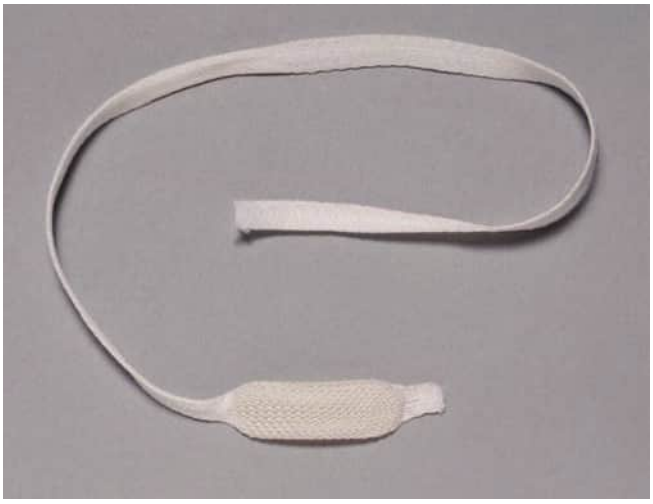

FIGURE 26-1 Cervidil vaginal insert contains 10 mg of dinoprostone designed to release approximately 0.3 mg/hr during a 10-hour period.

Thomas and colleagues (2014) provided a Cochrane review of 70 trials that included 11,487 women given vaginal prostaglandins or either placebo compared with no treatment. They noted a higher vaginal delivery rate within 24 hours when prostaglandins were used. They also reported a threefold greater risk of tachysystole accompanied by fetal heart rate changes, but cesarean delivery rates were not significantly decreased. Similar results were noted in another Cochrane review of intracervical dinoprostone gel (Boulvain, 2008). Compared with placebo or no treatment, a reduced risk of cesarean delivery was found only in a subgroup of women with an unfavorable cervix and intact membranes.

Last, the Foley catheter versus vaginal PGE_2 gel for induction of labor at term—PROBAAT-P and M trials—were unblinded, randomized trials comparing these two options (Jozwiak, 2011, 2013, 2014). The cesarean delivery rate did not differ, a finding consistent with accompanying metaanalyses.

Side Effects

Uterine tachysystole follows vaginally administered PGE_2 in 1 to 5 percent of women (Hawkins, 2012). Although definitions of abnormal uterine activity vary among studies, most use the definition recommended by the American College of Obstetricians and Gynecologists (2019b). *Uterine tachysystole* is defined as >5 contractions in a 10-minute period. It should always be qualified by the presence or absence of fetal heart rate abnormalities. The terms *uterine hypertonus*, *hyperstimulation*, and *hypercontractility* are terms no longer defined, and their use is not recommended.

Because uterine tachysystole associated with fetal compromise may develop when prostaglandins are used with preexisting spontaneous labor, such use is not recommended. If tachysystole follows the 10-mg insert, its removal by pulling on the tail of the surrounding net sac will usually reverse this effect. Irrigation to remove the gel preparation has not been shown to be helpful.

The manufacturers recommend caution when these preparations are used in women with ruptured membranes. This concern is also extended to women with glaucoma or asthma. However, in a review of 189 women with asthma, dinoprostone was not associated with asthma worsening or exacerbation

(Towers, 2004). Other contraindications listed by the manufacturers include prior dinoprostone hypersensitivity, suspicion of fetal compromise or cephalopelvic disproportion, unexplained vaginal bleeding, six or more prior term pregnancies, and contraindications to vaginal delivery. Others are women already receiving oxytocin, those with a contraindication to oxytocin, or those who may be endangered by prolonged uterine contractions, for example, those with prior cesarean delivery or uterine surgery.

Administration

PGE_2 preparations should be administered only in or near the delivery suite. Moreover, uterine activity and fetal heart rate should be monitored (American College of Obstetricians and Gynecologists, 2019a). These guidelines stem from the risk of uterine tachysystole. When contractions begin, they are usually apparent in the first hour and show peak activity in the first 4 hours. According to manufacturer guidelines, oxytocin induction that follows prostaglandin use for cervical ripening should be delayed for 6 to 12 hours following PGE_2 gel administration or for at least 30 minutes after removal of the vaginal insert.

■ Prostaglandin E_1

Misoprostol—*Cytotec*—is a synthetic prostaglandin E_1 (PGE_1) that is approved as a 100- or 200-μg tablet for peptic ulcer prevention. These tablets can be split to administer 25- or 50-μg doses. The drug is absorbed from both vaginal, oral, and buccal administration. Randomized trials of labor induction with misoprostol have evaluated various induction regimens with differing primary outcomes (Table 26-4).

Misoprostol is widely used "off label" safely for preinduction cervical ripening (American College of Obstetricians and Gynecologists, 2019a). The tablets are stable at room temperature, and the drug currently is the preferred prostaglandin for cervical ripening at Parkland Hospital.

Vaginal Administration

Compared with intracervical or intravaginal PGE_2, vaginally administered misoprostol tablets offer equivalent or superior efficacy for cervical ripening or labor induction (Hofmeyr, 2010). Compared with oxytocin or with intravaginal or intracervical dinoprostone, vaginal misoprostol increased the vaginal delivery rate within 24 hours. Although the uterine tachysystole rate was higher, this did not affect cesarean delivery rates. Moreover, compared with dinoprostone, misoprostol lowered the need for oxytocin induction, but it raised the frequency of meconium-stained amnionic fluid. Higher doses of misoprostol are associated with a decreased need for oxytocin but with greater rates of uterine tachysystole, with and without fetal heart rate changes. The American College of Obstetricians and Gynecologists (2019a) recommends a 25-μg vaginal dose. The drug is evenly distributed among 100-μg tablets that are quartered.

Oral Administration

PGE_1 tablets are also effective when given orally, but with a faster peak concentration and decline compared with the

TABLE 26-4. Randomized Trials with 200 or More Subjects Designed to Compare Misoprostol (PGE_1) With or Without Foley Bulb

Study	Comparators	Primary Outcome	N	Findings
Kehl (2015)	Double balloon catheter + oral PGE_1 (50 μg) vs oral PGE_1 alone	TTD	326	Longer TTD with Foley + oral PGE_1 (32h) vs oral E_1 alone (22h) ($p = 0.004$)
Ten Eikelder (2016)	PROBAAT-II: Oral PGE_1 (50 μg) vs Foley	Neonatal asphyxia or EBL >1000 mL	1859	No difference in primary outcome: Foley (12%) vs oral PGE_1 (11.5%)
Levine (2016)	FOR MOMI: Vaginal PGE_1 (25 μg) + Foley vs oxytocin + Foley vs vaginal PGE_1 alone vs Foley alone	TTD	492	Shorter TTD with combinations: Foley + PGE_1 (13.1h), oxytocin + Foley (14.5h), PGE_1 alone (17.6h), Foley alone (17.7h) ($p < 0.001$)
Kruit (2016)	Foley vs oral PGE_1 (50–100 μg)	CD and infections	202	No difference in CD or maternal/neonatal infection rates
Mundle (2017)	Foley vs oral PGE_1 (25 μg)	VD within 24h	602	VD within 24h more common in oral PGE_1 (57%) vs Foley (47%) ($p = 0.014$)
Al-Ibraheemi (2018)	Vaginal PGE_1 (25 μg) ± Foley	TTD	200	TTD in combination group (15h) vs vaginal PGE_1 alone (19h) ($p = 0.001$)
Young (2020)	Oral PGE_1 (50 μg) vs vaginal PGE_1 (25–50 μg) vs dinoprostone gel (1 to 2 mg)	TTD	511	TTD differences not significant: oral PGE_1 (22.6h), vaginal PGE_1 (25.5h), vaginal dinoprostone (20.1h) ($p = 0.46$)
Adhikari (2020)	Oral PGE_1 (100 μg) ± Foley	VD	2227	No difference in VD rates: Foley + oral PGE_1 (78%), PGE_1 alone (77%)

CD = cesarean delivery; EBL = estimated blood loss; N = participant number; PGE_1 = prostaglandin E_1; TTD = time to delivery; VD = vaginal delivery.

vaginal route. One Cochrane metaanalysis of 76 trials reported that oral misoprostol compared with placebo significantly increased the rate of vaginal birth within 24 hours, while decreasing the need for oxytocin and lowering the cesarean delivery rate (Alfirevic, 2014). Comparisons of oral misoprostol and oxytocin and of oral misoprostol and dinoprostone also found significantly reduced rates of cesarean delivery with misoprostol. Similar efficacy was noted between oral misoprostol and vaginal administration, although oral administration was associated with significantly higher Apgar scores and less postpartum hemorrhage. Thorbiörnson and associates (2017) also reported lower rates of cesarean delivery with oral misoprostol compared with vaginal dinoprostone.

■ Nitric Oxide Donors

Over the years, agents that stimulate nitric oxide production have been studied for labor induction. Physiologically, nitric oxide is likely a mediator of cervical ripening. Cervical nitric oxide metabolite concentrations are increased at the beginning of uterine contractions.

Both *isosorbide mononitrate* and *glyceryl trinitrate* have been studied but are less effective clinically than prostaglandins for cervical ripening. In one metaanalysis, the rate of cesarean delivery was not reduced in those given nitric oxide donors compared with those given placebo, intravaginal or intracervical prostaglandins, intravaginal misoprostol, or intracervical catheter (Ghosh, 2016). However, nitric oxide donors were associated with significantly more headaches, nausea, and vomiting.

■ Mechanical Techniques

These include transcervical placement of a Foley catheter, with or without extraamnionic saline infusion; hygroscopic cervical dilators; and membrane stripping. In one metaanalysis, mechanical methods reduced the risk of uterine tachysystole compared with prostaglandins, although cesarean delivery rates were unchanged (Jozwiak, 2012). Trials comparing mechanical techniques and oxytocin found a lower rate of cesarean delivery with mechanical methods. Trials comparing mechanical options with dinoprostone found a higher rate of multiparas undelivered at 24 hours with mechanical methods. In another metaanalysis comparing Foley catheter and intravaginal dinoprostone inserts, cesarean delivery rates were similar, but uterine tachysystole was less frequent with catheter use (Jozwiak, 2013).

Transcervical Catheter

Generally, this option is only used with an unfavorable cervix because the catheter comes out as the cervix opens. It is suitable for women with membranes that are intact or ruptured. In most cases, a Foley catheter is placed through the internal cervical os, and downward tension is created by taping the catheter to the thigh (Mei-Dan, 2014). *Extraamnionic saline infusion (EASI)* is one modification. It adds a constant saline infusion through the catheter into the space between the internal os and placental membranes (Fig. 26-2). In one study, chorioamnionitis was significantly less frequent when infusion was added compared with no infusion—6 versus 16 percent (Karjane, 2006). Similarly,

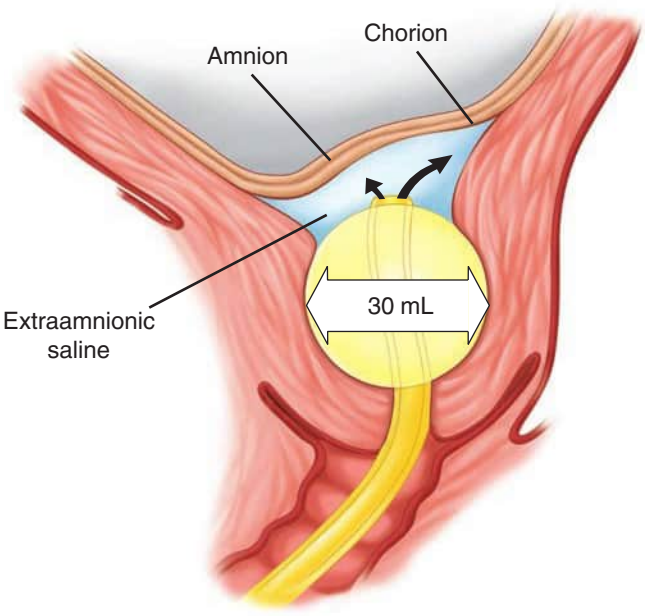

FIGURE 26-2 Extraamnionic saline infusion (EASI) through a 26F Foley catheter that is placed through the cervix. The 30-mL balloon is inflated with saline and pulled snugly against the internal os, and the catheter is taped to the thigh. Room-temperature normal saline is infused through the catheter port of the Foley at 30 or 40 mL/hour by intravenous infusion pump.

in a metaanalysis, transcervical catheters were not associated with higher rates of maternal or fetal infection (McMaster, 2015).

As discussed earlier, transcervical catheters do not reduce the cesarean delivery rate compared with prostaglandins. There were several iterations of the PROBAAT trials—I, P, M, and II—in which cervical ripening with a Foley catheter was compared with vaginal dinoprostone gel, dinoprostone vaginal inserts, and vaginal or oral misoprostol (Jozwiak, 2011, 2013, 2014; Ten Eikelder, 2016). These studies reported similar outcomes between the mechanical methods and the prostaglandin agents. Also, fewer overall cases of cardiotocographic changes were seen in the mechanical technique group.

Similar cesarean delivery rates are found in other comparison studies. Schoen and coworkers (2017) observed that concurrent oxytocin with a transcervical Foley catheter shortened the median time to delivery compared with a Foley catheter followed by oxytocin. However, rates of cesarean delivery were unchanged. Connolly and associates (2016) reported similar findings for women within intact membranes undergoing labor induction. Amorosa and colleagues (2017) found no benefit for transcervical catheter coupled with oxytocin compared with oxytocin alone for women with ruptured membranes. Other studies of concurrent misoprostol reported reduced time to delivery without affecting cesarean delivery rates (Carbone, 2013; Levine, 2016). With catheter induction plus misoprostol, one randomized trial found vaginal misoprostol to be superior to buccal administration (Gomez, 2021). Last, addition of tension does not appear to enhance catheter efficacy (Fruhman, 2017). These investigators randomly assigned 140 women to transcervical Foley catheter placement, with and without tension, and reported similar vaginal delivery rates.

One large trial at Parkland Hospital evaluated the addition of a Foley catheter to oral misoprostol. With catheter addition, investigators found no improvement in the vaginal delivery rate, but the chorioamnionitis rate was 30-percent higher (Adhikari, 2020). The unaltered vaginal delivery rate persisted in a stratified analysis of nulliparas and multiparas. In this study, our standard labor induction protocol with misoprostol alone achieved a 77-percent vaginal delivery rate.

Hygroscopic Cervical Dilators

Cervical dilation can be accomplished using hygroscopic or osmotic cervical dilators, which are illustrated in Chapter 11 (p. 209). Briefly, these include *Laminaria japonicum* or hygroscopic devices (Dilapan-S). Intuitive concerns of ascending infection have not been verified, and their use appears to be safe. Placement generally requires a speculum and positioning of the woman on an examination table. Studies comparing hygroscopic cervical dilators and prostaglandins found few benefits (Maier, 2018).

METHODS OF INDUCTION AND AUGMENTATION

Oxytocin has been used for labor induction for more than 70 years (Theobald, 1948). As discussed, other methods now include prostaglandins, which are used alone or in combination with oxytocin. Prostaglandins include misoprostol and dinoprostone. Mechanical methods encompass membrane stripping, artificial rupture of membranes, extraamnionic saline infusion, transcervical balloons, and hygroscopic cervical dilators. As recommended in *Guidelines for Perinatal Care*, each obstetrical department should have written protocols that describe administration of these methods for labor induction and augmentation (American College of Obstetricians, 2017).

Because preinduction cervical ripening frequently prompts labor, studies to determine induction efficacy for some of these agents have produced confusing results. The use of prostaglandins for labor augmentation has generally been considered experimental due to high rates of uterine tachysystole.

■ Prostaglandin E_1

Both vaginal and oral misoprostol are used for either cervical ripening or labor induction. For labor induction in women at or near term with either prematurely ruptured membranes or a favorable cervix, 100 μg of oral or 25 μg of vaginal misoprostol has similar efficacy compared with intravenous oxytocin. From these studies, evidence supports that oral misoprostol may be superior (Alfirevic, 2014; Hofmeyr, 2010; Lo, 2003). That said, misoprostol is associated with a greater rate of uterine tachysystole, particularly at higher doses. Also, induction with PGE_1 may prove ineffective and require subsequent induction or augmentation with oxytocin.

Thus, although there are trade-offs regarding the risks, costs, and ease of administration of each drug, either is suitable for labor induction. At Parkland Hospital, we administer an initial oral 100-μg dose, which may be repeated for inadequate labor after 6 hours. Four hours after the second dose or in those with tachysystole, an oxytocin infusion is begun, if needed, for hypotonic labor. One study compared oral misoprostol and a newer misoprostol vaginal insert that releases drug up to 24 hours. With the insert, cesarean delivery and adverse neonatal outcome rates were higher, but time to delivery was shorter (Döbert, 2018). Additional studies found these adverse outcomes were mitigated if the insert time was limited to 10 hours (Brandstetter, 2019, 2020).

For *labor augmentation*, results of a randomized controlled trial showed oral misoprostol, 75 μg given at 4-hour intervals for a maximum of two doses, to be safe and effective (Bleich, 2011). Although the uterine tachysystole rate was higher among women with labor augmented with misoprostol, the frequency of nonreassuring fetal status or cesarean delivery did not differ between oxytocin and misoprostol.

■ Oxytocin

As previously emphasized, in many instances, preinduction cervical ripening and labor induction are simply a continuum. In this regard "ripening" can also stimulate labor. If not, induction or augmentation may be continued with solutions of oxytocin given by infusion pump. Its use in augmentation is a key component in the *active management of labor*, described in Chapter 22 (p. 430). With oxytocin use, the American College of Obstetricians and Gynecologists (2019a) recommends fetal heart rate and uterine contraction monitoring. Contractions can be monitored either by palpation or by electronic means.

Intravenous Oxytocin Administration

A 1-mL vial contains 10 units of oxytocin. A typical infusate consists of 10 or 20 units, which is 10,000 or 20,000 mU, respectively, mixed into 1000 mL of crystalloid or dextrose solution. This mixture results in an oxytocin concentration of 10 or 20 mU/mL, respectively, and is administered by infusion pump. To avoid bolus administration, the infusion should be inserted into the main intravenous line close to the venipuncture site.

The goal of induction or augmentation is to effect uterine activity sufficient to produce cervical change and fetal descent, while avoiding development of a nonreassuring fetal status. According to the American College of Obstetricians and Gynecologists (2019a), the latter is a category III fetal heart rate tracing. In general, oxytocin is discontinued if the number of contractions persists with a frequency of more than five in a 10-minute period or more than seven in a 15-minute period or with a persistent nonreassuring fetal heart rate pattern. Oxytocin discontinuation nearly always rapidly lowers contraction frequency. When oxytocin is stopped, its concentration in plasma rapidly falls because the half-life is approximately 3 to 5 minutes.

The uterus contracts within 3 to 5 minutes of beginning an oxytocin infusion, and a plasma steady state is reached in 40 minutes (Seitchik, 1984). Response varies greatly and depends on preexisting uterine activity, cervical status, pregnancy duration, and individual biological differences. Caldeyro-Barcia and Poseiro (1960) reported that the uterine response to oxytocin increases from 20 to 30 weeks' gestation and rises rapidly at term.

TABLE 26-5. Various Low- and High-Dose Oxytocin Regimens Used for Labor Induction

Regimen	Starting Dose (mU/min)	Interval (min)	Incremental Increase (mU/min)
Low-dose	0.5–1.5	15–40	1–2
	2	15	4, 8, 12, 16, 20, 25, 30
High-dose	4	15	4
	4.5	15–30	4.5
	6	20–40[a]	3–6[b]

[a]Uterine tachysystole is more common with shorter intervals.
[b]With uterine tachysystole and after oxytocin infusion is discontinued, it is restarted at one half the previous dose and then increased at 3-mU/min incremental doses.
From American College of Obstetricians and Gynecologists, 2019a; Hauth, 1986; Satin, 1992, 1994; Son, 2021; Tesemma, 2020.

Oxytocin is generally very successful when used to stimulate labor. In one large Cochrane metaanalysis, oxytocin was compared with expectant management, and fewer women—8 versus 54 percent—failed to deliver vaginally within 24 hours with oxytocin (Alfirevic, 2009). This analysis studied different oxytocin dosing regimens.

Oxytocin Regimens

Several evidence-based regimens for labor stimulation are now recommended by the American College of Obstetricians and Gynecologists (2019a). These and others are shown in Table 26-5. Initially, only variations of low-dose protocols were used in the United States. Subsequently, O'Driscoll and colleagues (1984) described their Dublin protocol for the active management of labor that called for oxytocin at a starting dosage of 6 mU/min and advanced in 6-mU/min increments. Subsequent comparative trials during the 1990s studied high-dose (4 to 6 mU/min) versus conventional low-dose (0.5 to 1.5 mU/min) regimens, both for labor induction and for augmentation.

From Parkland Hospital, Satin and associates (1992) evaluated an oxytocin regimen using an initial and incremental dosage of 6 mU/min compared with one using 1 mU/min. Among 1112 women undergoing induction, the 6-mU/min regimen resulted in a shorter mean admission-to-delivery time, fewer failed inductions, and no cases of neonatal sepsis. Among 1676 women who had labor augmentation, those who received the 6-mU/min regimen had a shorter duration-to-delivery time, fewer forceps deliveries, fewer cesarean deliveries for dystocia, and lower rates of intrapartum chorioamnionitis or neonatal sepsis. With this protocol, uterine tachysystole was managed by oxytocin discontinuation followed by resumption when indicated and at half the stopping dosage. Thereafter, the dosage was increased at 3 mU/min when appropriate, instead of the usual 6-mU/min increase used for women without tachysystole. No adverse neonatal effects were observed. More recently, Son and colleagues (2021) confirmed these findings in a randomized clinical trial.

In 1990 at Parkland Hospital, routine use of the 6-mU/min oxytocin beginning and incremental dosage was incorporated and continues through today. In other labor units, a 2-mU/min beginning and incremental oxytocin regimen is preferred and administered. With either regimen, dosages are employed for either labor induction or augmentation.

Interval Between Incremental Dosing

Intervals to increase oxytocin doses vary from 15 to 40 minutes (see Table 26-5). Satin and associates (1994) addressed this aspect with a 6-mU/min regimen providing increases at either 20- or 40-minute intervals. Women assigned to the 20-minute interval regimen for labor augmentation had a significantly reduced cesarean delivery rate for dystocia compared with that for the 40-minute interval regimen—8 versus 12 percent. As perhaps expected, uterine tachysystole was significantly more frequent with the 20-minute escalation regimen.

Other investigators reported even more frequent incremental increases. Frigoletto (1995) and Xenakis (1995) and their coworkers gave oxytocin at 4 mU/min with increases as needed every 15 minutes. Merrill and Zlatnik (1999) started with 4.5-mU/min doses and increased this every 30 minutes. López-Zeno and associates (1992) used 6-mU/min doses and 15-minute intervals.

Maximal Oxytocin Dosage

The *maximal* effective dose of oxytocin to achieve adequate contractions in all women is different. In one study of 1151 consecutive nulliparas, the likelihood of progression to vaginal delivery decreased at and beyond an oxytocin dosage of 36 mU/min (Wen, 2001). Still, at a dosage of 72 mU/min, half of the nulliparas were delivered vaginally. Thus, if contractions are not adequate—less than 200 Montevideo units—and if the fetal status is reassuring and labor has arrested, an oxytocin infusion dose greater than 48 mU/min has no apparent risks (Tesemma, 2020).

■ Risks versus Benefits

Unless the uterus is scarred, uterine rupture associated with oxytocin infusion is rare, even in parous women. Flannelly and associates (1993) reported no cases of uterine rupture, with or without oxytocin, in 27,829 nulliparas. Eight instances of overt uterine rupture during labor were noted in 48,718 parous women. Only one of these was associated with oxytocin use. A population-based retrospective review from Denmark reported a rupture rate of 3.3 per 100,000 women without prior cesarean, with the highest risk among multiparas (Thisted, 2015). Our experience from Parkland Hospital is that oxytocin induction and augmentation are associated with uterine rupture. During an 8-year period in which there were almost 95,000 births, 15 women suffered a primary uterine rupture, and 14 of these cases were associated with oxytocin use. In half of these women, prostaglandins were also given before augmentation with oxytocin.

Oxytocin has amino-acid homology similar to arginine vasopressin (AVP) and has significant antidiuretic action. When infused at doses of 20 mU/min or more, renal free water clearance drops markedly. If aqueous fluids are infused in appreciable amounts along with oxytocin, *water intoxication* can lead to convulsions, coma, and even death. In general, if

oxytocin is to be administered in high doses for a considerable period of time, its concentration should be increased rather than raising the flow rate of a more dilute solution. Consideration also should be given to use of crystalloids—either normal saline or lactated Ringer solution.

Uterine Contraction Pressures

Contraction forces in spontaneously laboring women range from 90 to 390 Montevideo units (Chap. 24, p. 462). Early researchers found that the mean or median spontaneous uterine contraction pattern between 140 and 150 Montevideo units resulted in progression to vaginal delivery (Caldeyro-Barcia, 1950; Seitchik, 1984).

Labor arrest in first-stage labor is described in Chapter 23 (p. 434). In the management of active-phase arrest, and with no contraindication to intravenous oxytocin, decisions must be made with knowledge of the safe upper range of uterine activity. Hauth and colleagues (1986) described an effective and safe protocol for oxytocin augmentation for active-phase arrest. With it, more than 90 percent of women achieved an average of at least 200 to 225 Montevideo units. They later reported that nearly all women in whom active-phase arrest persisted despite oxytocin generated more than 200 Montevideo units (Hauth, 1991). Importantly, despite no labor progression, no adverse maternal or perinatal effects were noted in those ultimately requiring cesarean delivery. Data regarding the safety and efficacy of contraction patterns in women with a prior cesarean delivery, with twins, or with an overdistended uterus are lacking.

Amniotomy for Induction and Augmentation

Elective amniotomy with the intention of accelerating labor is often performed. For labor induction, artificial rupture of the membranes—sometimes called *surgical induction*—can be used and always implies a commitment to delivery. The main disadvantage of amniotomy used alone for labor induction is the unpredictable and occasionally long interval until labor onset. That said, in a randomized trial, Bakos and Bäckström (1987) found that amniotomy alone or combined with oxytocin was superior to oxytocin alone. Mercer and colleagues (1995) randomly assigned 209 women undergoing oxytocin induction to either early amniotomy at 1 to 2 cm or late amniotomy at 5 cm. Early amniotomy was associated with a 4-hour reduction in labor duration. With early amniotomy, however, the incidence of chorioamnionitis was elevated. In a metaanalysis, De Vivo and associates (2020) reported that early amniotomy did not increase the risk of cesarean delivery yet reduced the interval from induction to delivery.

For labor augmentation, amniotomy is commonly performed when labor is abnormally slow. Shown in Table 26-6, amniotomy at approximately 5-cm dilation accelerated spontaneous labor by 1 to 1½ hours. Importantly, neither the need for oxytocin stimulation nor the overall cesarean delivery rate was higher. Although the incidences of mild and moderate cord compression patterns were increased following amniotomy, cesarean delivery rates for fetal distress were not greater. Most importantly, there were no adverse perinatal effects.

Rouse and associates (1994) also found that amniotomy with oxytocin augmentation for arrested active-phase labor shortened the time to delivery by 44 minutes compared with that of oxytocin alone. Although amniotomy did not alter the delivery route, one drawback was that it significantly increased the incidence of chorioamnionitis.

Regardless of the indication, amniotomy is associated with a risk of cord prolapse. To minimize this risk, disengagement of the fetal head during amniotomy is avoided. Toward this goal, fundal or suprapubic pressure or both may be helpful. Some clinicians prefer to rupture membranes during a contraction. If the vertex is not well applied to the lower uterine segment, a gradual egress of amnionic fluid can sometimes be accomplished by several membrane punctures with a 26-gauge needle held with a ring forceps and with direct visualization using a vaginal speculum. Alternatively, the trumpet used for pudendal blockade can sheath the needle and manually guide it through the cervix for amniotomy. In many of these cases, however, membranes tear and fluid is lost rapidly. Because of the risk of cord prolapse, or rarely placental abruption, the fetal heart rate is assessed before and immediately after amniotomy.

Membrane Stripping for Labor Induction

Labor induction by membrane "stripping" or "sweeping" is a frequent practice. Several studies have suggested that membrane stripping is safe and lowers the incidence of postterm pregnancy without consistently raising the incidence of ruptured

TABLE 26-6. Randomized Clinical Trials of Elective Amniotomy in Early Spontaneous Labor at Term

		Effects of Amniotomy					
Study	Number	Mean Dilation at Amniotomy	Mean Shortening of Labor	Need for Oxytocin	Cesarean Delivery Rate	Abnormal Tracing	Neonatal Effects
Fraser (1993)	925	<5 cm	125 min	None	None[a]	None	None
Garite (1993)	459	5.5 cm	81 min	Decreased	None	Increased[b]	None
UK Amniotomy Group (1994)	1463	5.1 cm	60 min	None	None	NA	None

[a]No effect on overall rate; cesarean delivery for fetal distress significantly increased.
[b]Increased mild and moderate umbilical cord compression patterns.
NA = not assessed.

membranes, infection, or bleeding. Randomized trials are limited and a metaanalysis of two of these reported sweeping to be ineffective (Hamidi, 2020). Downsides are discomfort and associated bleeding (Boulvain, 2005).

SECTION 8

DELIVERY

CHAPTER 27

Vaginal Delivery

The natural culmination of second-stage labor is controlled vaginal delivery of a healthy neonate with minimal trauma to the mother. Although some clinical settings favor cesarean delivery, for most fetuses, vaginal birth is preferred. For the mother, spontaneous vaginal vertex delivery poses the lowest risk of most maternal comorbidity, and comparisons with cesarean delivery are found in Chapter 30 (p. 548). Delivery is usually spontaneous, although some maternal or fetal complications may warrant operative vaginal delivery, described in Chapter 29 (p. 533). Last, a malpresenting fetus or multifetal gestation in many cases may be delivered vaginally but requires special techniques. These are described in Chapters 28 and 48.

DELIVERY TECHNIQUE

Preparation

The end of second-stage labor is heralded as the perineum begins to bulge, and the fetal scalp is seen through the separating labia. Perineal pressure from the fetal head creates reflexive pushing efforts. At this time, additional staff to attend the neonate and instruments are readied for delivery. Fetal heart rate monitoring continues. As one example, a nuchal cord often tightens with fetal descent and may lead to deepening variable decelerations. If the bladder is distended, catheterization can provide added pelvic space.

During second-stage labor, pushing positions may vary. But for delivery, the dorsal lithotomy position is most common and often the most satisfactory. Leg holders or stirrups are often used to assist. With or without their use, perineal laceration rates were equal in one randomized study of 214 parturients (Corton, 2012). With positioning, legs are not separated too widely or placed one higher than the other. Legs are not strapped into the stirrups. This permits quick flexion of the thighs backward onto the abdomen should shoulder dystocia develop. Legs may cramp during second-stage pushing, and cramping can be relieved by creating gentle muscle stretch, by brief massage, or both.

Preparation for delivery includes vulvar and perineal cleansing. If desired, sterile drapes are placed to cover the legs and abdomen and expose only the perineum. Scrubbing, gowning, gloving, and donning protective mask and eyewear protect both the gravida and accoucheur from infectious agents.

Delivery of the Head

By the end of second-stage labor, the position of the occiput is usually known. In some cases, however, molding and caput formation may have precluded early accurate identification. At this time, careful assessment is again performed as described in Chapter 22 (p. 429). In most cases, position is occiput anterior (OA) or is rotated slightly oblique. But, in perhaps 5 percent, an occiput posterior (OP) position persists.

With each contraction, the vulvovaginal opening is dilated by the fetal head to gradually form an ovoid and finally, an

almost circular opening. This encirclement of the largest head diameter by the vulvar ring is termed *crowning*. The anus becomes greatly stretched, and the anterior wall of the rectum is easily seen through it. The perineum thins and may spontaneously lacerate. Third- and fourth- degree perineal lacerations, which by definition involve the anal sphincter and perineal body, are collectively termed obstetric anal sphincter injuries (OASIS). Because of their associated morbidity (p. 508), one main goal during delivery is OASIS prevention.

To improve perineal elasticity and protect against laceration, some perform daily antepartum perineal massage starting at 34 to 35 weeks' gestation. With a lubricant, the woman or her partner inserts one or two fingers 3 cm into the vagina and applies pressure, first downward for 2 minutes and then laterally to each side of the vaginal entrance for 2 minutes. In one large randomized study, nulliparas benefited mainly by lower rates of episiotomy and of first-degree laceration (Labreque, 1999). Third- and fourth-degree laceration rates are not lowered (Beckmann, 2013). As another tool, antepartum use of the *Epi-No* intravaginal pump balloon similarly aims to stretch the perineum. However, in randomized trials, it did not prevent episiotomy, perineal trauma, or levator injury (Brito, 2015; Kamisan Atan, 2016). Instead of antepartum use, perineal massage can be performed solely intrapartum during second-stage labor. In a large randomized study, the rates of episiotomy, OASIS, and intact perineum were similar to those in a nonmassage group (Stamp, 2001). In subsequent systematic reviews, this practice was noted to lower OASIS rates and raise rates of delivery over an intact perineum (Aasheim, 2017; Aquino, 2020a).

When the head distends the vulva and perineum enough to open the vaginal introitus to a diameter of 5 cm or more, slow delivery of the head and control of accelerative forces may minimize lacerations (Laine, 2008). One of two approaches may be instituted. With the *hands-on method*, the thumb and remaining fingers form a V pressed against the perineum to bolster it. The other hand maintains fetal neck flexion to deliver the smallest head diameter through the introitus and provides gentle pressure against rapid forward movement to avoid expulsive delivery. Instead, with the *hands-poised method*, hands touch neither the head or perineum but are applied only selectively to slow rapid head expulsion. In a large randomized trial with more than 5000 gravidas, rates of intact perineum or OASIS did not differ between groups. In the hands-poised cohort, episiotomy rates were lower (McCandlish, 1998). Subsequent systematic reviews of randomized trials similarly note lower episiotomy rates with a hands-poised approach. However, among these analyses, intact perineum or OASIS rates were not consistently benefitted by this method (Aasheim, 2017; Huang, 2020; Pierce-Williams, 2019).

Alternatively, if expulsive efforts are inadequate or an expedited delivery is needed, the *Ritgen maneuver* may be employed or an episiotomy cut. With the maneuver, gloved fingers grasp the fetal chin just behind or in the anus and exert upward pressure between contractions. As a counter, the other hand presses against the occiput to control forces against the perineum (Fig. 27-1) (Cunningham, 2008). Although expeditious, this maneuver does not alter OASIS rates (Aquino, 2020b).

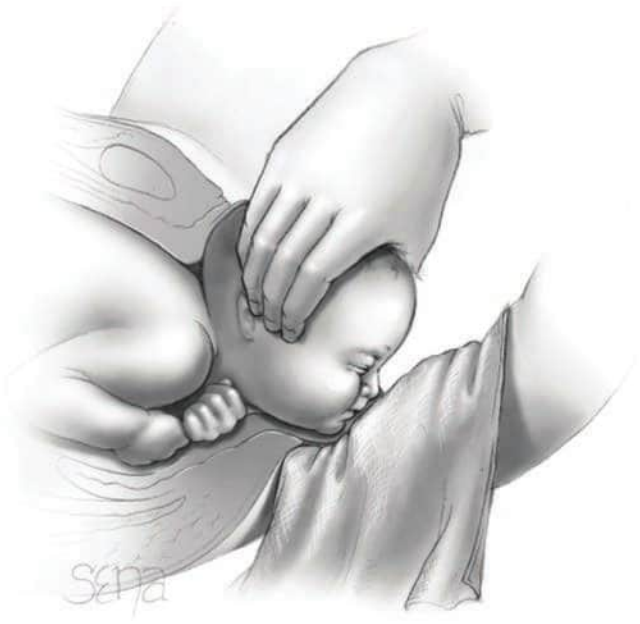

FIGURE 27-1 Modified Ritgen maneuver. Moderate upward pressure is applied to the fetal chin by the posterior hand covered with a sterile towel, while the occiput is held against the symphysis.

Delivery of the Shoulders

Following delivery of the fetal head, a finger is passed across the fetal neck to determine whether it is encircled by one or more umbilical cord loops. The nuchal cord incidence increases with gestational age and is found in nearly 25 percent of deliveries at term (Larson, 1997). If an umbilical cord coil is felt, it is slipped over the head if loose enough. If applied too tightly, the loop is cut between two clamps. Tight nuchal cords complicate approximately 6 percent of all deliveries but are not associated with worse neonatal outcomes than those without a cord loop (Henry, 2013).

Following its delivery, the fetal head falls posteriorly, bringing the face almost into contact with the maternal anus. The occiput promptly turns toward one of the maternal thighs, and the head assumes a transverse position. This external rotation indicates that the *bisacromial diameter*, which is the distance between the shoulders, has rotated into the anteroposterior diameter of the pelvis.

Most often, the shoulders appear at the vulva just after external rotation and are born spontaneously. If delayed, extraction aids controlled delivery. The sides of the head and neck are grasped with two hands, and if needed, *gentle* axial traction may be applied until the anterior shoulder appears under the pubic arch. Axial traction is aligned with the fetal spine, and lateral deviation of the neck does not exceed 25 to 45 degrees (American College of Obstetricians and Gynecologists, 2019c). Next, the posterior shoulder is delivered. During delivery, abrupt or powerful lateral extension of the neck is avoided to avert brachial plexus injury.

The rest of the body almost always follows the shoulders without difficulty. With prolonged delay, however, its birth may be hastened by moderate outward traction on the head and moderate pressure on the uterine fundus. Hooking the fingers

in the axillae is avoided. This can injure upper extremity nerves and produce a transient or possibly permanent paralysis. After the newborn, a gush of amnionic fluid that can be blood-tinged but not grossly bloody usually follows.

Previously, immediate nasopharyngeal bulb suctioning of the newborn was routine to remove secretions. However, suctioning of the nasopharynx may lead to neonatal bradycardia (Gungor, 2006). American Heart Association neonatal resuscitation recommendations eschew most suctioning immediately following birth—even with meconium present (Chap. 32, p. 589). Moreover, with meconium-stained fluid, routine intubation for tracheal suction is not recommended for vigorous or for nonvigorous neonates. Suctioning is reserved for neonates who have obvious obstruction to spontaneous breathing or who require positive-pressure ventilation (Wyckoff, 2015). For suctioning, options are bulb syringe or suction catheter aspiration and may include intubation and suctioning if the airway is obstructed.

Cord Clamping

The umbilical cord is cut between two clamps placed 6 to 8 cm from the fetal abdomen, and later an umbilical cord clamp is applied 2 to 3 cm from its insertion into the fetal abdomen.

For vigorous term neonates, umbilical cord clamping is ideally delayed 30 to 60 seconds to transfer blood to the newborn. Resting the newborn below the level of the uterus allows gravity to aid flow (Yao, 1974). As a result, higher total body iron stores and lower anemia rates for the neonate are sustained (Andersson, 2011; McDonald, 2013). This practice may be particularly valuable in populations in which iron deficiency is prevalent (World Health Organization, 2014). In general, delayed compared with early umbilical cord clamping does not worsen Apgar scores or umbilical cord pH values. For the mother, postpartum hemorrhage rates and puerperal hemoglobin status do not differ between early and delayed clamping groups (Andersson, 2013; Gomersall, 2021; Nudelman, 2020).

Of potential harms, a greater hemoglobin concentration raises risks for hyperbilirubinemia (Chap. 33, p. 606). Data are conflicting but suggest that neonatal phototherapy rates do not differ (Andersson, 2011; Chen, 2018; McDonald, 2013). That said, the American College of Obstetricians and Gynecologists (2020e) recommends that protocols should be in place that identify neonatal jaundice. Other cautions are cases requiring expedited maternal or fetal resuscitation. Others are those having abnormal placentation or compromised placental function, such as with abruption or fetal-growth restriction. Fewer data are available regarding cord "milking," in which the operator pushes blood through the cord toward the newborn. This maneuver appears safe for term newborns and may be advantageous if rapid cord clamping is clinically indicated (Panburana, 2020).

For the preterm neonate, delayed cord clamping for 30 seconds or longer has several benefits. From systematic reviews on the topic, these include decreased rates of blood transfusion and death before hospital discharge (Fogarty, 2018; Rabe, 2019). However, one large randomized study did not show an advantage for its primary outcome, which was a composite of death plus major neonatal morbidity (Tarnow-Mordi, 2017). The American College of Obstetricians and Gynecologists (2020e) recommends delayed cord clamping for vigorous term and preterm neonates not needing immediate resuscitation at birth.

Cord milking in the preterm neonate may pose potential harm. Although conflicting, some data suggest higher associated rates of severe interventricular hemorrhage in those <32 weeks' gestation (Katheria, 2019, 2020; Kumbhat, 2021). Because of rapid blood volume changes, organizations currently recommend against the routine use of cord milking for neonates born <29 weeks' gestation (Seidler, 2021; Wyckoff, 2015).

Occiput Transverse Position

In some cases, pelvic shape leads to a persistent occiput transverse (OT) position that is not easily overcome during second-stage pushing. A platypelloid pelvis is flattened anteroposteriorly and an android pelvis is heart shaped (Fig. 2-16, p. 29). With these, space may be inadequate for occipital rotation to either an anterior or posterior position.

In the absence of a pelvic architectural abnormality or asynclitism, the OT position is usually transitory. Thus, unless contractions are hypotonic, the head usually rotates spontaneously to an OA position. If rotation ceases because of poor expulsive forces, vaginal delivery can be aided. The easiest is manual rotation of the occiput either anteriorly to an OA or, less commonly, posteriorly to an OP position. Kielland forceps also can rotate the occiput anteriorly. Both manual and forceps rotations are described in Chapter 29 (p. 540).

Persistent Occiput Posterior Position

Approximately 2 to 10 percent of singleton, term, cephalic fetuses deliver in an OP position (Cheng, 2010). Many fetuses delivering OP are OA in early labor but malrotate during labor. Predisposing risks include epidural analgesia, nulliparity, greater fetal weight, and prior delivery with OP positioning (Cheng, 2006a; Gardberg, 2004; Lieberman, 2005). Of pelvic shapes, an anthropoid pelvis and narrow subpubic angle can predispose (Barth, 2015; Ghi, 2016).

Women with a persistent OP position have higher associated rates of prolonged second-stage labor, cesarean delivery, and operative vaginal delivery. For women who deliver vaginally, rates of blood loss and of OASIS are increased (Senécal, 2005).

Newborns delivered from an OP position have higher complication rates than those born positioned OA. In one study of neonatal outcomes in 2591 women undergoing delivery from a persistent OP position, rates of acidemic umbilical cord gases, birth trauma, Apgar scores <7, and intensive care nursery admission, among others, were higher compared with an OA position (Cheng, 2006b). Others report similar findings (Fitzpatrick, 2001; Ponkey, 2003).

Fetal head position assessment is essential to management (Chap. 22, p. 429). However, digital examination for identification of fetal head position can be inaccurate, and transabdominal sonography may increase accuracy (Bellussi, 2017). The transducer is placed transversely just cephalad to

the maternal mons pubis. In the sonogram, fetal orbits and nasal bridge lie ventrally, whereas the occiput apposes the lower sacrum. Such information may explain prolonged second-stage labor and identify suitable candidates for rotation. Of other interventions, varying maternal position either antepartum or during labor does not appear to lower rates of persistent OP position (Kariminia, 2004; Le Ray, 2016).

If the bony pelvic outlet is roomy and the perineum is somewhat relaxed from prior deliveries, rapid spontaneous OP delivery can take place. Conversely, if the perineum is resistant to stretch, second-stage labor may be appreciably prolonged. During each maternal push, the head is driven against the perineum to a greater degree than when the head position is OA. This leads to greater rates of OASIS (Groutz, 2011). For these reasons, manual rotation with spontaneous delivery from an OA position has advantages. Lower rates of cesarean delivery, severe perineal laceration, chorioamnionitis, and maternal blood loss follow rotation to OA position (Shaffer, 2011). Alternatively, forceps rotation to an OA position may be attempted for those with suitable skills. Last, forceps or vacuum device also can be applied and delivery completed from an OP position. These operative vaginal techniques are detailed in Chapter 29 (p. 540).

Infrequently, protrusion of fetal scalp through the introitus can be erroneously encouraging. In these cases, findings reflect marked fetal head elongation from molding plus substantive scalp edema and not fetal descent. In some cases, the head may not even be engaged—that is, the biparietal diameter may not have passed through the pelvic inlet. Labor is characteristically long and descent of the head is slow. Careful palpation above the symphysis may disclose the fetal head to be above the pelvic inlet. Prompt cesarean delivery is appropriate.

SHOULDER DYSTOCIA

Following complete emergence of the fetal head during vaginal delivery, the remainder of the body may not rapidly follow. The anterior fetal shoulder can become wedged behind the symphysis pubis and fail to deliver with maternal pushing and gentle axial traction by the provider. One indicator may be retraction of the baby's head against the mother's perineum—the *turtle sign*. Because the umbilical cord is compressed within the birth canal, shoulder dystocia is an emergency. Several maneuvers may be performed to free the shoulder. This requires a team approach, and effective communication and leadership are critical.

Consensus regarding a specific definition of shoulder dystocia is lacking. Some, including the American College of Obstetricians and Gynecologists (2019c), diagnose it if maneuvers are required to free the shoulder. Spong and coworkers (1995) reported that the mean head-to-body delivery time in normal births was 24 seconds compared with 79 seconds in those with shoulder dystocia. These investigators proposed that a head-to-body delivery time >60 seconds be used to define shoulder dystocia. Currently, however, the diagnosis continues to rely on the clinical perception that the normal traction needed for fetal shoulder delivery is ineffective.

Because of these differing definitions, the incidence of shoulder dystocia varies. One review cites a clinically useful average of 1 percent of all deliveries (Ouzounian, 2016). The incidence has risen in recent decades, likely due to increasing fetal birthweight (Øverland, 2014). Greater recognition and documentation also may boost reported incidences (Kim, 2016).

■ Maternal and Neonatal Consequences

In general, shoulder dystocia poses greater risk to the fetus than to the mother. The main maternal risks are serious perineal tears and postpartum hemorrhage, usually from uterine atony but also from lacerations (Hehir, 2020; Rahman, 2009). In contrast, significant neuromusculoskeletal injury and asphyxia are neonatal concerns. These specific injuries are described fully in Chapter 33 (p. 599). In one review of 1177 shoulder dystocia cases, brachial plexus injury was diagnosed in 11 percent and clavicular or humeral fracture in 2 percent (Chauhan, 2014). MacKenzie and associates (2007) reviewed 514 cases. Of the neonates, 7 percent showed evidence of acidosis at delivery, and 1.5 percent required cardiac resuscitation or developed hypoxic ischemic encephalopathy (HIE). In another review of 200 cases, rates of severe fetal acidosis and HIE were each 0.5 percent if delivery was completed within 5 minutes. These rates rose to 6 and 24 percent, respectively, with delivery delays ≥5 minutes (Leung, 2011).

■ Prediction and Prevention

Although several factors are clearly associated with this complication, shoulder dystocia cannot be accurately predicted or prevented (American College of Obstetricians and Gynecologists, 2019c). Associated characteristics include fetal macrosomia, maternal obesity, prolonged second-stage labor, operative vaginal delivery, and a prior shoulder dystocia (Mehta, 2004; Zhang, 2018).

Of these, increasing birthweight creates a corresponding rise in the incidence of shoulder dystocia (Øverland, 2012). With fetal macrosomia, commonly associated maternal characteristics are obesity, postterm pregnancy, multiparity, and diabetes (Koyanagi, 2013). The combination of fetal macrosomia and maternal diabetes mellitus escalates the frequency of shoulder dystocia (Nesbitt, 1998). This predisposition may stem from anthropomorphic differences between comparable-weight fetuses of nondiabetic and diabetic mothers. The latter fetal group has larger shoulder and extremity circumferences and greater shoulder-to-head and chest-to-head size (Modanlou, 1982). However, translating these specific measurements into stand-alone sonographic thresholds shows poor predictive sensitivity (Burkhardt, 2014). Planned cesarean delivery should be considered for the nondiabetic woman with a fetus whose estimated fetal weight is >5000 g or for the diabetic woman whose fetus is estimated to weigh >4500 g (American College of Obstetricians and Gynecologists, 2019c).

As prevention, early labor induction has been evaluated. In one study, approximately 800 women with suspected macrosomic fetuses were randomly assigned to early induction between 37 and 39 weeks' gestation or to expectant care (Boulvain, 2015). Women with insulin-requiring diabetes were excluded. Dystocia rates were lowered by two thirds in the induction group, and neither group suffered brachial plexus injury. Other

neonatal outcomes were similar, except for a higher rate of hyperbilirubinemia and phototherapy in the induction group. A systematic review of four randomized trials again with the same compared groups showed no differences in rates of cesarean delivery, shoulder dystocia, or operative vaginal delivery. Fetal fracture rates were lower in the induction group (Magro-Malosso, 2017). Notably, when assessing the benefits, the poor accuracy of antepartum fetal weight prediction should be considered (Malin, 2016). Moreover, potential benefits of early induction are balanced against potential harms from early delivery. The American College of Obstetricians and Gynecologists (2019a,c) recommends against labor induction before 39 weeks for suspected macrosomia alone.

Of other risks, recurrent shoulder dystocia ranges from 4 to 13 percent in the three largest series (Al-Hawash, 2019). For many women with prior shoulder dystocia, labor may still be a reasonable option. The American College of Obstetricians and Gynecologists (2019c) recommends that estimated fetal weight, gestational age, maternal glucose intolerance, and severity of prior neonatal injury be evaluated. Antepartum, risks and benefits of cesarean delivery are discussed with any woman with a history of shoulder dystocia. After discussion and risk assessment, either mode of delivery is appropriate.

Management

Shoulder dystocia cannot be accurately predicted. Thus, the labor and delivery team, which includes nurses, obstetrical providers, and anesthesia staff, should be well versed in its management. An emergent call for assistance should assemble these members.

Because of ongoing cord compression with this dystocia, one goal is to reduce delivery time. This is balanced against the second goal, which is avoiding fetal and maternal injury from aggressive manipulations. Adequate analgesia assists maneuvers. Episiotomy may be needed to provide sufficient room for essential manipulations but itself does not lower brachial plexus injury rates (Gurewitsch, 2004; Paris, 2011).

Various techniques can be used to free the anterior shoulder from its impacted position behind the symphysis pubis. The *McRoberts maneuver* is often selected first. With it, legs are lifted from stirrups, hips are sharply flexed up onto the abdomen, and knees remain flexed. Gherman and colleagues (2000) analyzed the McRoberts maneuver using x-ray pelvimetry. The procedure causes straightening of the sacrum relative to the lumbar vertebrae, rotation of the symphysis pubis toward the maternal head, and a decrease in the angle of pelvic inclination. This does not increase pelvic dimensions, but pelvic rotation cephalad tends to free the impacted anterior shoulder. Gonik and coworkers (1989) tested the McRoberts position objectively with laboratory models and found that the maneuver reduced the forces needed to free the fetal shoulder. During McRoberts maneuver, an assistant can apply downward and laterally directed *suprapubic pressure* (Fig. 27-2). This abducts the anterior shoulder to create a shorter bisacromial diameter. It also rotates the shoulders into the oblique diameter, which at the pelvic inlet is longer than the anteroposterior diameter. If unsuccessful, most move next to the posterior shoulder or to rotation maneuvers.

FIGURE 27-2 The McRoberts maneuver. The maneuver consists of removing the legs from the stirrups and sharply flexing the thighs up onto the abdomen. Simultaneously, an assistant also provides suprapubic pressure that is directed down and lateral.

With *delivery of the posterior shoulder,* the provider inserts a hand into the posterior pelvis, carefully sweeps the posterior arm of the fetus forward across its chest, and delivers the arm (Fig. 27-3). If possible, the operator's fingers are aligned parallel to the long axis of the fetal humerus to lower fracture risks. With the arm now outside of the pelvis, the bisacromial diameter is diminished. Next, the shoulder girdle is rotated into one of the oblique diameters of the pelvic inlet. These steps resolve the disproportion to free the anterior shoulder.

Of the rotational maneuvers, the method recommended by Rubin (1964) aims to shorten the bisacromial diameter (Fig. 27-4). A pelvic hand reaches the most easily accessible fetal shoulder, often the posterior one, which is then pushed toward the anterior surface of the chest. This maneuver abducts the posterior shoulder and rotates both shoulders into one of the pelvic inlet's oblique diameters. Friction from the vagina also abducts the anterior shoulder to some degree during this rotation. Again, resolution of the disproportion can free the anterior shoulder.

Instead, Woods (1943) reported that by rotating the posterior shoulder progressively in a corkscrew fashion, the impacted anterior shoulder could be released. For performance, one hand

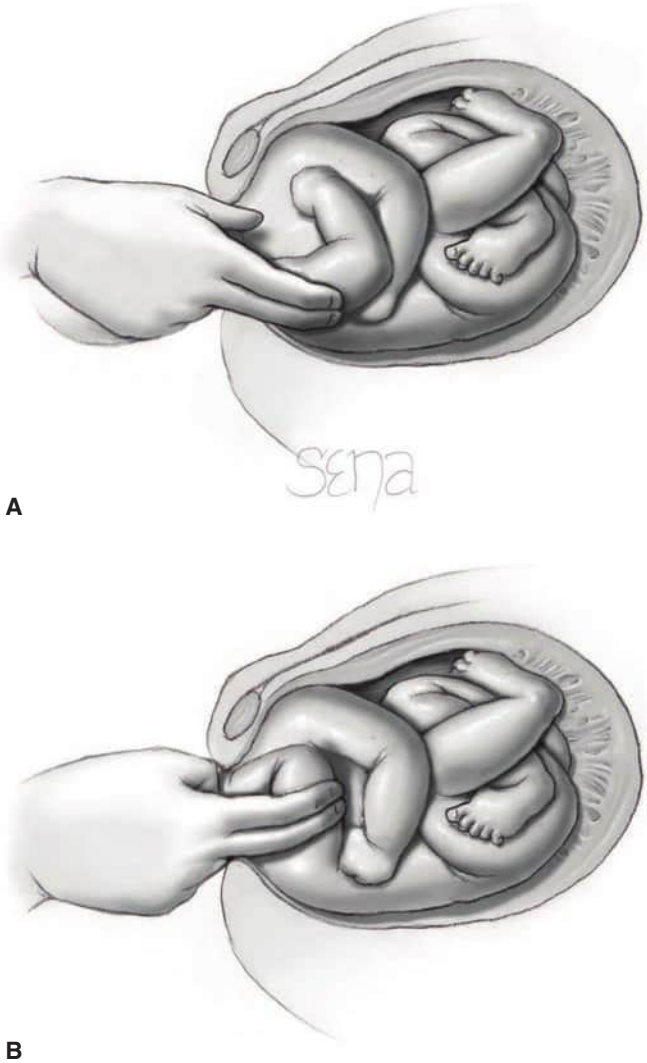

FIGURE 27-3 Delivery of the posterior shoulder for relief of shoulder dystocia. **A.** The operator's hand is introduced into the vagina along the fetal posterior humerus. **B.** The arm is splinted and swept across the chest, keeping the arm flexed at the elbow. **C.** The fetal hand is grasped and the arm extended along the side of the face. The posterior arm is delivered from the vagina.

is pressed against the anterior surface of the posterior shoulder, and pressure is directed toward the fetal back. The posterior shoulder is then rotated 180 degrees, and in doing so, it becomes the anterior-positioned limb. With rotation, this shoulder comes to lie beneath, not behind, the symphysis and can be delivered.

In a review of these four methods, all had similar neonatal injury rates (Spain, 2015). Importantly, delivery duration and the number of maneuvers raises neonatal injury rates.

If the above are initially unsuccessful, they may be repeated, and other methods may be elected. With an *all-fours maneuver*, also called the Gaskin maneuver, the parturient rolls onto her hands and knees. Here, axial traction against the head and neck attempts to free the posterior shoulder (Bruner, 1998). Challenges with this include immobility from regional analgesia and time lost in patient repositioning.

In some cases, the posterior arm is inaccessible for delivery. Cluver and Hofmeyr (2009) described *posterior axilla sling traction* to deliver the posterior arm. With this, suction tubing or a stiff urinary catheter is threaded under the fetal axilla, and both ends are brought together above the shoulder. This forms a loop beneath the axilla. Catheter traction then sweeps upward and outward to deliver the shoulder. Data continue to accrue. In a case series of 119 cases in which this was the first maneuver, the success rate was 96 percent (Ansell, 2019).

For refractory cases despite the above efforts, deliberate *fracture of the anterior clavicle* by using the thumb to press it toward and against the maternal pubic ramus can be attempted to free the shoulder impaction. In practice, however, deliberate fracture of a large neonate's clavicle is difficult. If successful, the fracture will heal rapidly and is usually trivial compared with brachial nerve injury, asphyxia, or death.

Symphysiotomy involves cutting of the intervening symphyseal cartilage and much of its ligamentous support to widen

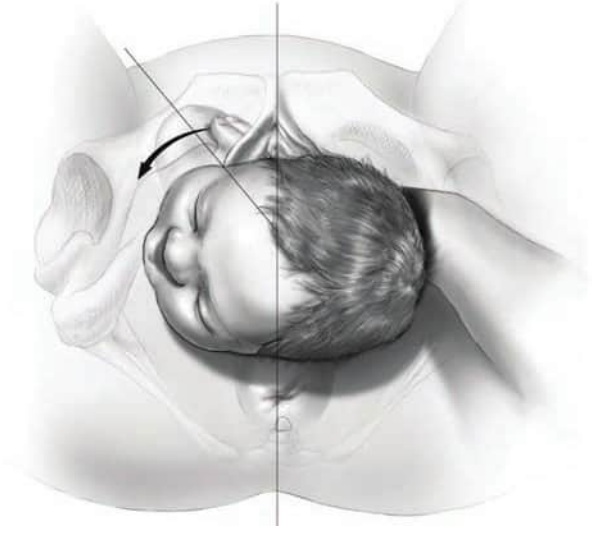

FIGURE 27-4 Rubin maneuver. The bisacromial diameter is aligned vertically. The more easily accessible fetal shoulder (the anterior is shown here) is pushed toward the anterior chest wall of the fetus (*arrow*). Most often, this results in abduction of both shoulders, which reduces the bisacromial diameter and frees the impacted anterior shoulder.

the symphysis pubis. In rare cases, it has been used successfully for shoulder dystocia (Goodwin, 1997). Using local analgesia, symphysiotomy surgically divides the intervening symphyseal cartilage and much of its ligamentous support to widen the symphysis pubis up to 2.5 cm (Basak, 2011). If feasible, a previously inserted urinary catheter is displaced from the midline with the index finger of the left hand, which is inside the vagina. Lack of provider training and potentially serious maternal pelvic or urinary tract injury explain its rare use in the United States.

The *Zavanelli maneuver* involves replacement of the fetal head into the pelvis followed by cesarean delivery (Sandberg, 1985). Terbutaline, 0.25 mg, is given subcutaneously to produce uterine relaxation. The operator first turns the head to an OA or OP position, flexes it, and slowly elevates it back into the vagina. Cesarean delivery is then performed. Sandberg (1999) reviewed 103 reported cases. It was successful in 91 percent of cephalic cases and in all cases of breech head entrapments. Despite successful replacement, fetal injuries were common but may have resulted from the multiple manipulations used before the Zavanelli maneuver (Sandberg, 2007).

Cleidotomy consists of cutting the clavicle with scissors or other sharp instruments. It is usually done for a dead fetus (Schramm, 1983).

In preparation for shoulder dystocia, clinical simulations aim to improve performance, documentation, and retention of drill steps. Their use has translated into improved neonatal outcome in some, but not all, investigations (Crofts, 2016; Fransen, 2017; Gurewitsch Allen, 2017; Walsh, 2011). At our institution, these drills involve resident, faculty, nursing, and anesthesia staff.

SPECIAL POPULATIONS

Home Birth

In 2017, 1.4 percent of deliveries in the United States were planned home births. Unplanned home births constituted 0.2 percent (MacDorman, 2019).

Of *unplanned* home births in a 15-year epoch in Norway, 69 of 6027 or 1.1 percent resulted in fetal or neonatal death. This high rate was attributable to infection, prematurity, and placental abruption (Gunnarsson, 2017). Multiparity and distance from the hospital were ascribed risks (Gunnarsson, 2014). In the United States, youth, lack of prenatal care, minority race, and lower educational attainment are risks (Declercq, 2010).

With *planned* home birth of a low-risk pregnancy, benefits include fewer medical interventions that include labor augmentation, episiotomy, operative vaginal delivery, and cesarean delivery (Bolten, 2016; Cheyney, 2014). Regarding the safety of planned home birth, data from randomized trials are lacking, and large observational studies derive from heterogeneous care systems, whose results may not be generalizable. For example, several developed countries deliver a large volume of carefully screened women at home. Gravidas are attended by midwives with substantial training and in a setting closely integrated with the local health-care system (Comeau, 2018; de Jonge, 2015). The level of such coordination in the United States is less uniform.

Overall, neonatal risks of home births in the United States are small but greater than those of hospital delivery. Midwife-attended home births carry a neonatal mortality risk of 1.3 per 1000 births. This is a nearly fourfold greater rate compared with midwife-attended hospital births (Grünebaum, 2020). The most common underlying causes of death are those attributed to labor and delivery events, to congenital anomalies, and to infection. Of neonatal injuries, rates of neonatal seizure and serious neurological dysfunction also are elevated in home-birth groups (Grünebaum, 2013, 2014, 2017; Snowden, 2015). Importantly, substantial risks attend home birth for those with preeclampsia, with multifetal gestation, with prior cesarean delivery, or with breech presentation (Caughey, 2019). The American College of Obstetricians and Gynecologists (2020b) specifically considers the last three to be absolute contraindications. Further, the College considers accredited hospitals and birthing centers to be the safest site for birth but recognizes the autonomy of the well-counseled patient.

Water Birth

As one option for pain relief, some women choose to spend part of first-stage labor in a large water tub. With this practice, one Cochrane review found lower rates of regional analgesia use and no greater adverse neonatal or maternal effects compared with traditional labor (Cluett, 2018).

For second-stage labor, water birth similarly aims to relieve pain, but it can pose neonatal risks. The rate of cord avulsion during water birth approximates 3 per 1000 births and stems primary from abruptly bringing the newborn out of the water (Schafer, 2014). Fresh-water drowning and pneumonia with sepsis are reported causes of neonatal death (Byard, 2010). The latter emphasizes the need for rigorous sanitizing protocols. Systematic reviews comment on the paucity of high-quality data but do not identify overall greater neonatal or maternal harms or benefits from water birth in low-risk, term, singleton gestations (Cluett, 2018; Taylor, 2016). Given the lack of robust data and potential for serious complications, the American College of Obstetricians and Gynecologists (2016) currently recommends that "birth occur on land, not in water."

Female Genital Mutilation

This practice refers to medically unnecessary vulvar and perineal surgical modification. In the United States, it is a federal crime to perform unnecessary genital surgery on a girl younger than 18 years and is condemned by major health organizations that include the American College of Obstetricians and Gynecologists (2019b). Despite this, forms of female genital mutilation are practiced in countries throughout Africa, the Middle East, and Asia (UNICEF, 2020).

The World Health Organization (WHO) (2018a) classifies female genital mutilation (FGM) into four types (Table 27-1). Some long-term risks include propensity for urogenital infection, chronic vulvar pain, and dyspareunia (Berg, 2014b). Thus, early in care, new gravidas are asked about these problems or prior obstetrical complications. The psychiatric consequences also can be profound, and referral for psychological assessment can be offered (Low-Beer, 2018).

TABLE 27-1. World Health Organization Classification of Female Genital Mutilation

Type I	Partial or total removal of the clitoris and/or prepuce
Type II	Partial or total removal of the clitoris and the labia minora, with or without labia majora excision
Type III	Partial or total labial minora and/or majora excision, followed by fusion of the wound, termed infibulation, to cover and narrow the vagina. With or without clitoridectomy
Type IV	Pricking, piercing, incising, scraping, cautery, or other injury to female genitalia

With physical examination, a finger or cotton swab assesses elasticity and caliber of the vaginal opening. Parturients with types I, II, and IV typically require only routine obstetrical care. Those with type III FGM or with extensive scarring have higher delivery risks. If an obstruction to childbirth is recognized, the advantages of surgical release are ideally discussed early antenatally. Division of midline scar tissue to reopen the vulva is termed *defibulation* but also called *deinfibulation* or *anterior episiotomy* (Kalis, 2012).

FGM is associated with some adverse maternal and neonatal complications. Moreover, vaginal obstruction can delay diagnosis of other pregnancy conditions. From a prospective study, the WHO (2006) estimated that FGM raised perinatal morbidity rates by 1 to 2 percent. For mothers with FGM, rates for prolonged labor, perineal lacerations and episiotomy, and postpartum hemorrhage were higher than those without prior FGM (Berg, 2014a; Chibber, 2011). Evidence supports that gravidas with type III FGM who undergo defibulation benefit from lower rates of cesarean delivery and OASIS (Berg, 2018; Rodriguez, 2016). To prevent obstetrical complications, the WHO (2016) recommends defibulation, which can be completed antepartum or intrapartum (Fig. 27-5). In our and other's experiences, intrapartum defibulation allows successful vaginal delivery without major complications (Rouzi, 2012).

In discussing defibulation, cultural sensitivity is essential, and some women may be offended by the suggestion that they have been assaulted or mutilated (American College of Obstetricians and Gynecologists, 2014). Preoperative counseling ideally discusses expected anatomic and physiologic changes. *Partial defibulation* uncovers the vagina and urethra, and *total defibulation* extends the incision to reveal the clitoris, if present. Women with infibulation often have a slow urine stream, and they perceive menses and urine to originate from the same opening. Both will change after scar incision. Affected women may be unfamiliar with normal vaginal anatomy, which will be visible following surgery. One excellent review is provided by Abdulcadir and associates (2018). Wound complications such as hematoma, cellulitis, or incisional dehiscence are rare but are discussed during counseling. Postoperative dyspareunia is uncommon, and in most studies, female sexual functioning scores improve (Berg, 2018; Nour, 2006).

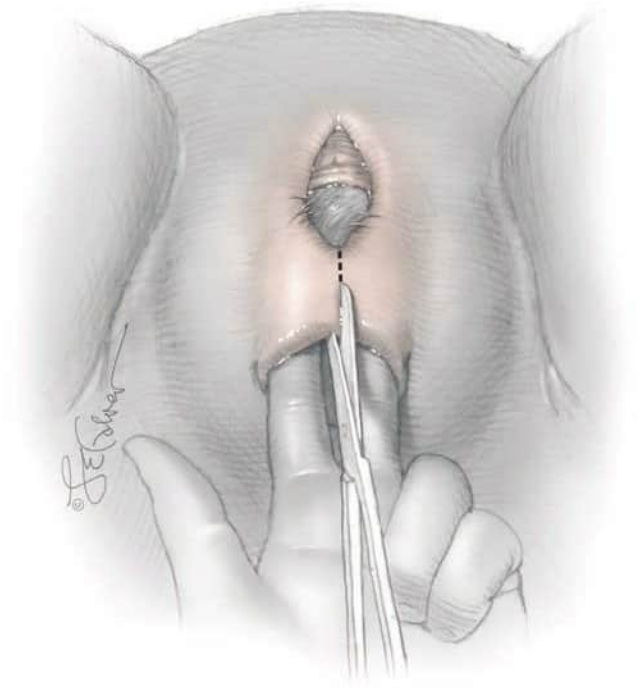

FIGURE 27-5 Deinfibulation. Although not shown here, lidocaine is first infiltrated along the planned incision if regional analgesia is not in place already. To protect underlying structures, two fingers or the tips of a narrow clamp are insinuated behind the shelf created by fused labia but in front of the urethra and crowning head. The shelf is then incised in the midline. After delivery, the raw edges are sutured with rapidly absorbable material to secure hemostasis. (Reproduced with permission from Hawkins JS: Lower genital tract procedures. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

Prior Pelvic Reconstructive Surgery

These surgeries are performed with increasing frequency in reproductive-aged women, and thus pregnancy following them is not uncommon. Major concerns are the degradation of repair by pregnancy and by vaginal birth.

After midurethral sling surgery and then a subsequent pregnancy, continence is preserved for most. Multiple pregnancies, however, may raise recurrence risk. Evidence does not favor a delivery route, and vaginal delivery is suitable (Adams-Piper, 2016; Cavkaytar, 2014; Dyrkorn, 2020).

Sacral neuromodulation units are recommended to be turned off because of unknown pregnancy effects from chronic electrical stimulation. From small reviews, lowered device efficacy and displaced or broken device leads can follow both vaginal and cesarean delivery (Mahran, 2017; Roulette, 2018). Data do not proscribe vaginal birth.

Hysteropexy aims to correct prolapse of the vaginal apex yet preserve the uterus. Available case series are few and small and do not allow estimates of recurrence rate or delivery route recommendations (Wieslander, 2020). Most undergo elective cesarean delivery.

Anomalous Fetuses

Rarely, delivery can be obstructed by extreme hydrocephaly, body stalk anomaly, conjoined twins, or massive fetal abdominal

enlargement from a greatly distended bladder, ascites, or organomegaly. Specifically, with milder forms of hydrocephaly, if the biparietal diameter is <10 cm or if the head circumference is <36 cm, vaginal delivery may be permitted (Anteby, 2003).

In rare cases in which neonatal death has occurred or is certain due to associated anomalies, vaginal delivery may be reasonable, but the head or abdomen must be reduced in size for delivery. Removal of fluid by cephalocentesis or paracentesis with sonographic guidance can be performed intrapartum. As described earlier, cleidotomy can shorten the bisacromial diameter. For hydrocephalic fetuses that are breech, cephalocentesis can be accomplished suprapubically when the aftercoming head enters the pelvis. Currently, these practices are more germane in developing countries.

THIRD STAGE OF LABOR

■ Delivery of the Placenta

Third-stage labor begins immediately after fetal birth and ends with placental delivery. Goals include delivering an intact placenta and avoiding uterine inversion or postpartum hemorrhage. The latter two, described in Chapter 42 (p. 731), are intrapartum emergencies.

Immediately after newborn birth, uterine fundal size and consistency are examined. If the uterus remains firm and bleeding is minimal, watchful waiting until the placenta separates is the usual practice. Neither massage nor downward fundal pressure is employed, but the fundus is frequently palpated to ensure that it does not become atonic and filled with blood from placental separation. *To prevent uterine inversion, umbilical cord traction must not be used to pull the placenta from the uterus.* Signs of separation include a sudden gush of blood into the vagina, a globular and firmer fundus, outward movement of the umbilical cord as the placenta descends into the vagina, and elevation of the uterus into the abdomen. With the last, the placenta, having separated, passes down into the vagina. Here, its bulk pushes the uterine body upward.

These signs appear within minutes after newborn delivery, and the median time ranges from 4 to 12 minutes (Frolova, 2016; Shinar, 2016b). Once the placenta has detached from the uterine wall, the mother can bear down, and intraabdominal pressure often expels the placenta into the vagina. These efforts may fail or may not be possible because of analgesia. After ensuring that the uterus is contracted firmly, the umbilical cord is kept slightly taut but is not pulled. Pressure is exerted by a hand wrapped around the fundus to propel the detached placenta into the vagina (Fig. 27-6). Concurrently, the heel of the same hand exerts pressure between the symphysis pubis and the uterine fundus and directs it toward the sacrum. This aims to prevent inversion. Once the placenta passes through the introitus, pressure on the uterus is relieved. The placenta is then gently lifted away. Care is taken to prevent placental membranes from being torn off and left behind. If the membranes begin to tear, they are grasped with a clamp and removed by gentle teasing (Fig. 27-7).

■ Management of the Third Stage

Practices within this stage of labor may be broadly considered as either expectant or active. Expectant management involves waiting for placental separation signs and allowing the placenta to deliver either spontaneously or aided by nipple stimulation or gravity (World Health Organization, 2012).

In contrast, active management of third-stage labor includes earlier cord clamping, controlled cord traction during placental delivery, and immediate prophylactic administration of a uterotonic agent. The goal of this triad is to limit postpartum hemorrhage. However, the value of this bundled approach is questioned (Begley, 2019). For example and as noted previously (p. 500),

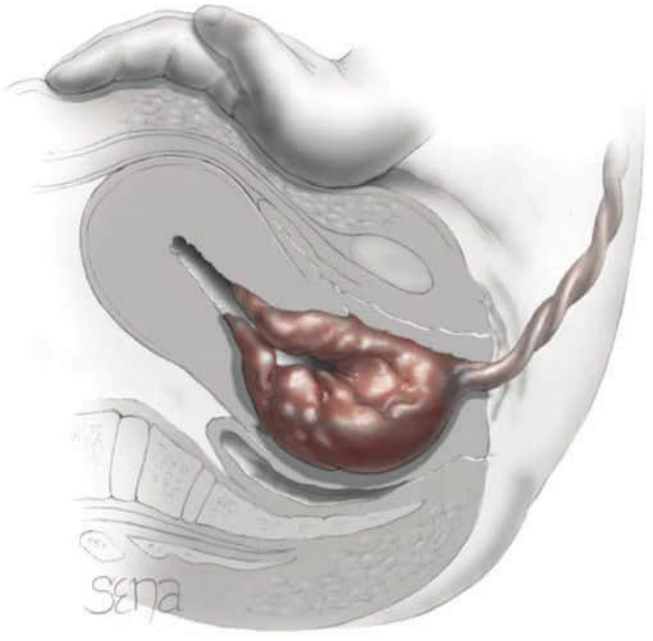

FIGURE 27-6 Expression of the detached placenta. Note that the hand is *not* trying to push the fundus through the birth canal! As the placenta leaves the uterus and enters the vagina, the uterus is pushed cephalad by the heel of the hand on the abdomen while the cord is held in position. The mother can aid in the delivery of the placenta by bearing down. As the placenta reaches the perineum, the cord is lifted, which in turn lifts the placenta out of the vagina.

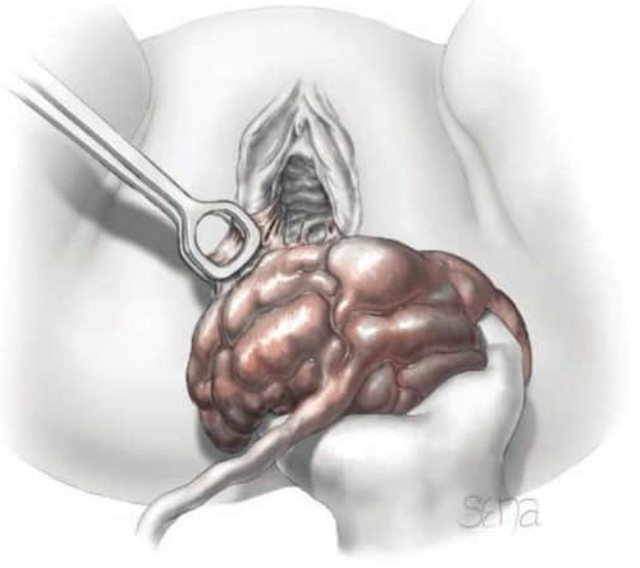

FIGURE 27-7 Membranes that were somewhat adhered to the uterine lining are separated by gentle traction with ring forceps.

delayed cord clamping does not raise postpartum hemorrhage rates, and thus early clamping is a less important component of this trio. Similarly, cord traction fails to prevent hemorrhage. Traction does lower manual placenta removal rates and shortens third-stage labor (Deneux-Tharaux, 2013; Hofmeyr, 2015). Following placental delivery, we support uterine massage to prompt uterine firming but recognize that evidence for its benefits to avoid postpartum hemorrhage is not strong (Saccone, 2018).

Therefore, uterotonic drugs play an essential preemptive role to decrease postpartum blood loss (Salati, 2019). A single agent is given either before or after placental expulsion, and timing does not affect rates of postpartum hemorrhage, placental retention, or third-stage labor length (Soltani, 2010). Choices for hemorrhage *prophylaxis* include oxytocin (Pitocin), misoprostol (Cytotec), and the ergots, namely ergonovine (Ergotrate) and methylergonovine (Methergine). In addition, a combination agent of oxytocin plus ergonovine (Syntometrine) is used outside the United States. Also in other countries, carbetocin (Duratocin), a long-acting oxytocin analogue, is available and effective for hemorrhage prevention (Kalafat, 2021). Prescribing information for carbetocin cites its use for cesarean delivery, but randomized trials reflect similar use for vaginal birth. Of agents, the WHO (2018) recommends oxytocin for first-line use.

High-dose Oxytocin

Synthetic oxytocin is identical to that produced by the posterior pituitary. Its action is noted at approximately 1 minute, and it has a mean half-life of 3 to 5 minutes. Recommended storage temperature is ≤25C°, which may pose problems in some low-resource countries. When given as a bolus, oxytocin can cause profound hypotension (Svanström, 2008). This hemodynamic change may be dangerous to women with hemorrhage-related hypovolemia or with certain cardiac conditions. Thus, oxytocin should be given as a dilute solution by continuous intravenous infusion or as an intramuscular injection.

Despite the routine use of oxytocin, no standard prophylactic dose has been established for its use following either vaginal or cesarean delivery. Water intoxication can result from the antidiuretic action of high-dose oxytocin if administered in a large volume of electrolyte-free dextrose solution (Whalley, 1963). Our practice is to add 20 units (2 mL) of oxytocin per liter of crystalloid solution. This is administered after delivery of the placenta at a rate of 10 to 20 mL/min—200 to 400 mU/min—for a few minutes until the uterus remains firmly contracted and bleeding is controlled. The infusion rate then is reduced to 1 to 2 mL/min until the mother is ready for transfer to the postpartum unit. The infusion is usually then discontinued. For women without intravenous access, 10 units of intramuscular oxytocin are injected.

Other Agents

Ergonovine and methylergonovine have similar activity in myometrium, but only methylergonovine is currently manufactured in the United States. These ergot alkaloid agents lower the rates of postpartum hemorrhage and the need for additional uterotonic drugs. However, blood pressure elevation is a concerning side effect (Liabsuetrakul, 2018). Methylergonovine is contraindicated in hypertensive women. If selected, a 200-μg dose of methylergonovine is given intramuscularly or is slowly injected intravenously in a period not less than 60 seconds to avoid sudden hypertension.

Misoprostol is a prostaglandin E_1 analogue, which has proved inferior to oxytocin for postpartum hemorrhage prevention (Tunçalp, 2012). However, in resource-poor settings that lack oxytocin, misoprostol is suitable for hemorrhage prophylaxis and is given orally as a single 400- or 600-μg dose (World Health Organization, 2018c). Side effects include fever and diarrhea.

From systematic reviews, carbetocin and oxytocin show equivalent efficacy for postpartum hemorrhage prevention after vaginal birth (van der Nelson, 2021; Widmer, 2018). Carbetocin is more expensive. A heat-stable form may have benefit in low-resource settings that may have inconsistent temperatures during supply distribution (Malm, 2018).

Tranexamic acid (TXA) is an antifibrinolytic agent and has been evaluated to *prevent* postpartum hemorrhage (Ahmadzia, 2018). In one metaanalysis, a 1-g intravenous TXA dose following delivery in addition to oxytocin was reported to lower the hemorrhage rate from 11.4 to 8.7 percent (Saccone, 2020). In a randomized trial of 3891 women, however, TXA plus oxytocin did not decrease the postpartum hemorrhage incidence compared with oxytocin alone (Sentilhes, 2018). Currently, TXA use is not recommended prophylactically (American College of Obstetricians and Gynecologists, 2019c). To *treat* hemorrhage, TXA use is described in Chapters 42 (p. 736) and 44 (p. 773).

■ Manual Removal of Placenta

In approximately 2 percent of singleton births, the placenta may not deliver promptly (Cheung, 2011). This may represent: (1) *placenta adherens*, in which uterine contractions are insufficient to detach the placenta; (2) lower uterine segment constriction and a detached but trapped placenta; or (3) placenta accreta spectrum. Consistent risks for retained placenta include stillbirth, prior cesarean delivery, prior retention, and preterm delivery (Belachew, 2014; Coviello, 2015; Endler, 2014). For the last, in one study with nearly 46,000 deliveries, analysis predicted that 90 percent of placentas would spontaneously deliver by 180 minutes for gestations at 20 weeks; 21 minutes at 30 weeks; and 14 minutes at 40 weeks (Dombrowski, 1995).

Postpartum hemorrhage can complicate a retained placenta, and bleeding risk accrues with the length of third-stage labor. In the absence of bleeding, evidence supports 15 to 20 minutes (Frolova, 2016; Shinar, 2016a; van Ast, 2019). The WHO (2012) cites a 60-minute threshold. Notably, if brisk bleeding ensues and the placenta cannot be delivered by standard technique, manual removal of the placenta is indicated (Fig. 27-8). When performed, some administer a single dose of intravenous antibiotics, however, one systematic review of observational studies found no benefits (Chibueze, 2015). The American College of Obstetricians and Gynecologists (2020d) concluded that data neither support nor refute this practice, but the WHO (2012) recommends prophylaxis. At our institution, we administer a single dose of cefazolin to women not already receiving antibiotics and not penicillin allergic.

IMMEDIATE POSTPARTUM CARE

The hour immediately following delivery of the placenta is critical. During this time, lacerations are repaired. Although uterotonic agents are administered, postpartum hemorrhage as the

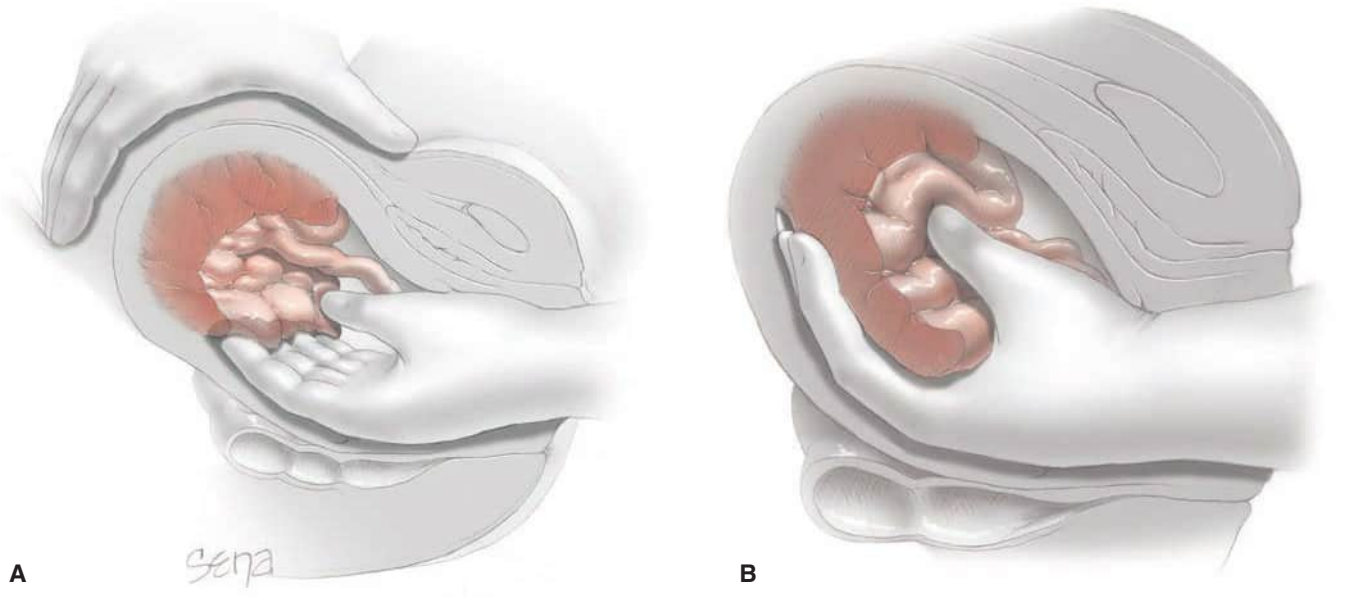

FIGURE 27-8 Manual removal of placenta. **A.** One hand grasps the fundus and the other hand is inserted into the uterine cavity and the fingers are swept from side to side as they are advanced. **B.** When the placenta detaches, it is grasped and removed.

result of uterine atony is most likely at this time. Hematomas may expand. Consequently, uterine tone and the perineum are frequently evaluated. The mother's blood pressure and pulse are recorded immediately after delivery and every 15 minutes for the first 2 hours. Her temperature is recorded every 4 hours during the first 8 hours and then every 8 hours thereafter. Vital signs may be obtained more frequently in patients at higher risk of postpartum complications (American Academy of Pediatrics, 2017). The placenta, membranes, and umbilical cord are examined for completeness and anomalies, as described in Chapter 6 (p. 107).

Skin-to-skin Contact

This practice aims to connect the mother and newborn dyad early to promote breastfeeding (American College of Obstetricians and Gynecologists, 2020a; Moore, 2016; World Health Organization, 2018b). Ideally, the mother lies in a semireclined position. After the newborn is dried to prevent cooling, its chest is placed against the mother's breast with access to her nipple. Its legs are flexed, and the mother's arm steadies its body. Covered with warm blankets and often a cap, the neonate's head is uncovered, turned to the side, and placed in a sniffing position. Mouth and nares should remain unobstructed (Widström, 2019). The dyad is continually monitored for physiologic stability, somnolence, unobstructed breathing, and safe positioning to avoid smothering or falls (Feldman-Winter, 2016).

Lower Genital Tract Lacerations

These lacerations may involve the cervix, vagina, or perineum. Those of the cervix and vagina are described in Chapter 42 (p. 739). In general, those of the perineum follow vaginal delivery, and most are first- and second-degree lacerations. Lacerations are classified by depth and involved anatomy, and complete definitions and visual examples are given in Figure 27-9. Of these, third-degree lacerations involve the anal sphincter and are subcategorized as:

(3a) <50 percent external anal sphincter (EAS) tear;
(3b) >50 percent EAS tear; and
(3c) EAS plus internal anal sphincter (IAS) tears.

Third- and fourth-degree perineal lacerations are considered obstetric anal sphincter injuries (OASIS), and their combined incidence is 0.1 to 5 percent (Blondel, 2016; Friedman, 2015). Risk factors for these more complex lacerations include nulliparity, midline episiotomy, persistent OP position, Asian race, increasing fetal birthweight, and operative vaginal delivery (Gurol-Urganci, 2013; Landy, 2011).

Morbidity rates rise as laceration severity increases. Compared with simpler lacerations, OASIS are associated with greater blood loss and puerperal pain. Wound disruption and infection rates are other risks (Goldaber, 1993; Lewicky-Gaupp, 2015). Stock and coworkers (2013) reported that approximately 7 percent of 909 OASIS had complications. Long term, OASIS are linked with approximately doubled rates of anal incontinence compared with vaginal delivery without OASIS (Evers, 2012; Schei, 2019). Fourth-degree lacerations pose greater anal incontinence risk than third-degree ones (Gommesen, 2020; Jangö, 2018). Evidence implicating OASIS in subsequent long-term dyspareunia are conflicting (Mous, 2008; O'Shea, 2018).

To ensure appropriate repair, identification and correct categorization is essential. Intrapartum endoanal ultrasound has been used to unmask clinically occult tears (Faltin, 2005). Few data currently support this imaging intrapartum, and the American College of Obstetricians and Gynecologists (2020c) does not recommended it.

For women with a prior OASIS, questions may arise as to subsequent pregnancy. In those without anal incontinence after OASIS repair, the rate of developing this incontinence is not increased by a subsequent vaginal birth (Jangö, 2016;

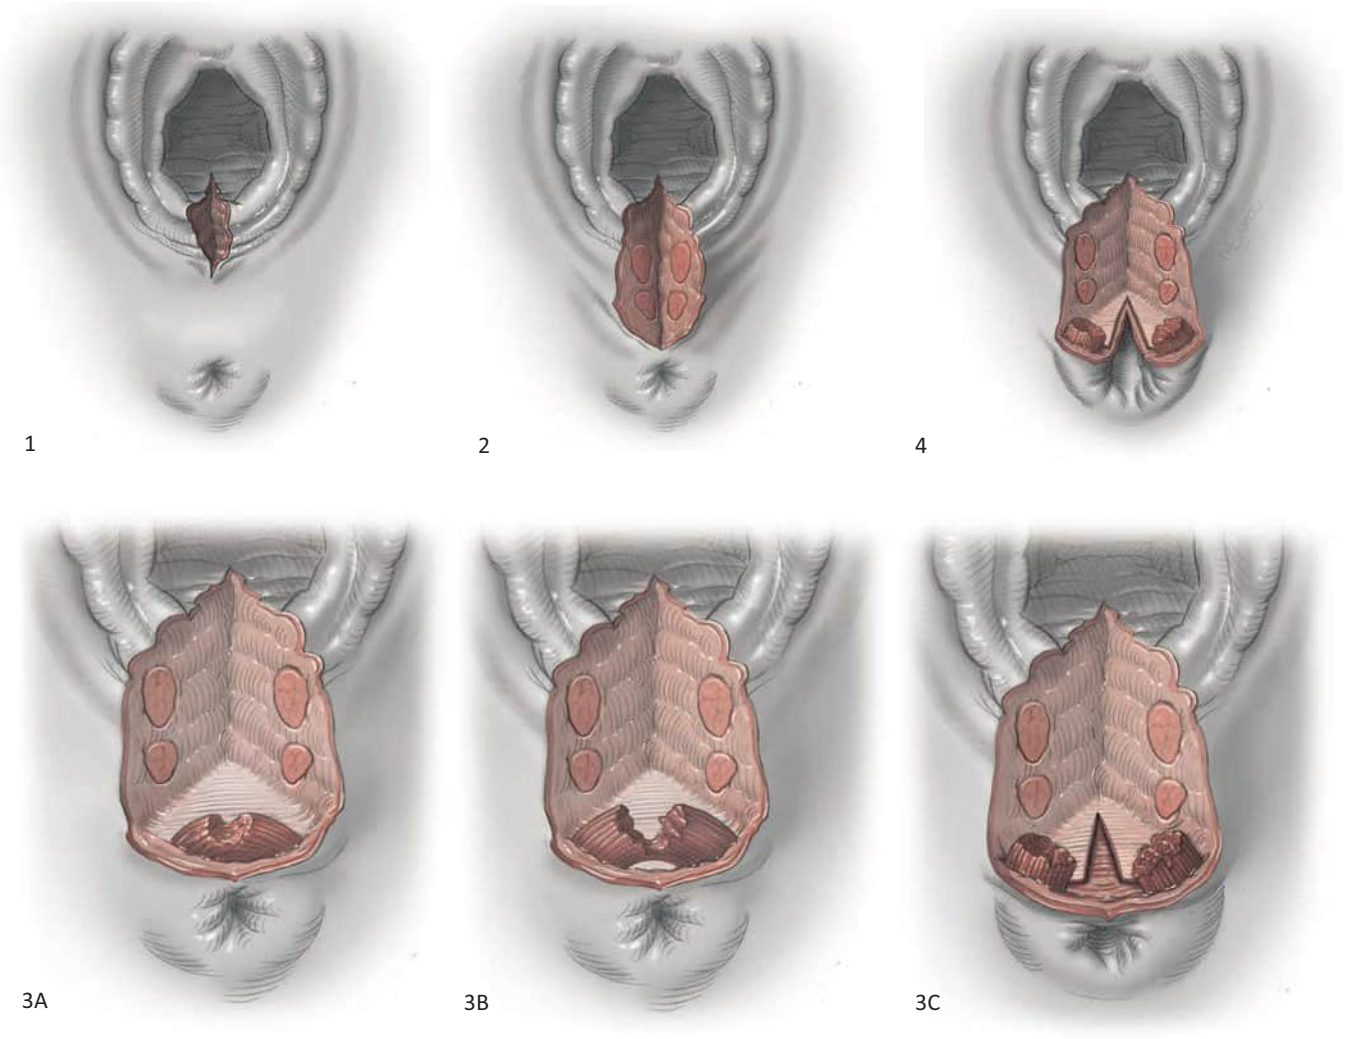

FIGURE 27-9 1. First-degree perineal laceration: injury to only the vaginal epithelium or perineal skin. **2.** Second-degree laceration: injury to perineum that spares the anal sphincter complex but involves the perineal muscles, which are the bulbospongiosus and superficial transverse perineal muscles. **3a.** Third-degree laceration: <50 percent of the external anal sphincter (EAS) is torn. **3b.** Third-degree laceration: >50 percent of the EAS is torn, but the internal anal sphincter (IAS) remains intact. **3c.** Third-degree laceration: EAS and IAS are torn. **4.** Fourth-degree laceration: the perineal body, entire anal sphincter complex, and anorectal mucosa are lacerated. (Reproduced with permission from Kenton K, Mueller M: Episiotomy and obstetric anal sphincter lacerations. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

Webb, 2017). Thus, a vaginal route is reasonable. However, women with a prior OASIS do have a higher recurrence rate with a subsequent delivery compared with multiparas without a prior OASIS (Edozien, 2014; Elfaghi, 2004). The risk mirrors that of primiparas in the general population and is low (Basham, 2013; Boggs, 2014). But, in those who experience a recurrent OASIS, the risk of anal incontinence can be substantial (Jangö, 2017). Fetal macrosomia and operative vaginal delivery are factors for OASIS recurrence and can influence counseling in future pregnancies. Specifically, patients may choose cesarean delivery to avoid repeat OASIS. This consideration may be most pertinent for those with prior postpartum anal incontinence, with OASIS complications that required a second repair, or with psychological trauma (American College of Obstetricians and Gynecologists, 2020c). Planned cesarean delivery is balanced against its associated operative risks (Chap. 30, p. 548).

■ Episiotomy

In contrast to spontaneous perineal tears, *episiotomy* is intended incision of the perineum. Its goal is enlargement of vaginal opening for birth. Textbooks and organizational guidelines often differ in their description. Kalis and colleagues (2012) presents one classification, and we agree with the need for terminology standardization.

Midline and mediolateral episiotomies are the two main types and vary by the angle of perineal incision. Involved structures mirror those found with second-degree laceration, and their repairs are analogous. The *midline episiotomy* begins at the fourchette, incises the perineal body in the midline, and ends well before the EAS is reached. The chosen incision length varies from 2 to 3 cm depending on perineal length, degree of tissue thinning, and outlet diameter needs for delivery. The *mediolateral episiotomy* begins at the midline of the fourchette

FIGURE 27-10 A mediolateral episiotomy is cut as the baby's head crowns. Fingers are insinuated between the perineum and head. The incision begins in the midline and is directed toward the ipsilateral ischial tuberosity at an angle 60 degrees off the midline. (Reproduced with permission from Kenton K, Mueller M: Episiotomy and obstetric anal sphincter lacerations. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

and is directed to the right or left at an angle 60 degrees off the midline (Fig. 27-10). This angle accounts for stretch distortion of perineal anatomy during crowning. After delivery and distortion resolution, it ultimately yields an incision 45-degrees from the midline for suturing (Kalis, 2011). Used less often, the *lateral episiotomy* begins at point 1 to 2 cm lateral from the midline of the fourchette. It too is angled toward either the right or the left ischial tuberosity.

The American College of Obstetricians and Gynecologists (2020c) recommends selective use of episiotomy rather than routine use. Evidence shows lower rates of severe perineal trauma in women undergoing spontaneous birth with a restrictive use of episiotomy (Dillon, 2019; Jiang, 2017). One potential indication is fetal jeopardy, and the quickly enlarged vaginal opening can speed delivery. Others are shoulder dystocia, breech delivery, fetal macrosomia, operative vaginal delivery, persistent OP position, and other instances in which failure to perform an episiotomy will result in significant perineal rupture. Surgical judgment and common sense should guide selection.

As a result of selective use, episiotomy rates have dropped. Oliphant and coworkers (2010) analyzed rates between 1979 and 2006 in the United States and noted a 75-percent decline. In the United States in 2012, episiotomy was performed in approximately 12 percent of vaginal births (Friedman, 2015).

Before episiotomy, analgesia is provided by existing labor regional analgesia, by bilateral pudendal nerve blockade, or by local infiltration of 1-percent lidocaine. Some instead advocate 2.5-percent lidocaine-prilocaine cream (EMLA cream). However, for efficacy, it requires application an hour before expected delivery, which may be logistically difficult (Abbas, 2020).

If episiotomy is performed unnecessarily early, incisional bleeding may be considerable before delivery. If it is performed too late, lacerations will not be prevented. Typically, episiotomy is completed when the head is visible during a contraction to a diameter of 4 to 5 cm.

Few data directly compare midline and mediolateral types. As noted, midline episiotomy has a greater likelihood of associated OASIS (Coats, 1980; de Leeuw, 2001). Short-term rates of pain and dyspareunia are similar or increased with mediolateral episiotomy (Fodstad, 2013, 2014; Sartore, 2004).

Even fewer studies compare lateral episiotomy to either mediolateral or midline. One randomized trial compared lateral and mediolateral types in nulliparas. Groups did not differ in pain scores, in sexual quality of life, or in vaginal or perineal trauma, including OASIS (Karbanova, 2014a,b; Necesalova, 2016). The authors also reported that mediolateral episiotomies required less time and suture for the repair. Thus, among the three, mediolateral episiotomy may be the preferred incision to reduce OASIS rates.

Laceration and Episiotomy Repairs

Typically, perineal repairs are deferred until the placenta has been delivered. This policy permits undivided attention to the signs of placental separation and delivery. A further advantage is that repair is not interrupted or disrupted by placenta delivery. This is especially true if manual placenta removal must be performed. The major disadvantage is continuing blood loss until the repair is completed. Direct pressure from an applied gauze sponge will help to limit this volume.

For suitable repair, an understanding of perineal anatomy is necessary (Chap. 2, p. 14). Adequate analgesia is imperative. Locally injected lidocaine can be used solely or as a supplement to bilateral pudendal nerve blockade. In those with epidural analgesia, additional doses can be given. Following any repair, needle and sponge counts are reconciled and recorded in the delivery note (Steelman, 2018).

First-degree lacerations do not always require repair, and sutures are placed to control bleeding or restore anatomy. Here, few data guide suture selection. A fine-gauge, absorbable suture such as chromic gut or a delayed-absorbable type such as polyglactin 910 (Vicryl) or poliglecaprone (Monocryl) are suitable. If a site is hemostatic, skin glue is another option (Feingenberg, 2014).

Second-degree laceration is shown in Figures 27-11. Midline and mediolateral episiotomy repairs use similar steps. Namely, these close the vaginal epithelium and reapproximate the bulbospongiosus and superficial transverse perineal muscles during restoration of the perineal body. Compared with placing interrupted sutures, a continuous suturing method closes the defect faster, and has lower short-term pain scores, but wound complications and long-term pain rates are comparable and low (Kettle, 2012; Kindberg, 2008; Valenzuela, 2009). Selected less often, blunt needles are suitable and aim to decrease the incidence of needle-stick injuries (Mornar, 2008). Commonly used suture materials are chromic catgut or 2–0 Vicryl. Compared with chromic catgut, Vicryl is associated with less short-term discomfort, but long-term pain rates are

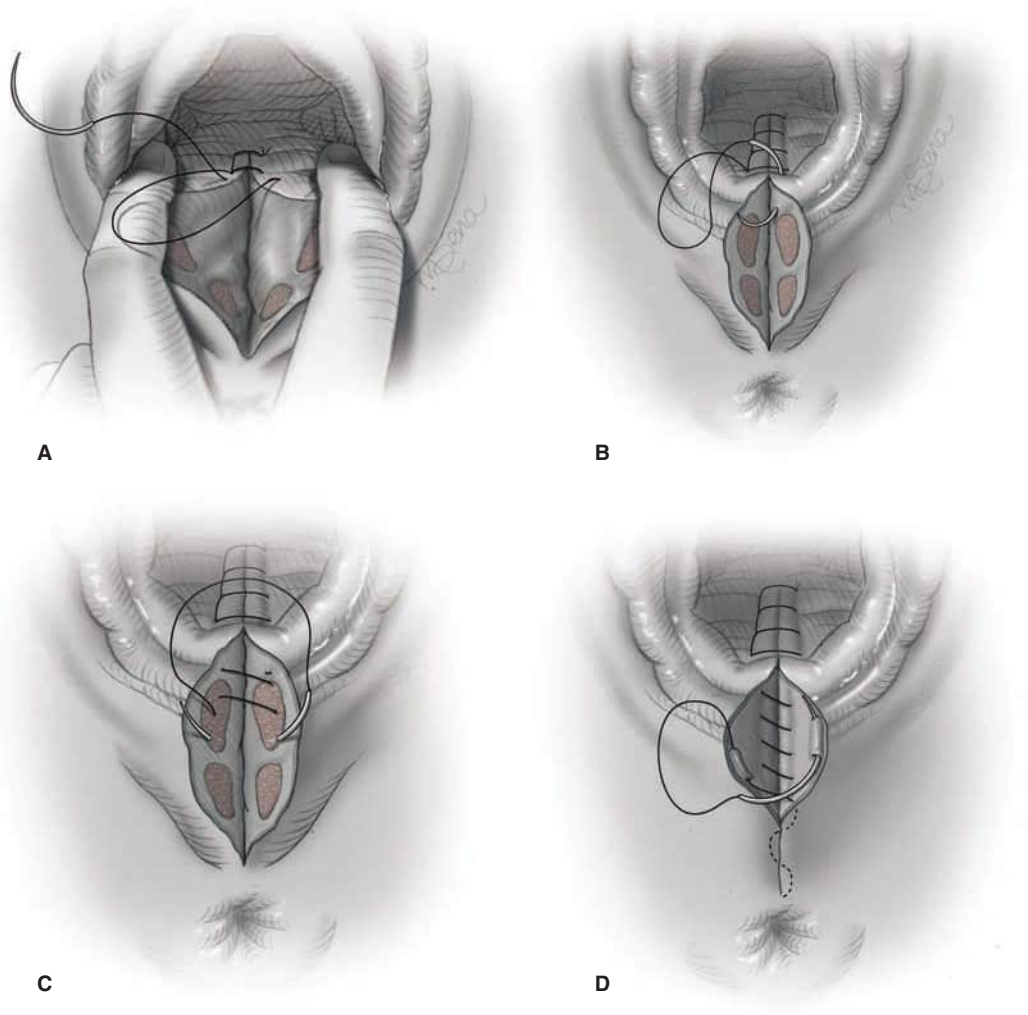

FIGURE 27-11 Midline episiotomy repair. **A.** An anchor stitch is placed above the wound apex to begin a running, locking closure with 2–0 suture to close the vaginal epithelium and deeper tissues and reapproximate the hymeneal ring. **B.** A transition stitch redirects suturing from the vagina to the perineum. **C.** The superficial transverse perineal and bulbospongiosus muscles are reapproximated using a continuous, nonlocking technique with the same length of suture. This aids restoration of the perineal body for long-term support. **D.** The continuous suture is then carried upward as a subcuticular stitch. The final knot is tied proximal to the hymeneal ring. (Reproduced with permission from Kenton K, Mueller M: Episiotomy and obstetric anal sphincter lacerations. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

comparable (Kettle, 2010). However, traditional Vicryl occasionally requires removal of residual suture from the repair site because of pain. This disadvantage may be reduced by selecting a rapidly absorbed polyglactin 910 suture (Vicryl Rapide) (Greenberg, 2004; Kettle, 2002). Other delayed absorbable options include Monocryl or polydioxanone (PDS II). The perineal skin is closed by a running subcuticular stitch with the same suture type used to close the perineal defect.

For third-degree laceration repair, two methods are available to repair the EAS. The first is an *end-to-end technique*, which we prefer, and is shown in Figure 27-12. Initially, the torn ends of the EAS, which often retract, are isolated. The EAS and its surrounding connective tissue are brought to the midline. As a misnomer, this connective tissue is often called a *capsule* (Maldonado, 2020). The strength of this closure is derived from the connective tissue surrounding the sphincter and less so from the striated muscle. Thus, serial interrupted sutures incorporate sphincter fibers and a substantial portion of the perisphincter connective tissue to bring EAS ends together. If the IAS is torn, a running, nonlocking closure is completed with 3-0 or 4-0 suture (see Fig. 27-13B). Few data guide suture selection for sphincter repair, but delayed-absorbable material can provide sustained tensile strength during healing (Williams, 2006). This theory is supported by the study by Jallad and coworkers (2016), which showed a higher perineal breakdown rate following OASIS repair with chromic catgut.

With the *overlapping technique,* the ends of the EAS are brought to the midline, lie atop one another, and are sutured in this position. This method is suitable only for type 3c lacerations—those with complete EAS rupture. Two rows of mattress sutures travel through both overlapping EAS ends to recreate the anal ring. In comparing the two methods, neither yields superior long-term anatomical or functional results (Farrell, 2012; Fernando, 2013; Fitzpatrick, 2000). Also with type 3c lacerations, the IAS is repaired before the EAS and is described next.

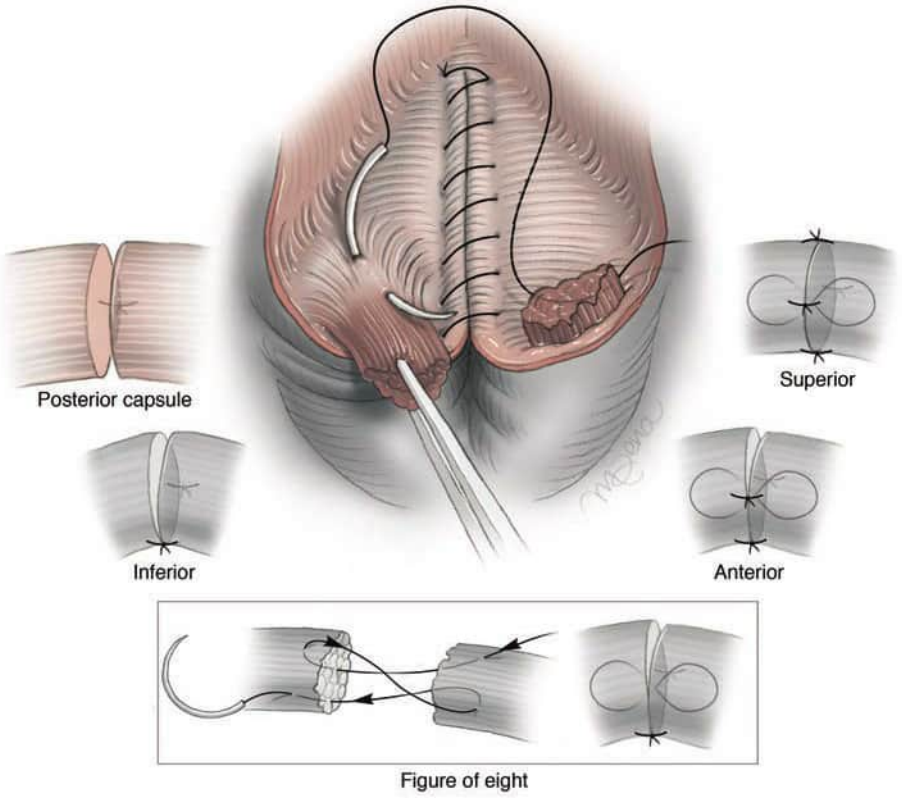

FIGURE 27-12 In overview, with end-to-end approximation of the external anal sphincter (EAS), a suture is placed through the EAS muscle, and four to six simple interrupted 2–0 or 3–0 sutures of polyglactin 910 are placed at the 3, 6, 9, and 12 o'clock positions through the perisphincter connective tissue. To begin, disrupted ends of the striated EAS muscle and capsule are identified and grasped. The first suture is placed posteriorly to maintain clear exposure. Another suture is then placed inferiorly at the 6 o'clock position. The sphincter muscle fibers are next reapposed by a figure-of-eight stitch. Last, the remainder of the fascia is closed with a stitch placed anterior to the sphincter cylinder and again with one placed superior to it. (Reproduced with permission from Kenton K, Mueller M: Episiotomy and obstetric anal sphincter lacerations. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

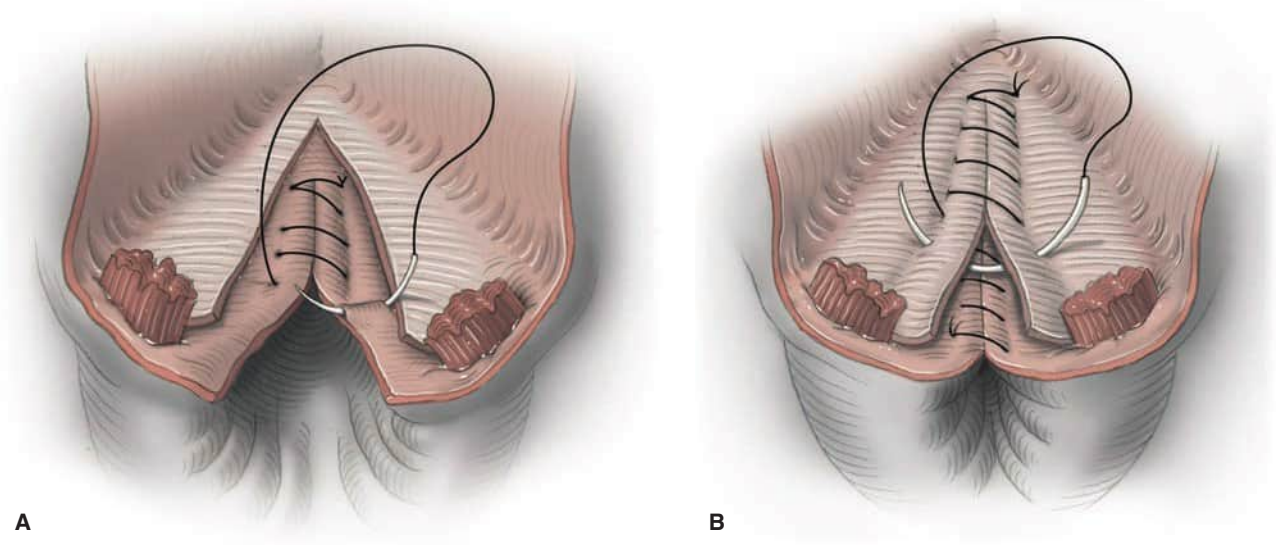

FIGURE 27-13 **A.** Suturing of the anorectal mucosa begins above the laceration apex using a continuous, nonlocking method with fine-gauge absorbable suture such as 3–0 or 4–0 chromic gut or polyglactin 910. Sutures are placed through the anorectal submucosa approximately 0.5 cm apart down to the anal verge. **B.** A second reinforcing layer uses 3–0 delayed-absorbable suture in a continuous, nonlocking fashion. This incorporates the torn ends of the internal anal sphincter (IAS), which can be identified as the glistening white fibrous structure lying between the anal canal submucosa and the fibers of the external anal sphincter. In many cases, the IAS retracts laterally and must be sought and retrieved for repair. (Reproduced with permission from Kenton K, Mueller M: Episiotomy and obstetric anal sphincter lacerations. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

With fourth-degree laceration repairs, both torn edges of the rectal mucosa are reapproximated first (see Fig. 27-13). Starting at a point 1 cm proximal to the wound apex, sutures are placed approximately 0.5 cm apart in the rectal muscularis and do not enter the anorectal lumen. Clinicians often use 4–0 delayed-absorbable suture or chromic gut for this running suture line. Some recommend a second reinforcing layer above this (Hale, 2007). The next layer to cover the anorectal mucosa is formed by reapproximation of the IAS.

For reduction of infectious morbidity associated with OASIS, a single dose of antibiotic at the time of repair may be considered (Buppasiri, 2014; Duggal, 2008; Lewicky-Gaupp, 2015; Stock, 2013). A single dose of a second-generation cephalosporin is suitable, or clindamycin for penicillin-allergic women. With OASIS, postoperatively, stool softeners are prescribed for a week, and enemas and suppositories are avoided.

■ Perineal Laceration Care

Initially, locally applied ice packs help reduce swelling and allay discomfort (de Souza Bosco Paiva, 2016). In subsequent days, warm sitz baths aid comfort and hygiene. Additionally, a small squirt bottle of warm water can cleanse the site after voiding or stooling. Analgesics containing codeine provide considerable relief. For lesser degrees of discomfort, nonsteroidal antiinflammatory drugs can be given.

Because pain may instead signal a large vulvar, paravaginal, or ischiorectal fossa hematoma or perineal cellulitis, these sites should be examined carefully if pain is severe or persistent. Management of these complications is discussed in Chapters 37 and 42 (pp. 657 and 740). In addition to pain, urinary retention may complicate episiotomy recovery, and management is described in Chapter 36 (p. 643).

For those with second-degree lacerations or OASIS, intercourse is usually proscribed until after the first puerperal visit. Compared with women with intact perineum, those with perineal trauma show higher rates of delayed intercourse at 3 and 6 months, but not at 1 year (McDonald, 2015; Rådestad, 2008; Signorello, 2001).

CHAPTER 28

Singleton Breech Delivery

CLASSIFICATION

Near term, the typical fetus spontaneously assumes a cephalic presentation. However, if the fetal buttocks or legs enter the pelvis before the head, the presentation is *breech*. At term, breech presentation persists in 2 to 5 percent of singleton deliveries (Bin, 2016; Cammu, 2014; Toijonen, 2019). Breech delivery of a second twin is discussed in Chapter 48 (p. 856).

The categories of frank, complete, and incomplete breech presentations differ in their varying relations between the lower extremities and buttocks. With a *frank breech*, lower extremities are flexed at the hips and extended at the knees, and thus the feet lie close to the head (Fig. 28-1). With a complete breech, both hips are flexed, and one or both knees are also flexed (Fig. 28-2). With an incomplete breech, one or both hips are extended. As a result, one or both feet or knees lie below the breech, and thus a foot or knee is lowermost in the birth canal. A footling breech is an incomplete breech with one or both feet below the breech.

Of singleton term breech fetuses, the neck may be extremely hyperextended in perhaps 5 percent, and the term *stargazing fetus* is used (Cimmino, 1975). With transverse lie and similar hyperextension of the fetal neck, the term *flying fetus* is applied. With these, fetal or uterine anomalies may be more prevalent and are sought if not previously identified (Phelan, 1983; Shipp, 2000). With hyperextension, vaginal delivery can injure the cervical spinal cord. Thus, if identified at term, cesarean delivery is indicated (Westgren, 1981). However, cases of spinal cord injury have been reported following uneventful

FIGURE 28-1 Frank breech presentation.

FIGURE 28-2 Complete breech presentation.

cesarean delivery of breech fetuses. Here, the flexion itself may be implicated (Hernandez-Marti, 1984; Weinstein, 1983).

DIAGNOSIS

Risk Factors

Understanding the clinical settings that predispose to breech presentation can aid early recognition. This fetal lie is more common remote from term, as earlier in pregnancy each fetal pole has similar bulk (Toijonen, 2019). Multifetal gestation is another (Chap. 48, p. 856). With singletons, other factors include extremes of amnionic fluid volume, fetal anomalies, structural uterine abnormalities, placenta previa, nulliparity, increased maternal age, female fetal gender, prior breech delivery, and size that is small for gestational age (Bin, 2016; Cammu, 2014; Noli, 2019; Roberts, 1999). One study found that following one breech delivery, the recurrence rate for a second breech presentation was 10 percent, and for a subsequent third breech it was 28 percent (Ford, 2010).

Examination

Leopold maneuvers to ascertain fetal presentation are discussed in Chapter 22 (p. 419). With the first maneuver, the hard, round fetal head occupies the fundus. The second maneuver identifies the hard, broad back to be on one side of the abdomen and the knobby small parts on the other. With the third maneuver, if not engaged, the softer breech is movable above the pelvic inlet. After engagement, the fourth maneuver shows the breech to be beneath the symphysis. The accuracy of this palpation varies (Lydon-Rochelle, 1993; Nassar, 2006). Thus, with unclear presentation, sonographic examination is indicated.

During cervical examination with a frank breech, no feet are appreciated, but the fetal ischial tuberosities, sacrum, and anus are usually palpable. After further fetal descent, the external genitalia also may be distinguished. When labor is prolonged, the fetal buttocks may become markedly swollen, rendering digital differentiation of a face and breech difficult. In some cases, the anus may be mistaken for the mouth and the ischial tuberosities for the malar eminences. With careful examination, however, the finger encounters muscular resistance with the anus, whereas the bony, less yielding jaws and palate are felt through the mouth. The finger, upon removal from the anus, may be stained with meconium. The mouth and malar eminences form a triangular shape, whereas the ischial tuberosities and anus lie in a straight line. With a complete breech, the feet may be felt alongside the buttocks. In footling presentations, one or both feet are inferior to the buttocks.

The fetal sacrum is palpated to establish position. As with cephalic presentations, fetal position is designated to reflect the relations of the fetal sacrum to the maternal pelvis. Thus, with left sacrum anterior (LSA), the fetus's back is up and its sacrum occupies the left upper (ventral) quadrant of the mother's pelvis. Other positions are right sacrum anterior (RSA), right or left sacrum posterior (RSP or LSP), and right or left sacrum transverse (RST or LST).

DELIVERY ROUTE

Multiple factors aid determination of the best delivery route. These include maternal parity and pelvic dimensions; coexistent pregnancy complications; provider experience; patient preference; hospital capabilities; and fetal size, anatomy, and gestational age (Table 28-1).

TABLE 28-1. Factors Favoring Cesarean Delivery of the Breech Fetus

Clinical characteristics
Lack of operator experience
Patient request for cesarean delivery
Prior perinatal death or neonatal birth trauma
Sonographic fetal characteristics
Large fetus: >3800 to 4000 g
Severe fetal-growth restriction; term weight <2500 to 2800 g
Oligohydramnios
Fetal anomaly incompatible with vaginal delivery
Incomplete breech presentation
Hyperextended neck
Apparently healthy, viable preterm fetus either with active labor or with indicated delivery
Maternal characteristics
Pelvic contraction or unfavorable pelvic shape determined clinically or with pelvimetry
Prior cesarean delivery

Compiled from text references.

Compared with their term counterparts, preterm breech fetuses have distinct complications related to their small size and immaturity. Accordingly, a separate discussion of term and preterm breech fetuses is presented.

Term Breech Fetus

Current obstetrical thinking regarding vaginal delivery of the term breech fetus was tremendously influenced by results of the Term Breech Trial (Hannah, 2000). This trial included 1041 women randomly assigned to planned cesarean and 1042 to planned vaginal delivery. These comparator groups reflect actual risks, and the planned vaginal delivery group included those who required intrapartum cesarean delivery. In the planned vaginal delivery group, 57 percent were actually delivered vaginally. Planned cesarean delivery was associated with a lower risk of perinatal mortality compared with planned vaginal delivery—3 per 1000 versus 13 per 1000. Cesarean delivery was also associated with a lower risk of "serious" neonatal morbidity—1.4 versus 3.8 percent. Short-term maternal morbidity was similar between groups.

Critics of the Term Breech Trial emphasize that fewer than 10 percent of candidates underwent radiological assessment of pelvic capacity. In addition, most of the outcomes included in the "serious" neonatal morbidity composite did not actually portend long-term infant disability (Whyte, 2004).

Since that trial, however, additional data favoring cesarean delivery has come from the World Health Organization (Lumbiganon, 2010). In more than 100,000 deliveries from nine participating Asian countries, planned cesarean delivery offered improved perinatal outcomes for the term breech fetus compared with planned vaginal delivery. Other studies also have found lowered neonatal morbidity and mortality rates with cesarean delivery (Lyons, 2015; Rietberg, 2005; Vistad, 2015). From one metaanalysis, the calculated absolute risk of perinatal mortality was 0.3 percent, and risk of fetal birth trauma or neurological morbidity was 0.7 percent (Berhan, 2016).

In contrast, other studies support vaginal delivery as a suitable option at term (Hofmeyr, 2015a). The *Presentation et Mode d'Accouchement (PREMODA)* study—which translates as presentation and mode of delivery—showed no differences in corrected neonatal mortality rates and neonatal outcomes according to delivery mode (Goffinet, 2006). Severe acute maternal morbidity scores were similar (Korb, 2019). This French prospective observational study involved more than 8000 women with term breech singletons. Strict criteria were used to select 2526 of these for planned vaginal delivery, and 71 percent of that group were delivered vaginally. Data from the Lille Breech Study Group in France also showed no excessive morbidity in term breech singletons delivered vaginally provided that strict fetal biometric and maternal pelvimetry parameters were applied (Michel, 2011). Other smaller studies support these findings as long as guidelines are part of the selection process (Alarab, 2004; Giuliani, 2002; Toivonen, 2012).

Long-term evidence supporting vaginal breech delivery comes from Eide and associates (2005). These investigators analyzed intelligence testing scores of more than 8000 men delivered breech, and delivery route did not affect later intellectual performance. Moreover, a 2-year follow-up from the Term Breech trial showed similar risks for death and for neurodevelopmental delay between delivery groups (Whyte, 2004). Other studies support these findings (Bin, 2017; Macharey, 2018).

Despite evidence for this debate, at least in the United States, rates of planned vaginal delivery attempts continue to decline (Grunebaum, 2016). Thus, as predicted, the number of skilled providers able to safely select and vaginally deliver breech fetuses steadily dwindles (Dotters-Katz, 2020). Moreover, obvious medicolegal concerns make physician training in such deliveries difficult. In response, some institutions have developed birth simulators to improve resident competence in vaginal breech delivery (Deering, 2006; Maslovitz, 2007).

In selecting suitable term breech vaginal delivery candidates, factors outlined in Table 28-1 are weighed. Of these, various national organizations recommend that the estimated term fetal weight lies between >2500 to 2800 g and <3800 to 4000 g (American College of Obstetricians and Gynecologists, 2018b; Impey, 2017b; Kotaska, 2019). Fetal-growth restriction and oligohydramnios are other contraindications, because of their inherent association with poor neonatal outcome (Chaps. 14 and 47, pp. 260 and 831). Data support this concern for the term breech fetus (Hinnenberg, 2019; Macharey, 2017a). Of uterine factors, prior hysterotomy carries an inherent risk for rupture in labor. The PREMODA, Term Breech Trial, and other studies allowed a trial of labor after cesarean for vaginal breech delivery, but in each, these constituted a small percentage of participants. Other studies have considered prior cesarean as a contraindication. Very limited data suggest a possible link with adverse perinatal outcome (Azria, 2012; Macharey, 2017a). Moreover, a prior cesarean delivery performed for arrested labor may suggest a relatively contracted pelvis and a greater labor risk. In contrast, parity and prior vaginal birth are positive factors and likely reflect sufficient pelvic capacity. Last, those with spontaneous labor and normal labor curves have higher successful vaginal birth rates.

Preterm Breech Fetus

In contrast to the term breech fetus, no randomized trials guide delivery selection for the preterm breech fetus. Comparison of the available observational studies is often hampered by their combining, splitting, or overlapping of gestational age groups. Other study biases include differing gestational age thresholds for planned neonatal resuscitation, assigning mortality causation to delivery rather than immaturity, and tendency to favor vaginal delivery for fetuses with a poor prognosis. In addition, the effects of precipitous vaginal delivery and associated incomplete antenatal prophylaxis with corticosteroids and antibiotics is difficult to evaluate.

Despite these limitations, for preterm breech fetuses as whole, data support that planned cesarean delivery confers a survival advantage compared with planned vaginal delivery. Reddy and associates (2012) reported data from deliveries between 24 and 32 weeks' gestation. For breech fetuses within these gestational ages, attempting vaginal delivery yielded a low success rate, and this group was associated with higher neonatal mortality rates compared with planned cesarean delivery.

From a metaanalysis incorporating data from more than 3500 parturients, similar mortality associations were reported (Bergenhenegouwen, 2014). In contrast, in their smaller cohort with gestational ages of 26 to 34 weeks, Lorthe and coworkers (2019) found similar rates of survival or of survival at discharge without severe morbidity.

For less mature subgroups—23 to 28 weeks—the data are more conflicting as to whether survival rates are improved with planned cesarean delivery (Bergenhenegouwen, 2015; Grabovac, 2018; Kayem, 2015; Thomas, 2016; Tucker Edmonds, 2015). In the balance, cesarean delivery is proposed to avoid fetal injury from vaginal birth that may include anoxia, trauma, and head entrapment. This is measured against maternal morbidity from a classical uterine incision, which is often needed in this early preterm group due to a poorly developed lower uterine segment. This incision typically poses a risk of greater blood loss, higher infection rate, and increased risk of uterine rupture in future pregnancies (Patterson, 2002; Reddy, 2015; Sciscione, 2008). The high-level skills needed for safe vaginal delivery of the very preterm fetus and the ultimate prognosis of the neonate are other directing factors. For *periviable fetuses*, defined by them as 20 to $25^{6/7}$ weeks, a consensus workshop of perinatal organizations concluded that "available data do not consistently support routine cesarean delivery to improve perinatal mortality or neurological outcomes for early preterm infants" (Raju, 2014). A subsequent joint statement by the American College of Obstetricians and Gynecologists and the Society for Maternal-Fetal Medicine (2017) suggested *consideration* for cesarean delivery for periviable fetuses beginning at $23^{0/7}$ weeks, with a recommendation for cesarean delivery at $25^{0/7}$ weeks.

For more mature preterm breech fetuses, that is, between 32 and 37 weeks, again limited data guide delivery route selection. Bergenhenegouwen and coworkers (2015) studied more than 6800 breech deliveries in a subgroup between 32 and 37 weeks. With planned cesarean delivery or planned vaginal birth, they found similar perinatal mortality and morbidity rates.

All these findings shape practice. Thus, individualized decision-making is needed for the preterm breech fetus for whom resuscitation is planned. Provider skill, gestational age, parity, labor curve, and facility capability weigh heavily in this process. For the fetus in which resuscitation is not planned, vaginal delivery is likely preferable.

Delivery Complications

Compared with cephalic-presenting fetuses, higher rates of maternal and perinatal morbidity can be anticipated with breech presentations. For the mother, with either cesarean or vaginal delivery, genital tract laceration can be problematic. With cesarean delivery, added stretching of the lower uterine segment by forceps or by a poorly molded fetal head can extend hysterotomy incisions. With vaginal delivery, especially with a thinned lower uterine segment, delivery of the aftercoming head through an incompletely dilated cervix or application of forceps may cause vaginal wall or cervical lacerations, and even uterine rupture. Manipulations may also extend an episiotomy, create deep perineal tears, require cervical incision, and raise infection risks. If needed in select cases, inhalant anesthesia sufficient to induce appreciable uterine relaxation during vaginal delivery may cause uterine atony and postpartum hemorrhage. Maternal death is rare, but rates appear higher in those with planned cesarean delivery for breech presentation—a case-fatality rate of 0.47 maternal deaths per 1000 births (Schutte, 2007). Other general short-term and long-term risks of cesarean delivery are listed in Chapter 30 (p. 548).

For the fetus, prematurity and its complications are frequently comorbid with breech presentation. Rates of congenital anomalies also are greater (Mostello, 2014). Compared with cephalic presentation, umbilical cord prolapse is more frequent with breech fetuses and with breech vaginal delivery (Behbehani, 2016; Critchlow, 1994). Collea (1980) reported that the incidence of prolapse approximated 0.5 percent with frank breech presentation, 5 percent with complete breech, and up to 15 percent with footling presentation.

Rare fetal morbidity includes humeral or clavicular fracture, brachial plexus injury, and sternocleidomastoid muscle trauma (Chap. 33, p. 609. These may occur with either route but more frequently complicate vaginal birth. However, cesarean birth does not appear to afford greater protection against femur or skull fractures (Ekéus, 2019; Goffinet, 2006; Hannah, 2000). Rarely, traction may separate scapular, humeral, or femoral epiphyses (Lamrani, 2011). The spinal cord may be injured or vertebrae fractured, especially if great force is employed (Vialle, 2007). Last, genitals may be injured with breech delivery (Saroha, 2015).

Some perinatal outcomes are inherent to the breech position rather than delivery. For example, development of hip dysplasia is more common in breech compared with cephalic presentation and is unaffected by delivery mode (de Hundt, 2012; Hinderaker, 1994).

Imaging

As noted, limited sonographic evaluation near term is reasonable to confirm presentation. Transabdominal sonography of the lower uterine segment in the sagittal plane shows the presenting fetal part. Prior to this and as part of prenatal care, sonographic fetal survey will have been performed in most cases. If not, gross fetal abnormalities, such as hydrocephaly or anencephaly, can be rapidly ascertained with sonography. This will identify many fetuses not suitable for vaginal delivery. It will also help to ensure that a cesarean delivery is not performed under emergency conditions for an anomalous fetus with no chance of survival.

In many fetuses—especially those that are preterm or growth restricted—the breech is smaller than the aftercoming head. Moreover, unlike cephalic presentations, the head of a breech-presenting fetus does not undergo appreciable molding during labor. Thus, if vaginal delivery is considered, fetal size, breech type, and degree of neck flexion are evaluated (Fontenot, 1997; Rojansky, 1994). If needed, simple two-view radiography of the maternal abdomen also can define fetal head inclination. Sonographic identification of a nuchal arm or nuchal cord loops may warrant cesarean delivery to avoid neonatal harm (Sherer, 1989).

The accuracy of fetal weight estimation by sonography is not altered by breech presentation (McNamara, 2012). For planned vaginal delivery at term, thresholds in Table 28-1 guide care. Moreover, a biparietal diameter (BPD) >90 to 100 mm is often considered exclusionary for vaginal delivery (Giuliani, 2002; Roman, 2008).

Pelvimetry

In addition to these requisite fetal parameters, some institutional protocols recommend pelvimetry to assess the maternal bony pelvis prior to planned vaginal term breech birth. Others, including our practice at Parkland Hospital, instead monitor the steady progression of fetal descent and cervical dilation to reflect adequate pelvic capacity.

For pelvimetry, one-view computed tomography (CT), magnetic resonance (MR) imaging, or plain film radiography is suitable. Comparative data among these modalities for pelvimetry are lacking, but CT is favored due to its accuracy, low radiation dose, and widespread availability (Thomas, 1998). Although variable, some suggest specific measurements to permit a planned vaginal delivery: inlet anteroposterior diameter ≥10.5 cm; inlet transverse diameter ≥12.0 cm; and midpelvic interspinous distance ≥10.0 cm (Azria, 2012; Vendittelli, 2006). Some have recommended maternal-fetal biometry correlation. Appropriate values include: the sum of the inlet obstetrical conjugate minus the fetal BPD is ≥15 mm; the inlet transverse diameter minus the BPD is ≥25 mm; and the midpelvis interspinous distance minus the BPD is ≥0 mm (Michel, 2011). From small studies of MR imaging, vaginal delivery success rates approximating 75 percent were noted if the interspinous distance was >11 cm and true obstetrical conjugate was >12 cm (Hoffmann, 2016; Klemt, 2019).

LABOR AND DELIVERY

Labor Management

On arrival to the labor unit, surveillance of fetal heart rate and uterine contractions begins, and immediate recruitment of necessary staff includes: (1) a provider skilled in the art of breech extraction, (2) an associate to assist with the delivery, (3) anesthesia personnel who can ensure adequate analgesia or anesthesia when needed, and (4) an individual trained in newborn resuscitation. For the mother, intravenous access is obtained. This allows, if required, emergency induction of anesthesia or maternal resuscitation following hemorrhage from lacerations or from uterine atony.

Assessing cervical dilation, membranes status, and presenting part station is essential for management. If labor is too far advanced, pelvimetry may be unsafe if fetal expulsion in the radiology department is a possibility. This alone, however, should not force the decision for cesarean delivery. Commonly, stepwise labor progression itself is a good indicator of pelvic adequacy (Biswas, 1993). Sonographic assessment, described earlier, is completed. Ultimately, the choice of abdominal or vaginal delivery is guided by factors listed in Table 28-1.

During labor, one-on-one nursing is ideal because of increased cord prolapse risks, and physicians must be readily available for such emergencies. Guidelines for monitoring the high-risk fetus are applied (Chap. 24, p. 461). For first-stage labor, most clinicians prefer continuous electronic monitoring. At minimum, the fetal heart rate is recorded every 15 minutes. A scalp electrode can be safely affixed to the buttock, but genitalia are avoided.

When membranes rupture, either spontaneously or artificially, the cord prolapse risk rises appreciably. A small or preterm fetus or a non-frank breech presentation raises this risk. Therefore, vaginal examination is performed immediately following rupture, and special attention is directed to the fetal heart rate for the first 5 to 10 minutes thereafter.

Continuous epidural analgesia is advocated by some. This may increase the need for labor augmentation and prolong second-stage labor (Chadha, 1992; Confino, 1985). These potential disadvantages are weighed against the advantages of better pain relief and increased pelvic relaxation should extensive fetal manipulation be required. Analgesia must be sufficient for episiotomy, for breech extraction, and for Piper forceps application. Nitrous oxide plus oxygen inhalation provides further relief from pain. If general anesthesia is required, it must be induced quickly.

Normal second-stage labor should show progressive fetal descent. An initial passive second stage allows the breech to advance to the perineum and is recommended. In the PREMODA study, this stage lasted <30 min for 60 percent of parturients and >60 min for only 20 percent (Goffinet, 2006). For this passive phase, some recommend cesarean if the breech is not visible after 1½ to 2 hours (Impey, 2017b; Kotaska, 2019).

Once the breech is visible, active pushing is encouraged. A hands-off approach in which hands are poised merely to support delivering parts is preferred to allow spontaneous delivery. In the PREMODA study, this active phase was <30 min for 95 percent of those with successful vaginal births (Goffinet, 2006). In their subanalysis of adverse neonatal outcome factors, an active second stage >20 min increased the risk (Azria, 2012). In the Term Breech Trial, the lowest risk for maternal and neonatal adverse outcomes was seen in the group with active second stages lasting <30 min (Su, 2003, 2007). In one small observational study, fetal adverse risks rose if this phase was >40 minutes (Macharey, 2017b). Canadian guidelines recommend cesarean if completed or imminent delivery is not accomplished after 60 min of pushing (Kotaska, 2019).

Labor Induction or Augmentation

Induction or augmentation of labor is controversial for term breech pregnancies. Here again, data are limited and mostly retrospective. With labor induction, Burgos and coworkers (2017) reported equivalent vaginal delivery rates compared with spontaneous labor. With induction, however, they reported higher rates of neonatal intensive care unit (NICU) admission. But, Marzouk and associates (2011) found perinatal outcomes and cesarean delivery rates not to differ. Last, others described greater cesarean delivery rates with induction but similar neonatal outcomes (Macharey, 2016). In a metaanalysis of studies, the NICU admission rate was 3 percent with labor induction and was double that of those delivered from spontaneous labor.

The cesarean delivery rate with induction was higher and was 33 percent (Sun, 2018).

Compared with cephalic presentations, breech labor in general proceeds more slowly, but steady cervical progress is a positive indicator of adequate pelvic capacity (Lennox, 1998). Thus, some protocols avoid augmentation for the breech-presenting fetus, whereas others recommend it only for hypotonic contractions (Alarab, 2004; Kotaska, 2019). In women with a viable fetus, at Parkland Hospital, we use amniotomy to promote contractions but prefer cesarean delivery instead of pharmacological labor induction or augmentation.

Vaginal Delivery Methods

Vaginal breech delivery is accomplished by one of three methods. With *spontaneous breech delivery*, the fetus is expelled entirely without any traction or manipulation other than support of the newborn. With *partial breech extraction*, the fetus is delivered spontaneously as far as the umbilicus, but the remainder of the body is delivered by provider traction and assisted maneuvers, with or without maternal expulsive efforts. With *total breech extraction*, the entire fetal body is extracted by the provider.

Spontaneous Breech Delivery

Similar to vertex delivery, spontaneous expulsion of a breech fetus entails sequential cardinal movements (Chap. 22, p. 421). First, engagement and descent of the breech usually take place with the bitrochanteric diameter in one of the oblique pelvic diameters. The anterior hip usually descends more rapidly than the posterior hip, and when the resistance of the pelvic floor is met, internal rotation of 45 degrees usually follows, bringing the anterior hip toward the pubic arch and allowing the bitrochanteric diameter to occupy the anteroposterior diameter of the pelvic outlet.

After rotation, descent continues until the perineum is distended by the advancing breech, and the anterior hip appears at the vulva. By lateral flexion of the fetal body, the posterior hip then is forced over the perineum, which retracts over the fetal buttocks, thus allowing the fetus to straighten out when the anterior hip is born. The legs and feet follow the breech and may be born spontaneously or require aid.

After the birth of the breech, there is slight external rotation, with the back turning anteriorly as the shoulders are brought into relation with one of the oblique diameters of the pelvis. The shoulders then descend rapidly and undergo internal rotation, with the bisacromial diameter occupying the anteroposterior plane. Immediately following the shoulders, the head, which is normally sharply flexed on the thorax, enters the pelvis in one of the oblique diameters and then rotates to bring the posterior portion of the neck under the symphysis pubis. The head is then born in flexion.

Infrequently, rotation renders the fetal back to lie posteriorly instead of anteriorly. Such rotation is prevented if possible. Although the head can be delivered by allowing the chin and face to pass beneath the symphysis, the slightest traction on the body may cause extension of the head. With this, a longer diameter of the head must pass through the pelvis.

Partial Breech Extraction

With breech delivery, successively larger and less compressible parts are born. Thus, spontaneous expulsion is the exception, and vaginal delivery typically requires skilled provider participation for the fetus to navigate the birth canal. Noteworthy clinical pearls are provided by Yeomans (2017) in *Cunningham and Gilstrap's Operative Obstetrics*, 3rd edition.

First, with all breech deliveries, unless the perineum is considerably lax, an episiotomy is made and is an important adjunct to delivery. As discussed in Chapter 27 (p. 510), mediolateral episiotomy may be preferred for its lower associated risk of anal sphincter lacerations. Ideally, the breech is allowed to deliver spontaneously to the umbilicus. Delivery of the breech draws the umbilicus and attached cord into the pelvis. Therefore, once the breech has passed beyond the vaginal introitus, the abdomen, thorax, arms, and head must be delivered promptly either spontaneously or assisted.

The posterior hip will deliver, usually from the 6 o'clock position, and often with sufficient pressure to evoke passage of thick meconium. The anterior hip then delivers, followed by external rotation to a sacrum anterior position. The mother is encouraged to continue to push as the fetus descends until the legs are accessible. The legs are sequentially delivered by splinting the femur with the operator's fingers positioned parallel to the long axis of the femur. This helps avoid femoral fracture. Pressure is exerted upward and laterally to sweep each leg away from the midline (Fig. 28-3).

Following delivery of the legs, the fetal bony pelvis is grasped with both hands. The fingers should rest on the anterior superior iliac crests and the thumbs on the sacrum. This minimizes

FIGURE 28-3 To deliver the left leg, two fingers of the provider's left hand are placed beneath and parallel to the femur. The thigh is then slightly abducted and pressure from the fingertips in the popliteal fossa should induce knee flexion and bring the foot within reach. The foot is then grasped to gently deliver the entire leg outside the vagina. A similar procedure is followed on the right. (Reproduced with permission from Yeomans ER: Vaginal breech delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al [eds]: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

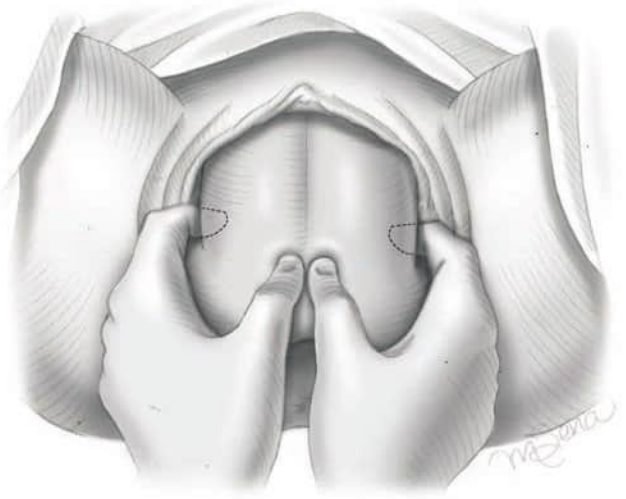

FIGURE 28-4 To deliver the body, thumbs are placed over the sacrum, and each index finger wraps over the top of the corresponding fetal iliac crest. Gentle downward traction is applied until the scapulas are clearly visible. (Reproduced with permission from Yeomans ER: Vaginal breech delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al [eds]: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

the chance of fetal abdominal soft-tissue injury (Fig. 28-4). Maternal expulsive efforts are again used in conjunction with downward traction to affect delivery.

A cardinal rule in successful breech extraction is to employ steady, gentle, downward traction until the lower halves of the scapulas are delivered. Subsequent delivery of the shoulders and arms is not attempted until one axilla becomes visible. It makes little difference which shoulder is delivered first, and two methods are suitable for their delivery. In the first method, with the scapulas visible, the trunk is rotated either clockwise or counterclockwise to bring the anterior shoulder and arm into view (Fig. 28-5). During delivery of the arm, fingers and hand are aligned parallel to the humerus and act as a splint. Perpendicular force risks humeral fracture. The body of the fetus is then rotated 180 degrees in the reverse direction to bring the other shoulder and arm into position for delivery.

The second method is employed if trunk rotation is unsuccessful. With this maneuver, the posterior shoulder is delivered first. For this, the feet are grasped in one hand and drawn upward over the inner thigh of the mother (Fig. 28-6). The operator's hand enters over the fetal shoulder, fingers are aligned parallel to the long axis of the fetal humerus, and the fetal arm is swept upward. The posterior shoulder slides out over the perineal margin and is usually followed by the arm and hand. Then, by depressing the body of the fetus, the anterior shoulder emerges beneath the pubic arch, and the arm and hand usually follow spontaneously. After both shoulders are delivered, the back of the fetus tends to rotate spontaneously to the symphysis. Delivery of the head may then be accomplished.

Nuchal Arm

During delivery, one or both fetal arms occasionally may lie across the back of the neck and become trapped at the pelvic inlet. With such a nuchal arm, delivery is more difficult and can be aided by rotating the fetus through a half circle in such a direction that the friction exerted by the birth canal will draw the elbow toward the face (Fig. 28-7). With a right nuchal arm, the body should be rotated counterclockwise, which rotates the fetal back toward the maternal right. With a left nuchal arm, the rotation is clockwise, which rotates the fetal back toward the maternal left. If rotation fails to free the nuchal arm, it may be necessary to push the fetus upward to a roomier part of the pelvis. If the rotation is still unsuccessful, still in this roomier part of the pelvic, the nuchal arm can be

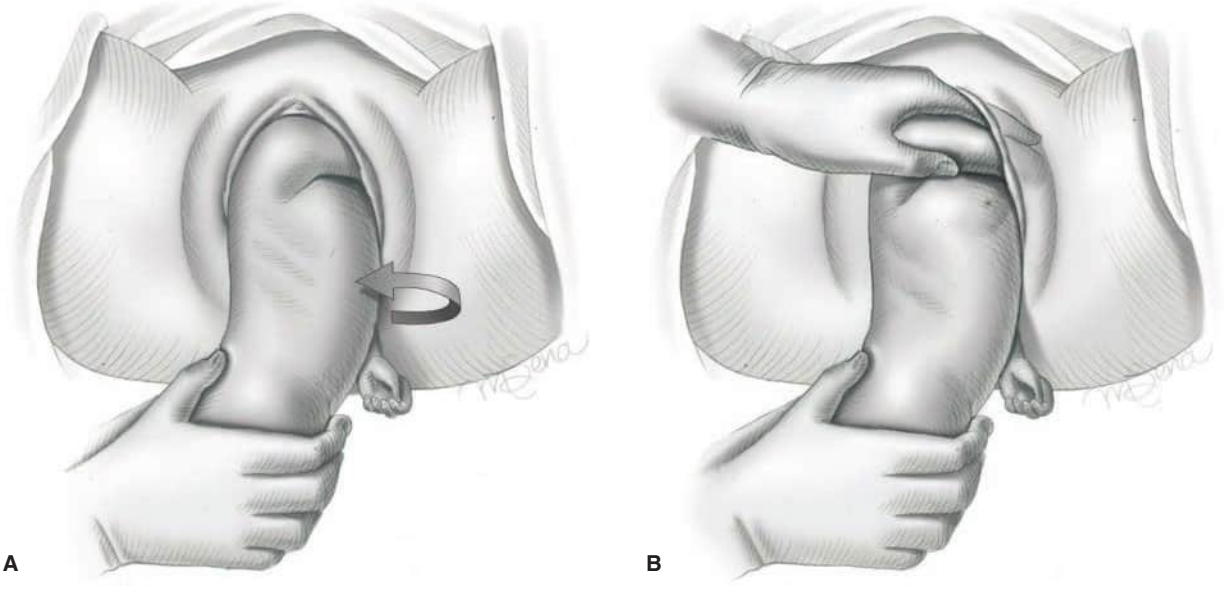

FIGURE 28-5 **A.** After delivery of the first arm, 180-degree rotation of the fetal body brings the sacrum to a right sacrum transverse (RST) position. **B.** Fingers of the provider's hand extended over the right shoulder and parallel to the humerus. These sweep the arm downward across the chest and out. (Reproduced with permission from Yeomans ER: Vaginal breech delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al [eds]: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

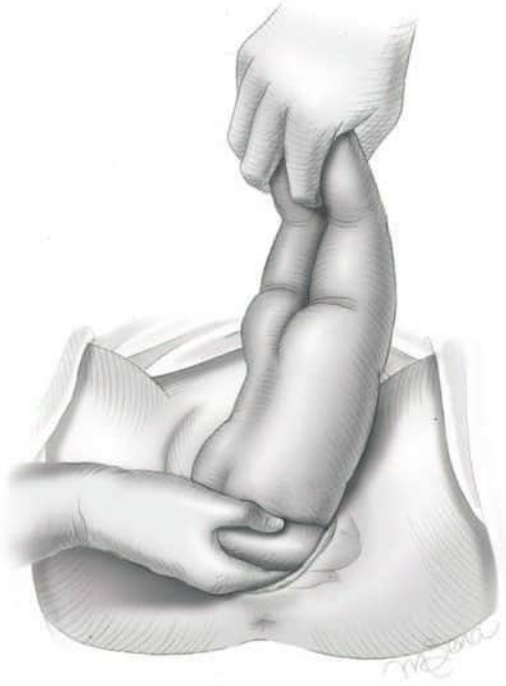

FIGURE 28-6 Infrequently, the posterior arm must be delivered first. For this, the lower half of the fetal body is raised up and over the maternal groin. The provider's fingers are inserted under the posterior shoulder and aligned with the humerus. (Reproduced with permission from Yeomans ER: Vaginal breech delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al [eds]: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

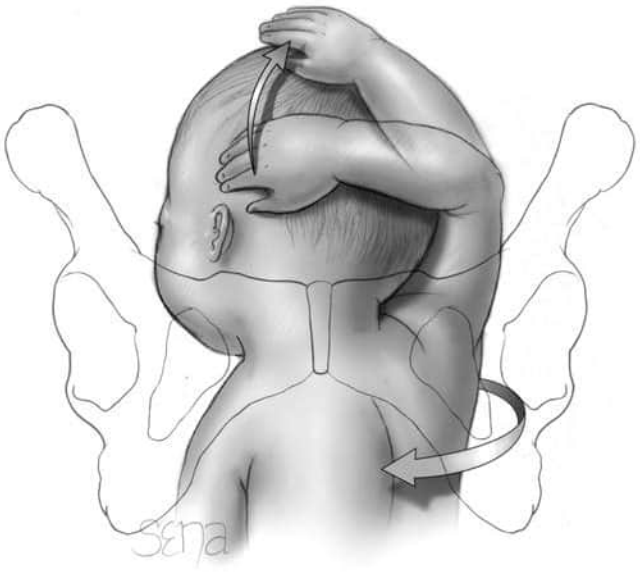

FIGURE 28-7 Reduction of a right nuchal arm is accomplished by rotating the fetal body 180 degrees counterclockwise, which directs the fetal back to the maternal right. Friction exerted by the birth canal will draw the elbow toward the face.

extracted. For this, the operator's hand enters over the fetal shoulder, and fingers are aligned parallel to the long axis of the fetal humerus. Downward pressure flexes the elbow, and the fetal arm is then swept forward and down the ventral body surface for delivery. In this event, fracture of the humerus or clavicle is common.

Delivery of the Aftercoming Head

The head of the fetus is normally extracted with one of the three maneuvers. With any of these, hyperextension of the fetal neck is avoided.

First, with the *Mauriceau maneuver*, the index and middle finger of one hand are applied over the maxilla, to flex the head, while the fetal body rests on the palm of the same hand and forearm (Fig. 28-8). Fetal legs straddle the forearm. Two fingers of the other hand hook over and grasp the shoulders. Downward traction is concurrently applied until the suboccipital region appears under the symphysis. Gentle suprapubic pressure simultaneously applied by an assistant helps keep the head flexed. The body is slightly elevated toward the maternal abdomen, and the mouth, nose, brow, and eventually the occiput emerge successively over the perineum. With this maneuver, the provider uses both hands simultaneously to exert continuous downward gentle traction while balancing forces between the fetal neck and maxilla to avoid neck hyperextension.

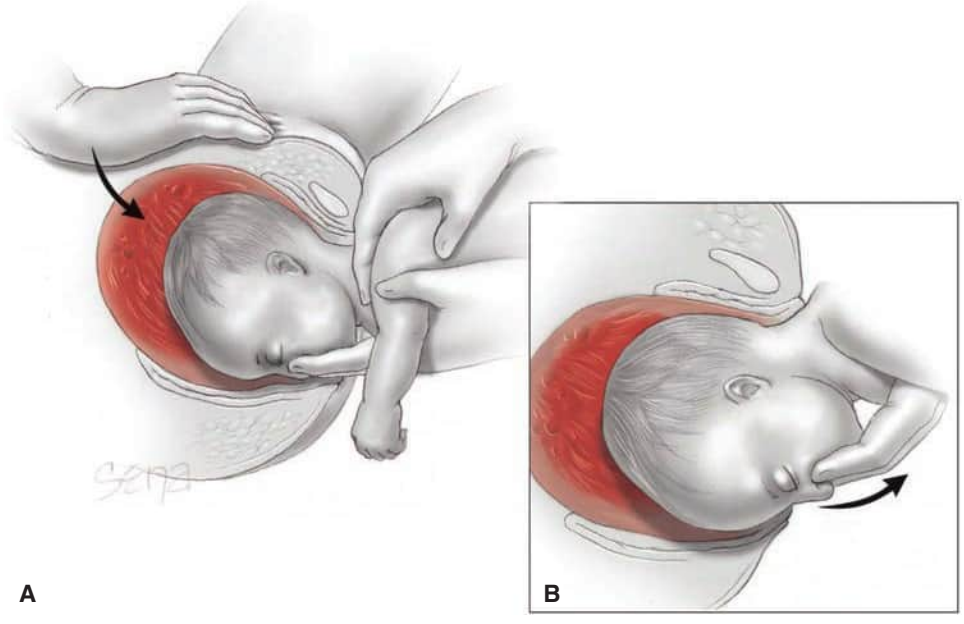

FIGURE 28-8 A. Delivery of the aftercoming head using the Mauriceau maneuver. Note that as the fetal head is being delivered, flexion of the head is maintained by suprapubic pressure provided by an assistant. **B.** Pressure on the maxilla is applied simultaneously by the operator as upward and outward traction is exerted.

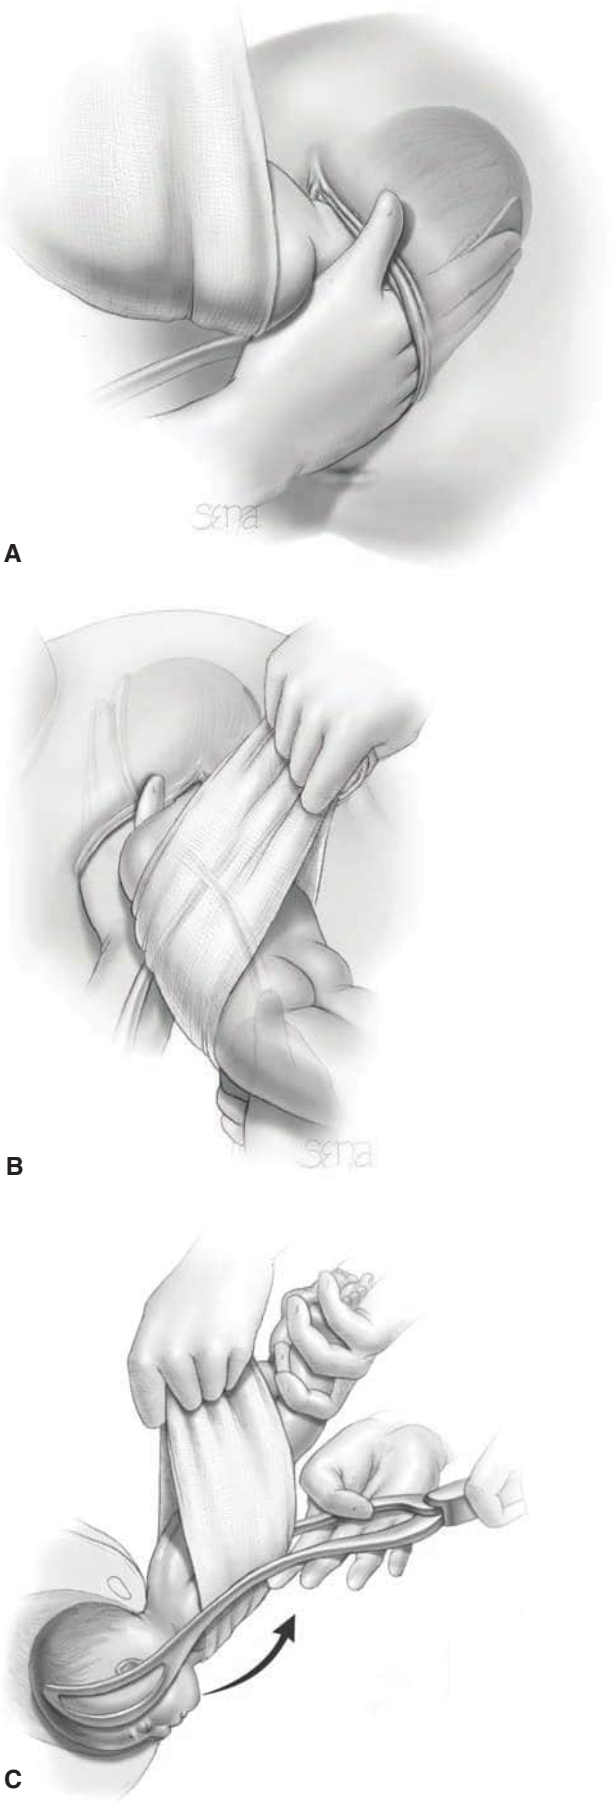

FIGURE 28-9 Piper forceps for delivery of the aftercoming head.

Second, specialized forceps can be used to deliver the aftercoming head. *Piper forceps*, shown in Figure 28-9, or *Laufe-Piper forceps* may be applied electively or when the Mauriceau maneuver cannot be accomplished easily. The blades of the forceps are not applied to the aftercoming head until it has been brought into the pelvis by gentle traction, combined with suprapubic pressure, and is engaged. Suspension of the body of the fetus in a towel effectively holds the fetus up and helps keep the arms and cord out of the way as the forceps blades are applied.

Because the forceps blades are directed upward from the level of the perineum, some choose to apply them from a one-knee kneeling position. Piper forceps have a downward arch in the shank to accommodate the fetal body and lack a pelvic curve. This shape permits direct application of the cephalic curve of the blade along the length of the maternal vagina and fetal parietal bone. The blade to be placed on the maternal left is held in the provider's left hand. The right hand slides between the fetal head and left maternal vaginal sidewall to guide the blade inward and around the parietal bone. The opposite blade mirrors this application.

Once in place, the blades are articulated, and the fetal body rests across the shanks. The head is delivered by pulling gently outward and slightly raising the handle simultaneously. This rolls the face over the perineum, while the occiput remains beneath the symphysis until after the brow delivers. Ideally, the head and body move in unison to minimize neck extension.

Last, in some cases, the back of the fetus fails to rotate to the symphysis. The fetus still may be delivered using the modified *Prague maneuver*. With this, two fingers of one hand grasp the shoulders of the back-down fetus from below while the other hand draws the feet up and over the maternal abdomen (Fig. 28-10).

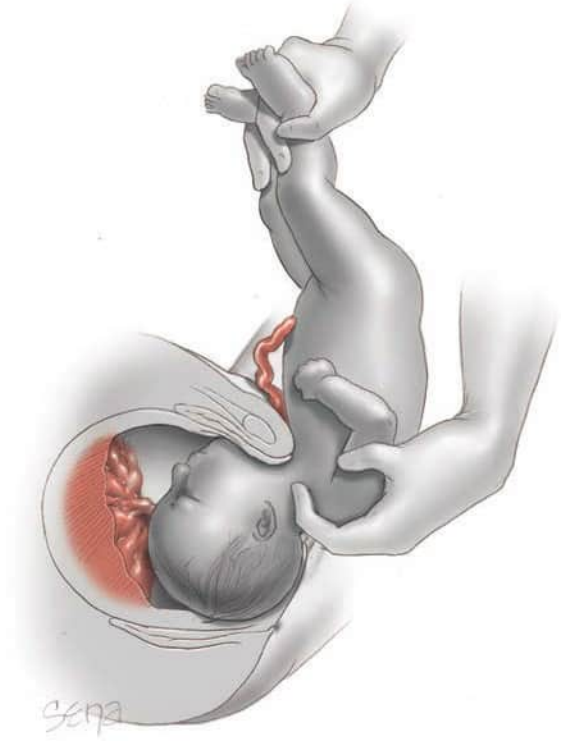

FIGURE 28-10 Delivery of the aftercoming head using the modified Prague maneuver necessitated by failure of the fetal trunk to rotate anteriorly.

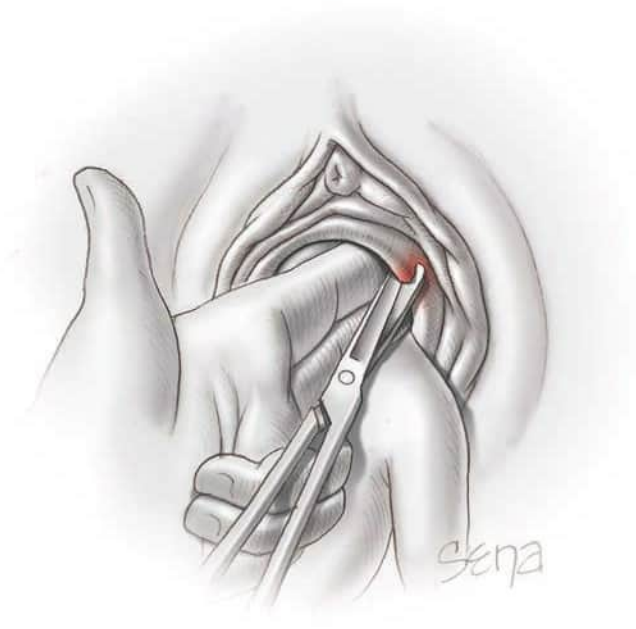

FIGURE 28-11 Dührssen incision being cut at 2 o'clock, which is followed by a second incision if needed at 10 o'clock. Infrequently, an additional incision is required at 6 o'clock. The incisions are so placed as to minimize bleeding from the laterally located cervical branches of the uterine artery. After delivery, the incisions are repaired as described in Chapter 42 (p. 740).

Head Entrapment

Either an incompletely dilated cervix or cephalopelvic disproportion can entrap the head. At this point, a true emergency exists because significant cord compression must be assumed.

First, an incompletely dilated cervix can constrict around the neck, especially with a small preterm fetus. With gentle traction on the fetal body, the cervix at times may be manually slipped over the occiput. If unsuccessful, Dührssen incisions may be needed (Fig. 28-11). General anesthesia with halogenated agents is another option to aid lower uterine segment relaxation. As an extreme measure, replacement of the fetus higher into the vagina and uterus, followed by cesarean delivery, can rescue an entrapped breech fetus. This *Zavanelli maneuver* is classically performed to relieve intractable shoulder dystocia (Sandberg, 1988). However, case reports have also described its use for an entrapped aftercoming head (Sandberg, 1999; Steyn, 1994).

Second, in cases with cephalopelvic disproportion and arrest of aftercoming head, the Zavanelli maneuver or symphysiotomy are options (Sunday-Adeoye, 2004; Wery, 2013). These are described in Chapter 27 (p. 504).

■ Total Breech Extraction

Frank Breech

During complete extraction of a frank breech, moderate traction is exerted by a finger in each groin and aided by a generous episiotomy. Once the breech is pulled through the introitus, the steps just described for partial breech extraction are completed.

Rarely during vaginal delivery, a frank breech will require decomposition inside the uterine cavity. Attributed to Pinard (1889), this procedure converts a frank breech into a footling breech. It is accomplished more readily if the membranes have ruptured only recently. It becomes extremely difficult if amniotic fluid is scant and the uterus is tightly contracted around the fetus. Pharmacological relaxation by general anesthesia or intravenous magnesium sulfate, nitroglycerin, or a betamimetic agent may be required. To begin, two fingers are carried up along one leg to externally rotate the hip by pressing on the medial side of the thigh parallel to the femur. Simultaneously, pressure in the popliteal fossa should prompt spontaneous knee flexion which brings the corresponding foot into contact with the back of the provider's hand. The fetal foot then may be grasped and brought down. Delivery is then accomplished as for incomplete breech, described next.

Incomplete or Complete Breech

If rapid labor progress prohibits cesarean delivery, total extraction of an incomplete or complete breech may be required. A hand is introduced through the vagina, and both fetal feet are grasped. The ankles are held with the middle finger lying between them. With gentle traction, the feet are brought through the introitus (Fig. 28-12). As the legs begin to emerge through the vulva, downward gentle traction is continued. As the legs emerge, successively higher portions are grasped. When the breech appears at the vaginal outlet, gentle traction is applied until the hips are delivered. The thumbs are then placed over the sacrum and the fingers over the iliac crests. Breech extraction is then completed, as described for partial breech extraction.

If only one foot can be grasped, it can be brought down into the vagina and held with the appropriate hand, right hand for right foot and left hand for left foot (Yeomans, 2017). With the first foot secure, the opposite hand is introduced, passed upward along the leg, and guided to locate the other foot. If the remaining hip is extended, the second foot is usually easily grasped and

FIGURE 28-12 Complete breech extraction begins with traction on the feet and ankles.

brought down. If the hip is flexed and knee extended, a finger is hooked into that groin, and traction will bring the lower half of the fetus down until the leg can be reached.

For cesarean delivery, these same total breech extraction maneuvers can be used. These steps can aid delivery of a frank, complete, or incomplete breech through the hysterotomy incision.

EXTERNAL CEPHALIC VERSION

With *version*, fetal presentation is altered by physically substituting one pole of a longitudinal presentation for the other, or converting an oblique or transverse lie into a longitudinal presentation. Manipulations performed through the abdominal wall that yield a cephalic presentation are termed *external cephalic version*. Manipulations accomplished inside the uterine cavity that yield a breech presentation are designated *internal podalic version*. This latter procedure is reserved for delivery of a second twin and described in Chapter 48 (p. 856).

Indications

External cephalic version (ECV) reduces the rate of noncephalic presentation at birth, and its success rate is 50 to 60 percent (Hofmeyr, 2015b; Melo, 2019). For women with a transverse lie, the overall success rate is significantly higher.

In general, ECV is attempted before labor in a woman who has reached $37^{0/7}$ weeks' gestation (American College of Obstetricians and Gynecologists, 2020; Impey, 2017a). This threshold aims to balance risks of fetal immaturity and the greater amnionic fluid volume seen in early-term pregnancies, which aids turning. In support of this, one systematic review found that ECV done before $37^{0/7}$ weeks raised ECV success rates but did not lower the ultimate cesarean delivery rate and increased the risk of late-preterm birth (Hutton, 2015). Before this time, breech presentation also still has a high likelihood of correcting spontaneously. And, if ECV is performed too early, time may allow a reversion back to breech (Bogner, 2012). Last, if attempts at version cause a need for immediate delivery, complications of iatrogenic early-term delivery generally are not severe.

Absolute contraindications to ECV are few. It is contraindicated if vaginal delivery is not an option, such as with placenta previa. Relative contraindications are early labor, oligohydramnios or ruptured membranes, known nuchal cord, structural uterine abnormalities, fetal-growth restriction, multifetal gestation, and prior abruption or its risk factors (Rosman, 2013). Little data guide the decision for ECV for women with a prior cesarean delivery. In one pooled series of small studies that contained more than 100 attempts, no uterine ruptures were reported (Impey, 2018). At Parkland Hospital, we do not attempt ECV in these women.

Several factors can improve the chances of an ECV attempt. These are multiparity, unengaged presenting part, nonanterior placenta, nonobese patient, and abundant amnionic fluid (Lauterbach, 2021; Kok, 2008, 2009). To augment the last parameter, neither a preprocedural 2-L intravenous fluid bolus nor amnioinfusion raised ECV success rates (Burgos, 2014; Diguisto, 2018). Dedicated breech teams may increase these rates (Hickland, 2018; Thissen, 2019).

Complications

Patient counseling includes a discussion regarding small but real risks for placental abruption, preterm labor, and fetal compromise. Bradycardia is common during or following ECV, but emergent cesarean rates are ≤0.5 percent. Uterine rupture, fetomaternal hemorrhage, alloimmunization, amnionic fluid embolism, and maternal or fetal deaths are rare (Grootscholten, 2008; Rodgers, 2017). Overall, compared with expectant management, perinatal morbidity and mortality rates are not greater with ECV (Krueger, 2018; Son, 2018).

Even after successful ECV, several reports suggest that the cesarean delivery rate does not completely revert to the baseline for vertex presentations. Specifically, dystocia, malpresentation, and nonreassuring fetal heart patterns may be more common in these fetuses who have undergone successful ECV (Chan, 2004; de Hundt, 2014; Vézina, 2004).

Technique

ECV should be carried out in an area that has ready access to a facility equipped to perform emergency cesarean delivery. Because of the risk for surgical intervention, intravenous access is obtained. Patients also abstain from eating for 6 hours, but clear liquids can be consumed up to 2 hours prior. Sonographic examination is performed to confirm nonvertex presentation, document amnionic fluid volume adequacy, exclude obvious fetal anomalies if not done previously, and identify placental location and fetal spine orientation. Preprocedural external monitoring is performed to document fetal heart rate reactivity. Anti-D immune globulin is given to Rh D–negative women. Tocolysis and regional analgesia may be elected, and rationale for these is provided in subsequent sections.

The woman is placed in left lateral tilt to aid uteroplacental perfusion, and Trendelenburg positioning helps during elevation of the breech. During the procedure, we prefer to monitor fetal heart motion sonographically. An abundant abdominal coating of ultrasound gel permits this and also minimizes painful skin friction (Vallikkannu, 2014).

A forward roll of the fetus usually is attempted first. One or two providers may participate, and one hand grasps the head. The fetal buttocks are then elevated from the maternal pelvis and displaced laterally (Fig. 28-13). These are then gently guided toward the fundus, while the head is simultaneously directed toward the pelvis. If the forward roll is unsuccessful, a backward flip is attempted. ECV attempts are discontinued for excessive discomfort, for persistently abnormal fetal heart rate, or after multiple failed attempts. Failure is not always absolute. Ben-Meir and colleagues (2007) reported a spontaneous version rate of 7 percent among 226 failed versions—2 percent among nulliparas and 13 percent among multiparas.

If ECV is successful, a nonstress test is repeated until a normal test result is obtained. A transient abnormal fetal heart rate tracing during or after ECV complicates 6 to 9 percent of cases. This should prompt a traditional resuscitative response with intravenous fluids, oxygen, and lateral tilt. Rates of abnormal tracings prompting immediate cesarean delivery range from only 0.2 to 0.4 percent (Collaris, 2004; Grootscholten, 2008).

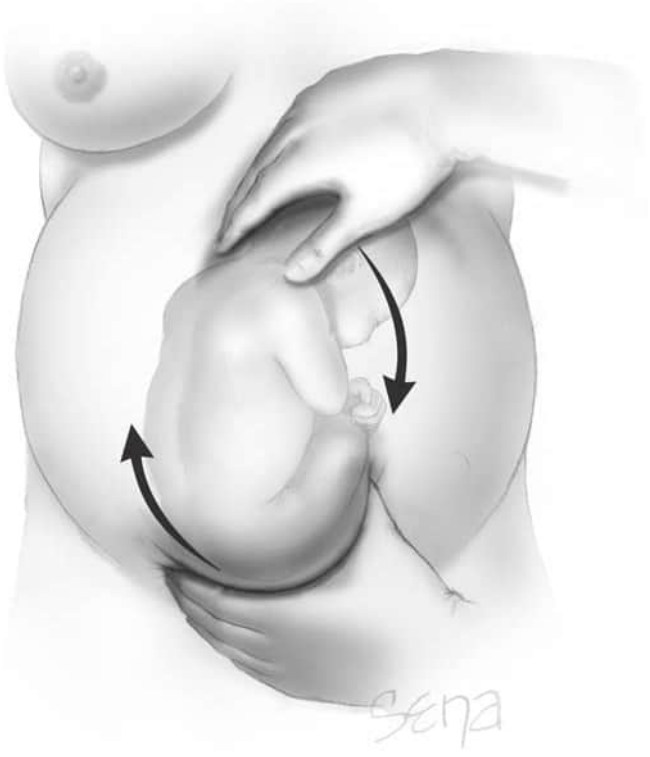

FIGURE 28-13 External cephalic version. With an attempted forward roll, clockwise pressure is exerted against the fetal poles.

Once resolved, Kuppens and coworkers (2017) found that a transient abnormal tracing did not predict later fetal distress in subsequent labor.

If ECV is completed before 39 weeks' gestation, awaiting spontaneous labor and fetal maturity is preferred. In some studies, immediate labor induction is linked to higher cesarean delivery rates (Burgos, 2015; Kuppens, 2013).

Tocolysis

By relaxing the uterus prior to an ECV attempt, tocolysis raises success rates. Most data support the use of the betamimetics terbutaline and ritodrine for this (Cluver, 2015). In one such trial, Fernandez and coworkers (1996) reported that the success rate with subcutaneous terbutaline—52 percent—was significantly higher than without—27 percent. Our policy at Parkland Hospital is to administer 250 μg of terbutaline subcutaneously to most women before attempted ECV. When maternal tachycardia—a known side effect of terbutaline—is noted, the attempt is begun. Terbutaline readily crosses the placenta, and mild elevation of fetal heart rate baseline also is possible (Ingemarsson, 1981; Roth, 1990). Data are limited and in some cases are nonsupportive for other agents that include calcium-channel blockers, such as nifedipine; nitric oxide donors, such as nitroglycerin; the oxytocin-receptor antagonist atosiban; and another betamimetic salbutamol (Burgos, 2010; Cluver, 2015; Hilton, 2009; Levin, 2019; Vani, 2009; Wilcox, 2011).

Conduction Analgesia

Epidural analgesia coupled with tocolysis has been reported to raise ECV success rates compared with tocolysis alone (Goetzinger, 2011; Magro-Malosso, 2016). Moreover, rates of complications that include fetal heart rate aberrations, emergency cesarean delivery, or placental abruption are not greater with regional analgesia. In trials, spinal and epidural have both shown success and are reasonable options (Khaw, 2015; Weiniger, 2010). Although uncommon, risks specific to regional analgesia, such as spinal headache, are possible. Currently, the superior technique and best drugs to administer are unclear. In contrast, from limited data, intravenous sedation or nitrous oxide does not appear to improve ECV success (Burgos, 2016; Dochez, 2019; Khaw, 2015; Straube, 2021).

■ Moxibustion

This is a traditional Chinese medicine technique that burns a cigarette-shaped stick of ground *Artemisia vulgaris*—which is also known as mugwort or in Japanese as *moxa.* At the BL 67 acupuncture point, the stick is directly placed against the skin or indirectly heats an acupuncture needle at the site to increase fetal movement and promote spontaneous breech version (Ewies, 2002). It is performed usually between 33 and 36 weeks' gestation to permit a trial of ECV if not successful. Results from randomized controlled studies are conflicting (Bue, 2016; Coulon, 2014; Coyle, 2012; Sananes, 2016; Vas, 2013).

CHAPTER 29

Operative Vaginal Delivery

Operative vaginal delivery (OVD) is birth accomplished with assistance from forceps or a vacuum-cup device. Once these are applied to the fetal head, outward traction generates forces that augment maternal pushing to deliver the fetus.

INCIDENCE AND INDICATIONS

From national data, forceps or vacuum-assisted vaginal delivery aided 3.1 percent of births in the United States in 2015. This is a decline from 9 percent in 1990 (Martin, 2017). For these procedures, a vacuum is disproportionately selected, and the vacuum-to-forceps delivery ratio approximates 4:1 (Yeomans, 2010). Most of these procedures are successful in effecting vaginal birth. From 2006 United States data, only 0.4 percent of forceps trials and 0.8 percent of vacuum extraction attempts failed to result in vaginal birth (Osterman, 2009). In the specific group of nulliparas with term gestations, higher failure rates of 4.4 and 6.4 percent, respectively, were found in a study of 25 academic hospitals (Bailit, 2016).

If technically safe, termination of second-stage labor by OVD is considered for any condition that threatens the mother or fetus and that is likely to be relieved by delivery. Of maternal indications, the most common are maternal exhaustion and prolonged second-stage labor. However, a specific, maximum second-stage length beyond which all women should be considered for OVD has not been defined (American College of Obstetricians and Gynecologists, 2019). Other maternal reasons are preexisting or intrapartum conditions that limit effective pushing or warrant expedited delivery. Severe or acute pulmonary compromise, decompensation from intrapartum infection, neurological disease, and serious cardiac disorders are examples. Frequent fetal indications include nonreassuring fetal heart rate and premature placental separation (Schuit, 2012).

CLASSIFICATION AND PREREQUISITES

Classification of OVD is summarized in Table 29-1. It emphasizes that station and rotation are the two most important discriminators of risk for both mother and neonate. Station is measured by the number of centimeters, either above or below, an anatomical zero station, which is a line drawn between the ischial spines. Stations range from −5 to 0 to +5. Procedures are categorized as outlet, low, and midpelvic, and most are low or outlet deliveries. *High forceps, in which instruments are applied above 0 station, have no place in current obstetrics*.

To aid patient selection, the Society for Maternal–Fetal Medicine (2020) published a preprocedural checklist and documentation template. Once station and rotation are determined, the prerequisites listed in Table 29-1 are assessed. For vacuum extraction, fetuses ideally are not younger than 34 weeks' gestation because of cranial hemorrhage vulnerability at earlier ages (Åberg, 2014). Also prior to vacuum use, although infrequently used in the United States, fetal scalp blood sampling should not have been recently performed. Of requisites, ascertaining

TABLE 29-1. Operative Vaginal Delivery Prerequisites and Classification According to Station and Rotation[a]

Procedure	Criteria
Outlet forceps	Scalp is visible at the introitus without separating the labia Fetal skull has reached pelvic floor Fetal head is at or on perineum Head is OA or OP ***or*** Head is right or left OA or OP position but rotation ≤45 degrees
Low forceps (2 types)	Fetal station is ≥+2 cm but not on the pelvic floor, and: (a) Rotation ≤45 degrees is required ***or*** (b) Rotation >45 degrees is required
Midforceps	Fetal station is between 0 and +2 cm

Prerequisites		
Engaged head	Experienced operator	No fetal coagulopathy
Vertex presentation[b,c]	Ruptured membranes	No fetal demineralization disorder
Known fetal head position	Completely dilated cervix	Informed consent completed
CPD not suspected	Adequate anesthesia	Willingness to abandon OVD
Fetal weight estimated	Emptied maternal bladder	

[a]Classification for the vacuum delivery is the same as for forceps except that vacuum is used for traction but not rotation.
[b]Forceps, but not vacuum extractor, may be used for delivery of a mentum anterior face presentation.
[c]Piper forceps may be used to deliver the head during breech delivery.
CPD = cephalopelvic disproportion; OA = occiput anterior; OP = occiput posterior; OVD = operative vaginal delivery.

correct head position is essential, and Figure 29-1 shows fetal skull anatomy. In unclear cases, sonography can help identify fetal orbits and nasal bridge to aid orientation (Ghi, 2018).

Regional analgesia is preferable for low or midpelvic procedures. Pudendal blockade may prove adequate for outlet deliveries. As a causative factor, newer epidural methods or placement during early labor do not raise OVD rates (Anim-Somuahm, 2018; Liu, 2004).

The bladder is emptied to provide additional pelvic space and minimize bladder trauma. Urinary retention and bladder dysfunction are frequent short-term effects of OVD (Mulder, 2012; Pifarotti, 2014). Notably, episiotomy and epidural analgesia, both common associates of OVD, also are risks for urinary retention. Retention usually resolves after 24 to 48 hours of passive catheter bladder drainage (Chap. 36, p. 643).

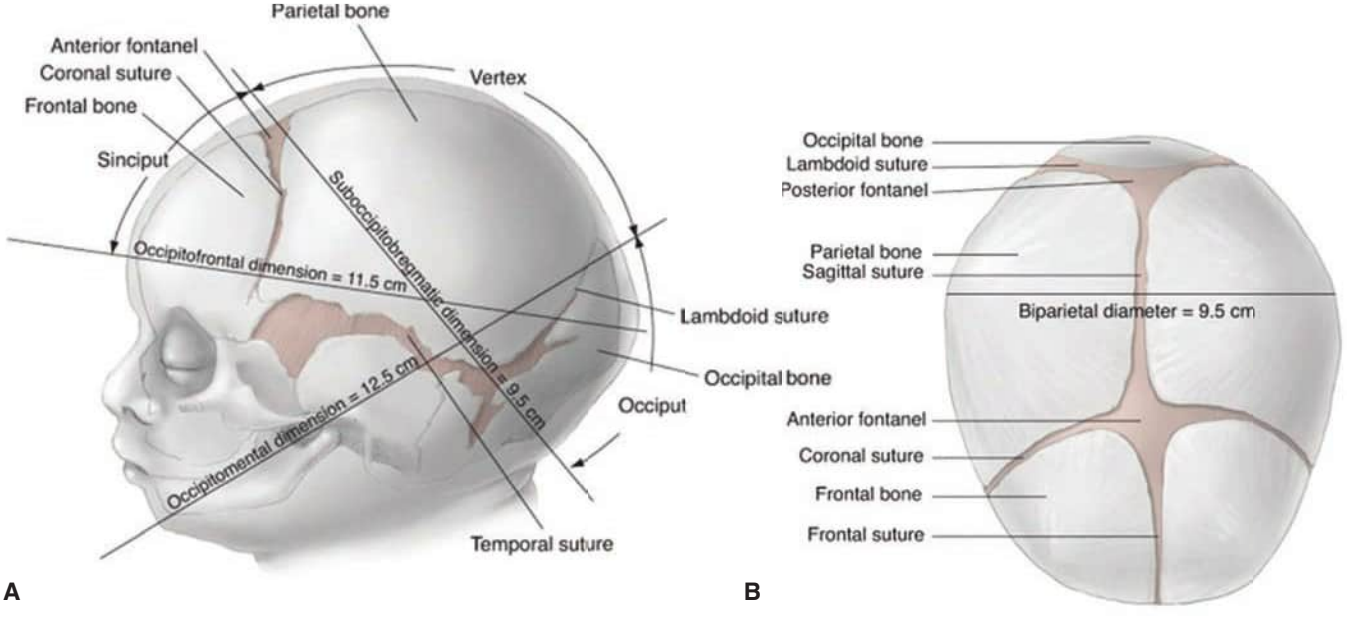

FIGURE 29-1 Fetal head **(A–B)** at term showing fontanels, sutures, and various dimensions.

MORBIDITY

Maternal Morbidity

OVD carries increased risk of certain morbidities for both mother and fetus. In general, a higher station and greater degrees of rotation raise procedure difficulty and the chance of injury. Morbidity is most properly compared with morbidity from cesarean delivery and not with that from spontaneous birth. This is the most appropriate comparator because the alternative to indicated OVD is cesarean delivery.

Lacerations

The very indications that prompt OVD are among those that also increase the need for episiotomy and the likelihood of lacerations (de Leeuw, 2008). That said, higher rates of third- and fourth-degree perineal lacerations, vaginal wall lacerations, and less often cervical tears do complicate OVD compared with spontaneous birth (Friedman, 2015; Gurol-Urganci, 2013; Landy, 2011). These rates with OVD are also substantially higher than with cesarean delivery. Third- and fourth-degree perineal lacerations are grouped as *obstetrical anal sphincter injuries (OASIS)*. In general, these tears more frequently attend forceps delivery compared with vacuum extraction, and especially if an episiotomy is midline (Kudish, 2006; O'Mahony, 2010).

With OVD, *indicated* episiotomy rather than *routine* use is recommended. If required, a mediolateral episiotomy affords greater protection against OASIS than midline incision (Gurol-Urganci, 2013; Jangö, 2014; van Bavel, 2018). But, short-term rates of pain and dyspareunia are similar or increased with mediolateral episiotomy (Chap. 27, p. 510). As another OASIS protection, early forceps disarticulation and removal can avoid the full perineal distention created by the blades and crowning head. Moreover, cessation of maternal pushing during disarticulation or as the head begins to crown allows the clinician sole control of outward forces against the perineum. Similarly, adding a dedicated assistant to bolster the perineum can lower OASIS rates, and this is our practice (Wan, 2020). Last, OASIS are more common with an occiput posterior (OP) position (Damron, 2004). Thus, manual or forceps rotation to an occiput anterior (OA) position may lower rates of lower reproductive tract injury (Bradley, 2013).

Infection and Subsequent-pregnancy Morbidity

As detailed in Chapter 30 (p. 548), cesarean delivery carries greater maternal morbidity compared with spontaneous birth. For OVD, in one study of more than 1 million births, cesarean delivery, but not OVD, was a risk for peripartum hysterectomy (Spiliopoulos, 2011). Further, avoiding cesarean delivery can minimize rates of subsequent pregnancy complications, such as placenta previa, placenta accreta spectrum, uterine rupture, and adhesion-related surgical organ injury.

In addition, postpartum wound or uterine infection is more frequent in women following cesarean compared with OVD (Bailit, 2016; Halscott, 2015). Still, to address peripartum infection, investigators in the ANODE trial randomly assigned nearly 3500 gravidas undergoing OVD to receive either placebo or a single intravenous dose of amoxicillin plus clavulanic acid (Knight, 2019). The puerperal infection rate was 11 percent after antibiotic prophylaxis compared with 19 percent in those given placebo. Notably, these infections often coincide with long labors and multiple cervical examinations, both of which are common with women requiring OVD. Thus, we believe that provision of antibiotics to those undergoing OVD without other infection-related risks warrants further study. Indeed, the American College of Obstetricians and Gynecologists (2020a) notes that this prophylaxis is *reasonable* but recommends against routine antibiotic prophylaxis for all women undergoing OVD. However, the College (2020b) does note that a single antibiotic dose with third- and fourth-degree perineal laceration is reasonable. Several studies support this practice (Duggal, 2008; Lewicky-Gaupp, 2015; Stock, 2013a).

Pelvic Floor Disorders

This term encompasses urinary incontinence, anal incontinence, and pelvic organ prolapse (POP). OVD has been implicated as a possible risk for each. Proposed mechanisms include structural compromise or pelvic floor denervation secondary to forces exerted during delivery.

For urinary incontinence, parity and specifically vaginal delivery are risk factors (Gyhagen, 2013; Rortveit, 2003). But, many studies do not support a higher risk from OVD compared with the risk from vaginal birth alone (Gartland, 2016; Leijonhufvud, 2011; MacArthur, 2016).

Evidence linking anal incontinence with OVD is conflicting. Some studies show that OASIS, but not delivery mode, is the main etiological link (Bols, 2010; Evers, 2012; Nygaard, 1997). In contrast, others directly associate OVD with anal incontinence (Dolan, 2010; MacArthur, 2013). But, these studies may not be incongruous—recall that OVD is associated with increased rates of OASIS. Importantly, several studies and reviews have not found cesarean delivery to be protective long term against anal incontinence (Nelson, 2010).

Similarly for POP, evidence linking it to OVD is mixed (Gyhagen, 2013; Volløyhaug, 2015). First, pelvic floor mechanisms leading to POP are complex and incompletely defined (Gordon, 2019). Despite this, obstetrical avulsion of the levator ani muscle from the pelvic sidewall has been implicated, and OVD, especially forceps delivery, is one risk for this injury (DeLancey, 2007; Dietz, 2008; Friedman, 2019). Again, the pelvic floor injury rather OVD itself may be the causative agent, as those with OVD but no avulsion did not suffer greater POP rates in one recent analysis (Handa, 2019).

Perinatal Morbidity

Acute Perinatal Injury

OVD carries higher risk for fetal injury than cesarean delivery or spontaneous birth. Both OVD methods are implicated, and factors can include delivery duration and the number of pulls or cup pop-offs (Åberg, 2019; Levin, 2019; Miller, 2020). Injuries are more frequent with vacuum extraction, and injuries with this device include cephalohematoma, subgaleal hemorrhage, retinal hemorrhage, neonatal jaundice secondary to these hemorrhages, clavicular fracture, and scalp lacerations. Cephalohematoma and subgaleal hemorrhage are both extracranial

lesions illustrated in Figure 33-2 (p. 608). Shoulder dystocia has been linked to both methods (Dall'Asta, 2016). Forceps delivery has higher rates of facial nerve injury, brachial plexus injury, depressed skull fracture, and corneal abrasion (American College of Obstetricians and Gynecologists, 2020a; Demissie, 2004; Dupuis, 2005). With intracranial hemorrhage, some studies have associated vacuum extraction with higher rates, whereas others show similar rates with either OVD method (Towner, 1999; Wen, 2001; Werner, 2011).

Compared with cesarean delivery, OVD carries higher risk of extracranial hematomas, fractures, nerve injuries, retinal hemorrhage, and head lacerations. However, rates of fetal acidemia or hypoxic encephalopathy are not higher with OVD compared with second-stage cesarean delivery (Bailit, 2016; Contag, 2010; Walsh, 2013). Intracranial hemorrhage rates are similar among newborns delivered by vacuum extraction, forceps, or cesarean delivery during labor (Towner, 1999). But, intracranial hemorrhage rates are higher than among those delivered spontaneously or by cesarean delivery before labor. These authors suggest that the common risk factor for intracranial hemorrhage is abnormal labor. Werner and associates (2011), in their evaluation of more than 150,000 singleton deliveries, reported that forceps delivery was associated with fewer total neurological complications that included seizures, intraventricular hemorrhage, and subdural hemorrhage compared with vacuum-assisted birth or any cesarean delivery.

Compared with rotational OVD, second-stage cesarean delivery has similar maternal and neonatal morbidity rates (Aiken, 2015; Bahl, 2013; Stock, 2013b). For example, in their large series, Tempest and associates (2013) found similar morbidity rates among malpositioned fetuses during second-stage labor that underwent Kielland rotation, rotational vacuum extraction, or emergency cesarean delivery.

Midforceps by definition are performed from a higher station. The bulk of data are from older studies, and most show comparable neonatal morbidity between low and midforceps procedures (Dierker, 1985; Gilstrap, 1984). In a recent report also comparing these two, Ducarme and coworkers (2015) found comparable neonatal and maternal composite morbidity scores.

Comparing midpelvic OVD and second-stage cesarean delivery, most studies support neonatal safety (Bashore, 1990; Cibils, 1990; Hagadorn-Freathy, 1991). But, others have found increased rates of trauma and umbilical cord blood acidemia with midforceps delivery (Robertson, 1990). More recently, Muraca and associates (2018) compared midpelvic OVD methods against second-stage cesarean delivery. For the indication of dystocia, fetal and maternal morbidity composite scores were higher with OVD. With distress as the indication, the neonatal morbidity score was greater only with midpelvic vacuum-assisted OVD, whereas the maternal morbidity score was higher only with midforceps. In another study comparing both midpelvic OVD methods, maternal morbidity was greater with forceps, and neonatal morbidity differed only in a higher cephalohematoma rate with vacuum-assisted delivery (Baerthlein, 1986).

Mechanisms of Acute Injury

The types of fetal injury with OVD can usually be explained by the forces exerted. In cases of cephalohematoma or subgaleal hemorrhage, suction and perhaps rotation during vacuum extraction may lead to a primary vessel shearing. Intracranial hemorrhage may result from skull fracture that lacerates vessels or from vessel rupture alone due to exerted forces. With facial nerve palsy, one of the forceps blades compresses the nerve against the facial bones. To explain brachial plexus injury, Towner and Ciotti (2007) proposed that as the fetal head descends down the birth canal, the shoulders may stay above the pelvic inlet. Thus, similar to shoulder dystocia at the symphysis, this "shoulder dystocia at the pelvic inlet" is overcome by traction forces but with concomitant stretch on the brachial plexus.

Long-term Infant Morbidity

Evidence regarding long-term neurodevelopmental outcomes in children born by OVD is reassuring (Seidman, 1991; Wesley, 1992). Moreover, no association between forceps delivery and later epilepsy was found in a cohort study of more than 21,000 births (Murphy, 2004). In their review, O'Callaghan and colleagues (2011) reported no link between cerebral palsy and OVD. Last, the incidence of neurodevelopmental morbidity was similar in those undergoing successful forceps delivery, failed forceps with cesarean delivery, or cesarean delivery without forceps in one study (Bahl, 2007). Similarly, with midpelvic OVD, long-term neurodevelopment is not harmed in most analyses (Dierker, 1986; Friedman, 1984; Nilsen, 1984; Wesley, 1993).

Trial of Operative Vaginal Delivery

If an attempt to perform OVD is expected to be difficult, it should be considered a trial. Moving the woman to an operating room for this attempt, which could be followed by immediate cesarean delivery if OVD fails, has merit. If forceps cannot be satisfactorily applied, the procedure is stopped. Either a trial of vacuum-assisted delivery or cesarean delivery is then performed. With the former, if the fetus does not descend with traction, the trial should be abandoned and cesarean delivery performed.

With such caveats, cesarean delivery after an OVD attempt was not associated with adverse neonatal outcomes if the fetal heart rate was concurrently reassuring (Alexander, 2009). A similar study evaluated 122 women who had a trial of midpelvic OVD in a setting with full preparations for cesarean delivery (Lowe, 1987). Investigators found no significant difference in immediate neonatal or maternal morbidity compared with that of 42 women delivered for similar indications by cesarean but without such a trial. Conversely, in 61 women who had "unexpected" vacuum or forceps failure in which there was no prior preparation for immediate cesarean delivery, neonatal morbidity was higher.

Some factors associated with OVD failure are persistent OP positions and birthweight >4000 g (Ben-Haroush, 2007; Verhoeven, 2016). However, Palatnik and coworkers (2016) found that risk factors poorly predicted success. In general, to avert morbidity with failed OVD, the American College of Obstetricians and Gynecologists (2020a) cautions that these trials should be attempted only if the clinical assessment suggests a successful outcome. We also emphasize proper training.

Sequential instrumentation most often involves an attempt at vacuum-assisted OVD followed by one with forceps. This sequence likely reflects the overall higher completion rate with forceps. However, this practice significantly raises fetal trauma risks (Dupuis, 2005; Gardella, 2001; Murphy, 2011). The American College of Obstetricians and Gynecologists (2020a) recommends against the sequential use of instruments unless there is a "compelling and justifiable reason."

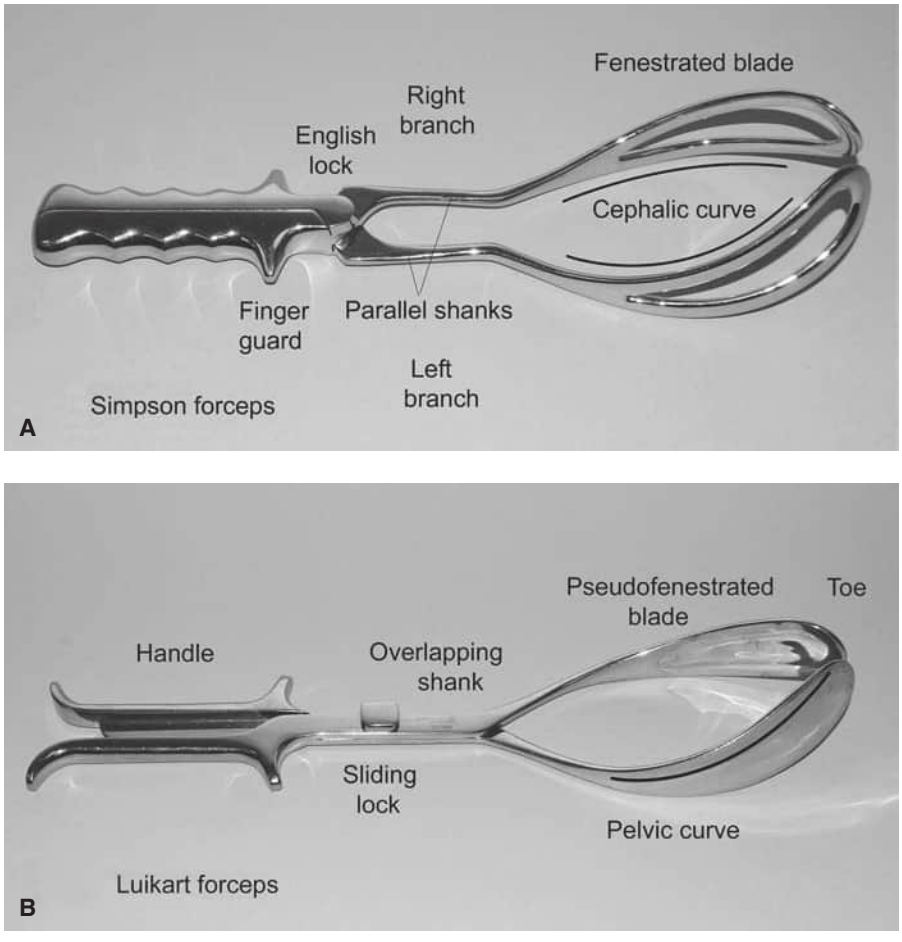

FIGURE 29-2 A. Simpson forceps have fenestrated blades, parallel shanks, and English lock. The cephalic curve accommodates the fetal head. **B.** Luikart forceps have pseudofenestrated blades, overlapping shanks, a sliding lock, and tongue-in-groove handles. The pelvic curve (*black curve*) is marked in this example.

FORCEPS DELIVERY

Design

Forceps refers to the paired instrument, and each member of this pair is called a branch. Branches are designated left or right according to the side of the maternal pelvis to which they are applied (Fig. 29-2A). Each branch has four components: blade, shank, lock, and handle (see Fig. 29-2B). Each blade has a toe, a heel, and two curves. Of these, the outward cephalic curve conforms to the round fetal head, whereas the upward pelvic curve corresponds to the curve of the birth canal. Some blades are *solid*, meaning smooth on both surfaces. Others have an opening within or a depression along the blade surface and are termed *fenestrated* or *pseudofenestrated*, respectively. A true window in the blade reduces the degree of head slippage within the blades during forceps rotation. Disadvantageously, it can increase blade thickness and friction against the vaginal wall. With pseudofenestration, the forceps blade is smooth on the outer maternal side but indented on the inner fetal surface. The goal is to reduce head slipping yet improve the ease and safety of application and removal of forceps. In most situations, however, despite these subtle differences, any are appropriate.

The blades are connected to shanks, which may be parallel or overlapping. *Parallel shanks* limit compression of blades against the fetal head and may be helpful with deliveries employing greater forces. These shanks, however, add width against the introitus. In comparison, overlapping shanks raise compression forces but distend the perineum less. This may offer greatest advantage for outlet deliveries.

Locks are found on all forceps and help to connect the right and left branches and stabilize the instrument. They can be located at the end of the shank nearest to the handles (English lock), at the ends of the handles (pivot lock), or along the shank (sliding lock). Although varied in design, handles, when squeezed, raise compression forces against the fetal head. Thus, forces to consider include traction and compression.

Blade Application and Delivery

Forceps blades grasp the head and are applied according to fetal head position. If the head is in an OA position, two or more fingers of the right hand are introduced inside the left posterior portion of the vulva and advanced into the vagina beside the fetal head. The handle of the left branch is grasped between the thumb and two fingers of the left hand (Fig. 29-3). The blade tip is then gently introduced along the posterior left vaginal wall. It is swept upward and inward between the fetal head and the palmar surface of the fingers (Fig. 29-4). This blade can be held in position by an assistant. For application of the right blade, two or more fingers of the left hand are introduced into the right posterior portion of the vagina to serve as a guide for the right blade. This blade is held in the right hand and introduced into the vagina. With each blade, the thumb is positioned behind the heel, and most of the insertion force comes from this thumb (Fig. 29-5). If the head is positioned in a left OA (LOA) or right OA (ROA) position, then the lower of the two blades is typically placed first.

The blades are constructed so that their cephalic curve is closely adapted to the sides of the fetal head (Fig. 29-6). The fetal head is perfectly grasped only when the long axis of the blades corresponds to the occipitomental diameter (see Fig. 29-1). As a result, most of the blade lies over the lateral face.

FIGURE 29-3 For OA or LOA positions, the left handle of the forceps is held in the left hand. The blade is introduced into the left side of the pelvis between the fetal head and the fingers of the operator's right hand.

Suboptimal blade placement can increase morbidity (Ramphul, 2015). For OA positions, appropriately applied blades are equidistant from the sagittal suture, and each blade is equidistant from its adjacent lambdoid suture. In OP positions, blades are symmetrically placed relative to the sagittal suture and to each coronal suture. After correct positioning, the branches can be articulated. If branches do not articulate, the blade's relationships to the sutures are reassessed. Applied in this way, forceps should not slip, and traction may be applied most advantageously. With most forceps, if one blade is applied over the brow and the other

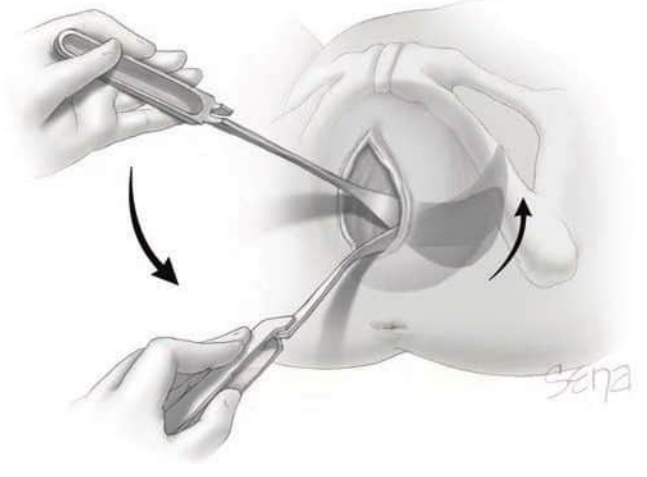

FIGURE 29-4 Insertion arc of the blade. Importantly, the thumb of the right hand, not shown here, guides the blade during placement.

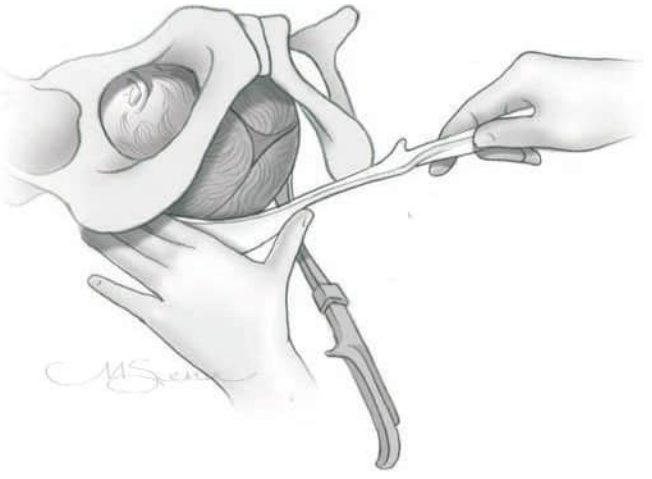

FIGURE 29-5 In applying the second blade, insertional force is generated mainly by the thumb. (Reproduced with permission from Yeomans ER: Operative vaginal delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

over the occiput, the instrument cannot be locked, or if locked, the blades will slip off when traction is applied.

With both branches in place, slow articulation of the handles will also typically correct mild asynclitism. For greater asynclitism, Luikart forceps can be placed and once positioned, one handle will extend further than the other along their long axis. Asynclitism is resolved by pulling and/or pushing each respective branch within the sliding lock along the instrument's long axis until the finger guards align.

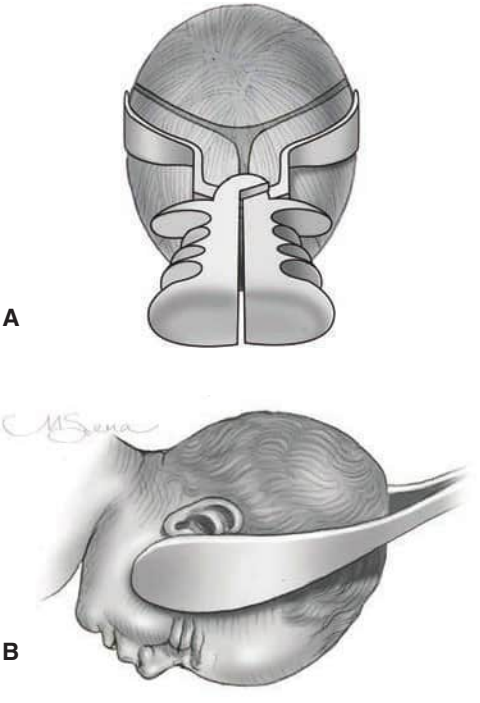

FIGURE 29-6 A. The forceps are symmetrically placed and articulated. **B.** The vertex is OA. (Reproduced with permission from Yeomans ER: Operative vaginal delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

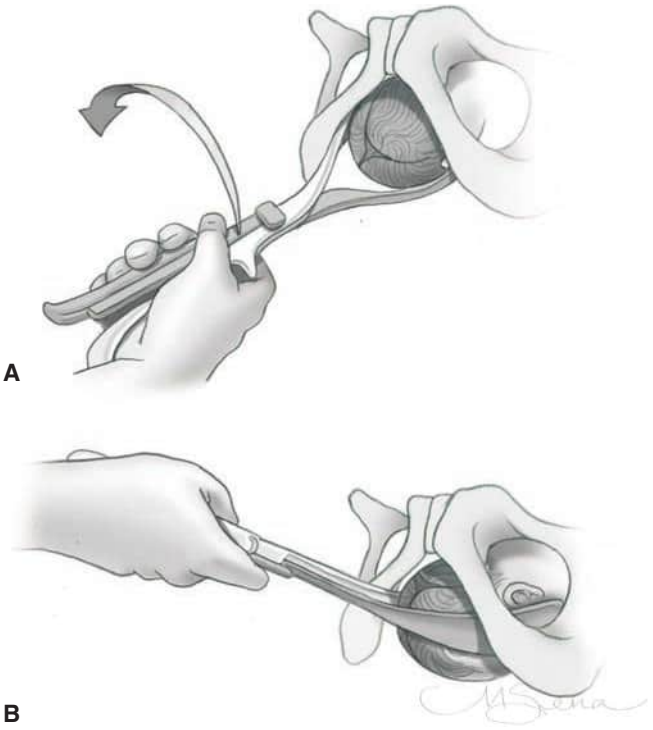

FIGURE 29-7 If LOA, the vertex is rotated from this position to OA (*arrow*). (Reproduced with permission from Yeomans ER: Operative vaginal delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

Once blades are placed satisfactorily, rotation to OA position is performed before traction is applied (Fig. 29-7). Next, gentle, intermittent, downward and outward traction is exerted concurrent with maternal efforts until the perineum begins to bulge. For most stations, the initial direction of traction is downward and brings the head beneath the symphysis.

With head descent, the vector of forces changes continuously and are gradually directed upward (Fig. 29-8). During the birth of the head, mechanisms of spontaneous delivery should be simulated as closely as possible. As a teaching tool for this, a *Bill axis traction device* can be attached over the finger guards of most forceps. The instrument has an arrow and indicator line. When the arrow points directly to the line, traction is along the path of least resistance.

It is impossible to ascertain the amount of force exerted by forceps for an individual patient. Thus, traction is ideally intermittent and relieved between contractions, as in spontaneous labor. Except when urgently indicated, delivery should be sufficiently slow, deliberate, and gentle to prevent undue head compression. It is preferable to apply traction only with each uterine contraction. Maternal pushing will augment these efforts.

With traction, as the occiput distends the vulva, an episiotomy may be performed if needed. The delivery may be completed in several ways. Some clinicians keep the forceps in place to control the head. However, this blade volume adds to vulvar distention and raises risks for laceration or episiotomy. To prevent this, the forceps may be removed, and delivery is then completed by maternal pushing (Fig. 29-9). Importantly, if blades are disarticulated and removed too early, the head

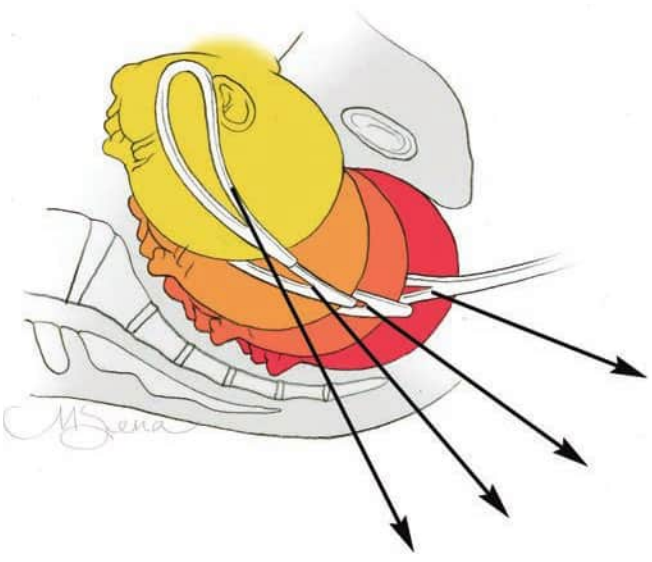

FIGURE 29-8 With low forceps, the direction of gentle traction for delivery of the head is indicated (*arrows*). (Reproduced with permission from Yeomans ER: Operative vaginal delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

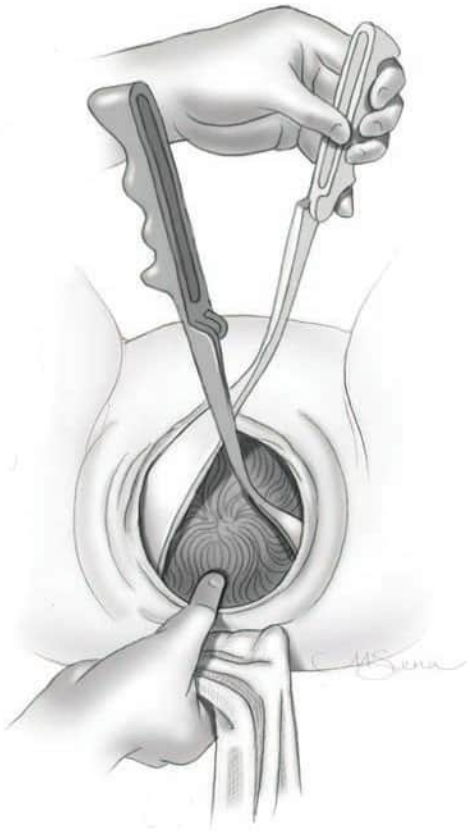

FIGURE 29-9 Branches are removed in the opposite order from that in which they were originally placed. The fingers of the right hand, covered by a sterile towel, bolster the perineum. The thumb is placed directly on the head to prevent sudden egress. (Reproduced with permission from Yeomans ER: Operative vaginal delivery. may recede and prolong delivery. Pushing in some cases may be aided by the modified Ritgen maneuver. We emphasize bolstering of the perineum to control outward forces.

Manual Rotation

In many cases, OT and OP head positions are often imperfectly flexed and present a wider head diameter. This can slow fetal descent and lengthen second-stage labor. By manually rotating the fetal occiput into the anterior pelvis (OA positions), cephalopelvic proportions improve to help hasten spontaneous birth. This is usually reserved for second-stage labor. Compared with no attempt, manual rotation is associated with lower rates of cesarean delivery, OVD, severe perineal laceration, and chorioamnionitis (Blanc, 2021; Shaffer, 2011). If OVD is still required, the new OA position lowers rates of perineal trauma.

In the simplest cases, *digital rotation* can correct OT or OP positioning. With head molding, the sutures override one another to create a bony ridge. Two fingers hooked against this ridge and forces directed parallel to the skull can rotate the occiput toward the anterior pelvis. This is done between contractions, and advancements are then held in place during pushing. Progressive degrees of rotation are attained with each attempt, and several may be needed to ultimately rotate the occiput into the anterior pelvis.

Instead, with *manual rotation*, an open hand is inserted into the vagina. For ROP position, the right palm cups the fetal head and straddles the sagittal suture. The operator's fingers wrap to one side of the fetal face, and the thumb extends along the other side. Rotation is clockwise to bring the occiput to an ROA position (Fig. 29-10). With LOP position, rotation is counterclockwise with the left palm. Three actions are performed simultaneously between contractions. The fetal head is flexed to provide a smaller diameter for rotation and subsequent descent within the pelvis. Next, slight *destationing* of the fetal head moves the head to a level in the maternal pelvis with sufficient room to complete the rotation. Importantly, destationing should not be confused with *disengaging* the fetal head, which is proscribed. Third, we and others prefer also to place the other hand externally on the corresponding side of the maternal abdomen to pull the back of the fetus up and toward the midline in synchrony with internal head rotation. Barth (2015) provides an excellent summary of this technique.

Le Ray and associates (2007, 2013) reported a success rate >90 percent with manual rotation. Complication were uncommon. In their report of 796 rotations, no cords prolapsed. Two women sustained cervical lacerations, which required simple vaginal repair. Notably, this study allowed rotations at advanced cervical dilation prior to second-stage labor, which may have enhanced cervical injury risk. In 71 percent, fetal heart rate (FHR) was normal during rotation, but severe FHR abnormalities were noted in 10 percent. However, the need for cesarean delivery after successful manual rotation was not associated with FHR abnormalities. Failure to rotate the head does not mandate cesarean delivery, and options are described next.

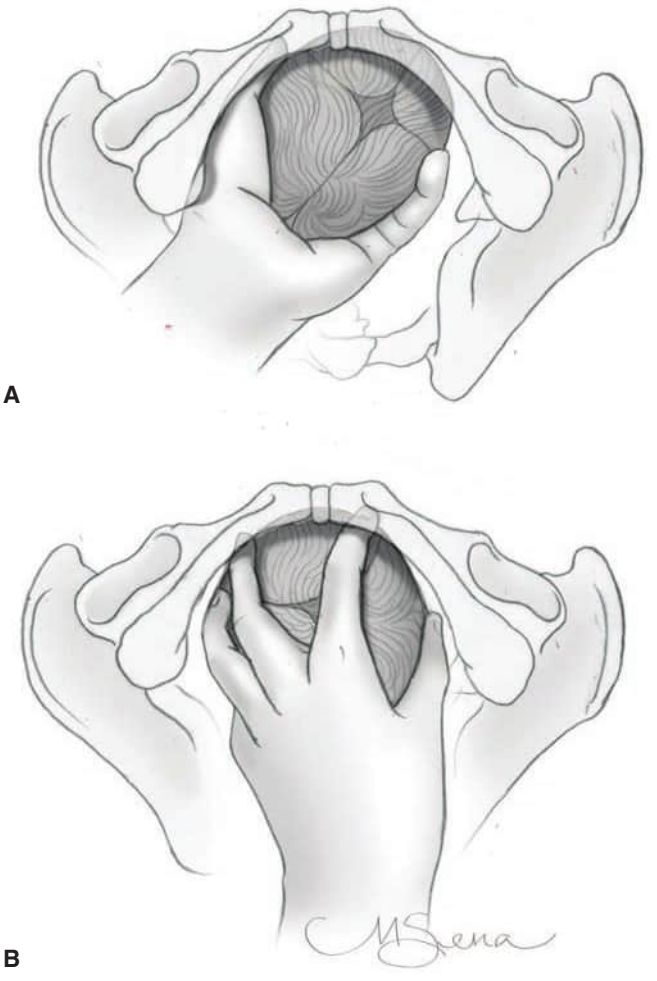

FIGURE 29-10 A. Manual rotation using the left hand, palm-up, to rotate from ROP. **B.** The head is flexed and destationed during clockwise rotation to reach an OA position. (Reproduced with permission from Yeomans ER: Operative vaginal delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

Persistent Occiput Posterior Positions

In cases with persistent OP positioning, the head may spontaneously deliver OP, may be manually or instrumentally rotated to an OA position, or may be delivered OP by forceps or vacuum (Bertholdt, 2019). In many cases, the cause of a persistent OP position and of the difficulty in accomplishing rotation is an anthropoid pelvis. This architecture opposes rotation and predisposes to posterior delivery (Fig. 2-16, p. 29).

With forceps delivery from an OP position, downward and outward traction is applied until the base of the nose passes under the symphysis (Fig. 29-11). The handles are then slowly elevated until the occiput gradually emerges over the perineum's fourchette. The forceps are directed downward again, and the nose, mouth, and chin successively emerge from the vulva.

OP delivery causes greater vulvar distention, and an episiotomy may be needed. OP deliveries have a higher incidence

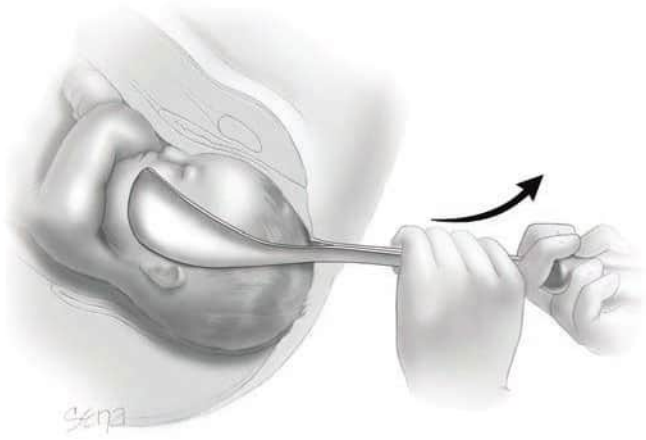

FIGURE 29-11 Outlet forceps delivery from an OP position. The head should be flexed after the bregma passes under the symphysis.

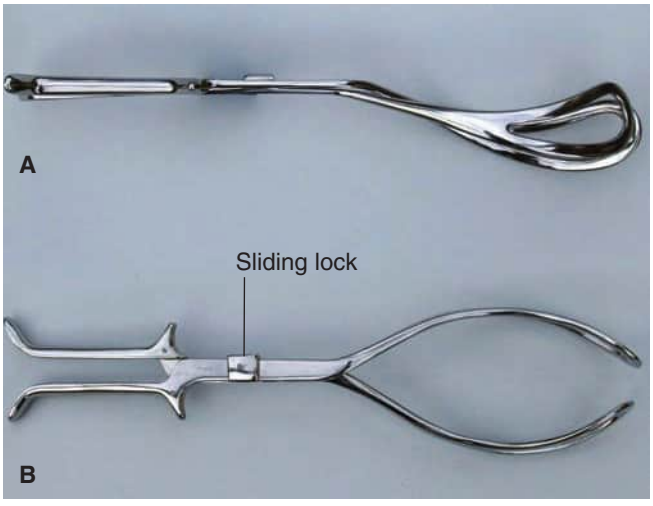

FIGURE 29-12 Kielland forceps. The characteristic features are minimal pelvic curvature **(A)**, sliding lock **(B)**, and light weight.

of severe perineal lacerations and of extensive episiotomy compared with OA positions (de Leeuw, 2008; Pearl, 1993). Also, newborns undergoing OVD from OP positions have a higher incidence of Erb and facial nerve palsies, 1 and 2 percent, respectively, than those delivered from OA positions. As expected, rotations to OA ultimately decrease perineal delivery trauma (Bradley, 2013).

For forceps rotations from an OP to OA position, Kielland forceps are preferred because they have a less pronounced pelvic curve (Fig. 29-12). *Cunningham and Gilstrap's Operative Obstetrics*, 3rd edition offers a more detailed description and illustration of this Kielland forceps procedure (Yeomans, 2017).

■ Occiput Transverse Positions

With occiput transverse (OT) fetal head positions, rotation is required for delivery. For this, the head may be manually or instrumentally rotated into an OA position. Manual rotation was described earlier in that section (p. 540).

Forceps rotation by experienced operators can offer high success rates with minimal maternal morbidity (Burke, 2012; Stock, 2013b). Either standard forceps or specialized forceps, such as Kielland forceps, are used. With the latter, each handle has a small knob, and branches are placed so that this knob faces the occiput.

Kielland described two methods of applying the anterior blade. In this example, placement with a left OT (LOT) position is described. With the wandering method, the anterior blade is first introduced into the posterior pelvis (Fig. 29-13). The blade is then arched around the face to an anterior position. To permit this sweep of the blade, the handle is held close to the left maternal buttock throughout the maneuver. The second blade is introduced posteriorly, and the branches are locked.

After checking the application, the provider pulls the handles of the Kielland forceps slightly to the patient's right to flex the fetal head and create a smaller diameter for rotation. The first and second fingers of the left hand are placed over the finger guards with the palm against the handles. This palm faces the maternal left. Concurrently, the first two fingers of the operator's right hand are placed against the anterior lambdoid suture. The fetal head is then elevated and slightly destationed. For rotation in a counterclockwise direction, the wrist of the left

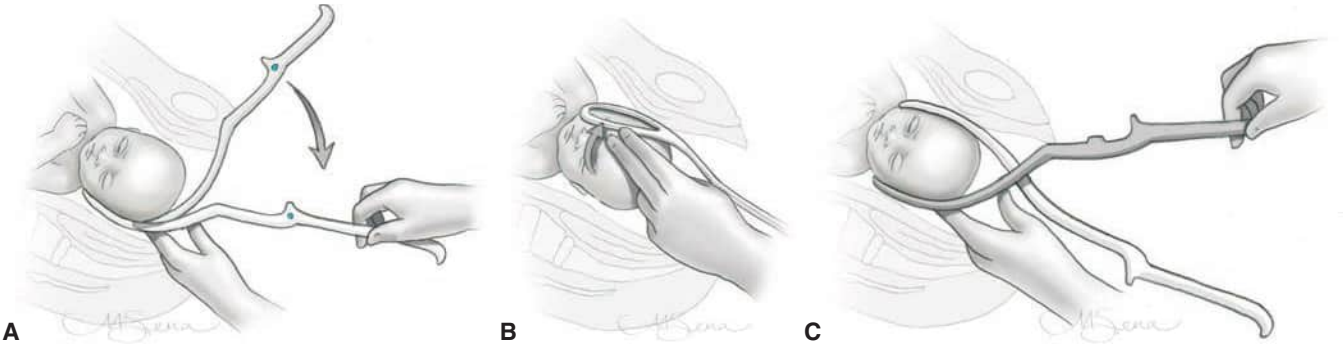

FIGURE 29-13 **A.** Application of the right branch of the Kielland forceps to a head in LOT position. The knob on this branch (*colored blue*) will ultimately face the occiput. **B.** The right branch is wandered to its final position behind the symphysis. **C.** Insertion of the left branch of the Kielland forceps directly posterior along the hollow of the sacrum. This branch is inserted to the maternal right of the anterior branch to aid in engaging the sliding lock. (Reproduced with permission from Yeomans ER: Operative vaginal delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

hand supinates, to direct this palm upward. Simultaneously, two fingers of the right hand press against the lambdoid suture ridge. This ensures that the fetal head turns with the blades and does not slip. As a newer adjunct, abdominal sonography can follow and document head rotation (Hinkson, 2021).

The second type of blade application introduces the anterior blade with its cephalic curve directed upward to curve under the symphysis. After it has been advanced far enough toward the upper vagina, it is turned on its long axis through 180 degrees to adapt the cephalic curvature to the head. The second blade is introduced posteriorly, and the branches are locked.

After rotation of the fetal occiput into the anterior pelvis, two acceptable methods for delivery are available. In one, the operator applies traction on the Kielland forceps using a bimanual grip described previously for conventional forceps (p. 539). When the posterior fontanel has passed under the subpubic arch, the handles can be elevated to the horizontal, but no further. Raising the handles above the horizontal may cause vaginal sulcus tears because of the reverse pelvic curve (Dennen, 1955). Alternatively, the Kielland forceps can be removed after rotation and replaced with conventional forceps. With this approach, moderate traction is first employed to seat the head before switching instruments.

Face Presentations

With a mentum anterior face presentation, OVD is an option. The blades are applied to the sides of the head along the occipitomental diameter, with the pelvic curve directed toward the neck (see Fig. 29-1). Downward traction is exerted until the chin appears under the symphysis. Then, by an upward movement, the face is slowly extracted, with the nose, eyes, brow, and occiput appearing in succession over the anterior margin of the perineum. *Forceps should not be applied to the mentum posterior presentation because vaginal delivery is impossible except in very small fetuses.*

VACUUM-ASSISTED DELIVERY

Vacuum Extractor Design

With vacuum-assisted OVD, suction is created within a cup placed on the fetal scalp such that traction on the cup aids fetal birth. In the United States, *vacuum extractor* is the preferred term, whereas in Europe it is commonly called a *ventouse* (Fig. 29-14). Theoretical benefits of this tool compared with forceps include simpler requirements for precise positioning on the fetal head and avoidance of space-occupying blades within the vagina to help mitigate maternal trauma.

Vacuum devices contain a cup, shaft, handle, and vacuum generator. Vacuum cups are metal or plastic and differ in their shape, size, and reusability. In the United States, plastic cups are generally preferred. Of these, the soft cup is a pliable bell-shaped dome, whereas the rigid type has a firm flattened mushroom-shaped cup and circular ridge around the cup rim (Table 29-2). When compared, rigid mushroom cups generate significantly more traction force (Hofmeyr, 1990; Muise, 1993). With OP positions or with asynclitism, the flatter cup also permits improved placement at the flexion point, which is typically less accessible with these head positions. The trade-off is that the flatter cups have higher scalp laceration rates. Thus, many manufacturers recommend soft bell cups for more straightforward OA deliveries.

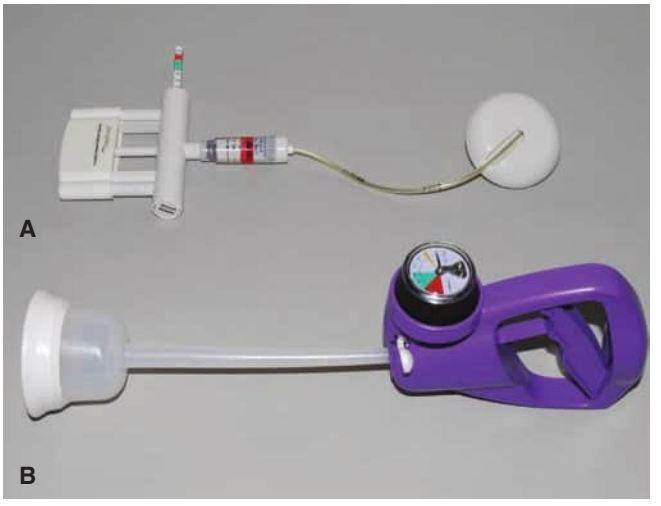

FIGURE 29-14 Vacuum delivery systems. **A.** The *Kiwi OmniCup* contains a handheld vacuum-generating pump, which is attached via flexible tubing to a rigid plastic mushroom cup. **B.** The *Mityvac Mystic II MitySoft Bell Cup* has a soft bell cup attached by a semirigid shaft to a handheld pump.

[a]Reusable cups.
[b]Suitable for occiput posterior positions or asynclitism.
[c]For extractions through a hysterotomy incision during cesarean delivery.

Several investigators have compared outcomes with various rigid and soft cups. Metal cups yield higher success rates but greater rates of scalp injuries, including cephalohematomas (O'Mahony, 2010). In another study, Kuit and colleagues (1993) found that the only advantage of the soft cups was a lower incidence of scalp injury. In a review, Vacca (2002) concluded that fewer scalp lacerations occurred with the soft cup, but that the rate of cephalohematomas and subgaleal hemorrhage was similar between soft and rigid cups. Importantly, high-pressure vacuum generates large amounts of force regardless of the cup used (Duchon, 1998).

Aside from the cup, the shaft that connects the cup and handle may be flexible or semiflexible. Tubing-like flexible shafts may be preferred for OP positions or asynclitism to permit better seating of the cup. Last, the vacuum generator may be handheld and actuated by the operator, or it may be held and operated by an assistant.

Technique

An important step in vacuum-assisted OVD is proper cup placement over the *flexion point*. This pivot point maximizes traction, minimizes cup detachment, flexes the neck, and delivers the smallest head diameter through the pelvic outlet. This improves success rates, lowers scalp injury rates, and lessens perineal trauma because the smallest head diameter distends the vulva (Baskett, 2008).

The flexion point is found along the sagittal suture, approximately 3 cm from the posterior fontanel's center and approximately 6 cm from the anterior fontanel's center. Because most cup diameters measure 5 to 6 cm, when properly placed, the cup rim lies at the posterior fontanel's border and 3 cm from the anterior fontanel (Fig. 29-15). Placement of the cup more anteriorly on the fetal cranium—near the anterior fontanel—is ideally avoided as it leads to neck extension during traction unless the fetus is small. Such placement delivers a wider head diameter through the vaginal opening. Last, asymmetrical placement relative to the sagittal suture may worsen asynclitism. Cup placement in OA positions is seldom difficult. In contrast, if the indication for delivery is failure to descend caused by occipital malposition, cup positioning can be difficult.

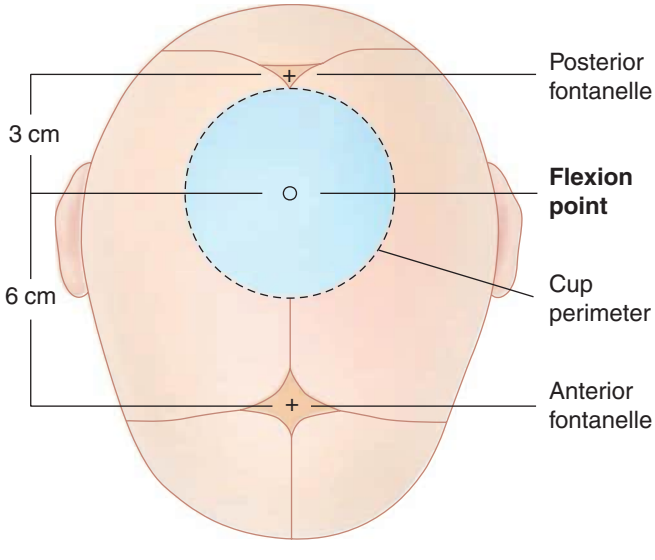

FIGURE 29-15 Drawing demonstrates correct cup placement at the flexion point. Along the sagittal suture, this spot lies 3 cm from the posterior fontanel and 6 cm from the anterior fontanel.

TABLE 29-3. Vacuum Pressure Conversions

mm Hg	cm Hg	Inches Hg	lb/in^2	kg/cm^2
100	10	3.9	1.9	0.13
200	20	7.9	3.9	0.27
300	30	11.8	5.8	0.41
400	40	15.7	7.7	0.54
500	50	19.7	9.7	0.68
600	60	23.6	11.6	0.82

During cup placement, maternal soft tissue entrapment predisposes the mother to lacerations and virtually ensures cup dislodgement, colloquially called a "pop off." Thus, the entire cup circumference should be palpated both before and after the vacuum has been created and again prior to traction to exclude such entrapment. Gradual vacuum creation is advocated by some and is generated by increasing the suction in increments of 0.2 kg/cm^2 every 2 minutes until a total negative pressure of 0.8 kg/cm^2 is reached (Table 29-3). That said, other studies have shown that negative pressure can be increased to 0.8 kg/cm^2 in <2 minutes without a significant difference in efficacy or in maternal and fetal outcomes (Suwannachat, 2011, 2012).

Once suction is created, the instrument handle is grasped, and traction is initiated. Similar to forceps delivery, traction angles mirror that in Figure 29-8 and should be steady without jerking or rocking. The number of needed pulls increases with higher station but typically ranges from one to four. Efforts are intermittent, and each pull is coordinated with maternal pushing. Manual torque to the cup is avoided as it can cause cup displacement or cephalohematomas and, with metal cups, "cookie-cutter"–type scalp lacerations. Thus, OA oblique positions are corrected not by rotation, but solely by downward outward traction. Similarly, for OP positions, rotational forces should not be applied. Instead, with correct flexion point placement and line of traction, the head will usually rotate by itself (van den Akker, 2019).

During pulls, the operator should place the nondominant hand within the vagina, with the thumb on the extractor cup and one or more fingers on the fetal scalp. So positioned, descent of the presenting part can be judged and the traction angle can be adjusted with head descent. In addition, the relationship of the cup edge to the scalp can be assessed to help detect cup separation.

Between contractions, some physicians will lower the suction levels to decrease scalp injury rates, whereas others will maintain suction in cases with a nonreassuring FHR to aid rapid delivery. No differences in maternal or fetal outcome were noted if the vacuum level was decreased between contractions or if an effort was made to prevent fetal loss of station (Bofill, 1997). Once the head is delivered, the vacuum pressure is relieved and the cup removed.

Vacuum extraction should be considered a trial. Without early and clear evidence of descent toward delivery, an

alternative delivery approach should be adopted. As a general guideline, progressive descent should accompany each traction attempt. Neither data nor consensus are available regarding the number of pulls required to effect delivery, the maximum number of cup pop-offs that can be tolerated, or optimal total duration of the procedure. Some manufacturers have recommendations regarding these (Clinical Innovations, 2018; CooperSurgical, 2018).

During a vacuum-assisted delivery trial, cup dislodgement due to technical failure or less than optimal placement should not be equated with dislodgement under ideal conditions of exact cup placement and optimal vacuum maintenance. Technical failures may merit either additional attempts at cup placement or, alternatively, a trial of forceps (Ezenagu, 1999; Williams, 1991). The least desirable cases are those in which traction without progress or multiple disengagements occur following correct cup application and appropriate traction. As with forceps, clinicians should embrace a willingness to abandon attempts at vacuum-assisted delivery if satisfactory progress is not made (American College of Obstetricians and Gynecologists, 2020a).

TRAINING

As the OVD rate has declined, so have opportunities for resident training (Fitzwater, 2015; Kyser, 2014). In accredited programs, the median number of these procedures completed by trainees has reached critically low levels, and for recent graduates it approximated only 20 (Accreditation Council for Graduate Medical Education, 2019; Dildy, 2016). For residents completing training in 2021, the Accreditation Council for Graduate Medical Education (2020) minimum requirement is 15 procedures.

To adapt, residency programs should have readily available skilled operators to teach these procedures by simulation as well as through actual cases (Spong, 2012). In one study, a 59-percent increase in forceps deliveries over 2 years was related to a single experienced and proactive instructor assigned to teach forceps to residents in labor and delivery (Solt, 2011).

In another, following implementation of a formal education program that included a manikin and pelvic model simulation, rates of neonatal morbidity and of severe maternal cervical, labial, and vaginal lacerations declined. However, OASIS rates were unchanged (Cheong, 2004). Gossett and associates (2016) found a 22-percent reduction in the OASIS rate following an OVD simulation curriculum.

CHAPTER 30

Cesarean Delivery and Peripartum Hysterectomy

In the United States, the cesarean delivery rate rose most dramatically from 4.5 percent in 1970 to 32.9 percent in 2009. The rate has since plateaued and was 31.9 percent in 2018 (Martin, 2019). Some indications for performing cesarean delivery are shown in Table 30-1. More than 85 percent of these operations are performed for four reasons—prior cesarean delivery, labor dystocia or arrest, fetal jeopardy, or abnormal fetal presentation. The latter three compose the main indications for primary cesarean delivery (Barber, 2011; Boyle, 2013). Efforts to lower these rates are outlined in *Safe Prevention of the Primary Cesarean Delivery* by the American College of Obstetricians and Gynecologists (2019b).

Reasons for persistently elevated cesarean rates are not completely understood, but some explanations include the following:

1. Women are having fewer children, thus, a greater percentage of births are among nulliparas, who are at increased risk for cesarean delivery.
2. Average maternal age is rising, and older women, especially older nulliparas, have a higher cesarean delivery risk.
3. Electronic fetal monitoring use is widespread and associated with a higher cesarean delivery rate compared with intermittent fetal heart rate auscultation.
4. Most breech fetuses are now delivered by cesarean.
5. The frequency of operative vaginal delivery has declined.
6. Obesity, which is a cesarean delivery risk, has reached epidemic proportions.
7. Rates of cesarean delivery in women with preeclampsia have risen, whereas labor induction rates for these patients have declined.
8. The vaginal birth after cesarean (VBAC) rate has decreased from a high of 28 percent in 1996 to 13.3 percent in 2018 (Martin, 2019).
9. Assisted reproductive technology is more widely used and is linked with greater cesarean delivery rates (Luke, 2019).

DEFINITIONS

Cesarean delivery defines the birth of a fetus by laparotomy and then hysterotomy. This definition is not applied to removal of the fetus from the abdominal cavity in the case of uterine rupture or of abdominal pregnancy. Rarely, hysterotomy is performed in a woman who has just died or in whom death is expected soon—*postmortem* or *perimortem cesarean delivery* (Chap. 50, p. 897).

In some cases, abdominal hysterectomy is indicated after delivery. When performed at the time of cesarean delivery, the operation is *cesarean hysterectomy*. If done shortly after vaginal delivery, it is *postpartum hysterectomy*. *Peripartum hysterectomy* is a broader term that combines these two. In most cases, *total hysterectomy* is performed and removes the uterine body and cervix. *Supracervical hysterectomy* is selected less often and removes only the uterine body. With either, adnexa are not usually

TABLE 30-1. Some Indications for Cesarean Delivery

Maternal
Prior cesarean delivery
Abnormal placentation
Maternal request
Prior classical hysterotomy
Unknown uterine scar type
Prior uterine incision extension
Uterine incision dehiscence
Prior full-thickness myomectomy
Genital tract obstructive mass
Invasive cervical cancer
Prior trachelectomy
Permanent cerclage
Prior pelvic reconstructive surgery
Prior significant perineal trauma
Pelvic deformity
HSV or HIV infection
Cardiac or pulmonary disease
Cerebral aneurysm or arteriovenous malformation
Pathology requiring concurrent intraabdominal surgery
Perimortem cesarean delivery
Maternal-Fetal
Cephalopelvic disproportion
Failed operative vaginal delivery
Placenta previa or vasa previa
Placental abruption
Fetal
Nonreassuring fetal status
Malpresentation
Macrosomia
Congenital anomaly
Abnormal umbilical cord Doppler study
Thrombocytopenia
Prior neonatal birth trauma

HIV = human immunodeficiency virus; HSV = herpes simplex virus.

excised. In most instances, a *simple hysterectomy*, which is also a type I hysterectomy, is performed. However, for women with invasive cervical cancer, *radical hysterectomy* removes the uterus, parametrium, and proximal vagina to achieve tumor excision with negative margins. For cases of placenta percreta that extend toward the pelvic sidewall, similar radical excision of the parametrium may be needed.

CESAREAN DELIVERY RISKS

To provide accurate informed consent, knowledge of maternal and neonatal risks and benefits with surgery is essential. In broad terms, cesarean delivery generally has higher maternal surgical risks for the current and subsequent pregnancies compared with spontaneous vaginal birth. This is balanced against lower rates of perineal injury and short-term pelvic floor disorders. For the neonate, cesarean delivery generally offers lower rates of birth trauma and stillbirth but greater rates of initial respiratory difficulties.

Maternal Mortality and Morbidity

For the mother, death attributable solely to cesarean delivery is rare in the United States. A review of nearly 1.5 million pregnancies found maternal mortality rates of 2.2 per 100,000 cesarean deliveries compared with 0.2 per 100,000 vaginal births (Clark, 2008). In a metaanalysis of 203 studies, Guise and coworkers (2010) reported a maternal mortality rate of 13 per 100,000 with elective repeat cesarean compared with 4 per 100,000 with trial of labor.

Some element of this risk may stem from the underlying indication for the cesarean delivery. For example, long first-stage labor increases not only cesarean risk but also rates of maternal fever and postpartum hemorrhage (Blankenship, 2020). Additionally, in a study of more than 100,000 deliveries in China, where cesarean birth without a medical indication is common, the maternal mortality rate was not higher in those with nonindicated cesarean delivery than in women with spontaneous vaginal birth (Hou, 2017).

Similar to mortality rates, the overall frequencies of some maternal morbidities are increased with cesarean delivery. Villar and associates (2007) reported that maternal morbidity rates were twofold higher with cesarean delivery than with vaginal birth. Principal among these are infection, hemorrhage, and venous thromboembolism (VTE). In addition, anesthetic complications, which also rarely include death, have a greater incidence with cesarean delivery compared with vaginal birth (Cheesman, 2009; Hawkins, 2011). Adjacent organs infrequently may be injured, which is described in detail later (p. 563).

Women who undergo a cesarean delivery are much more likely to be delivered by a repeat operation in subsequent pregnancies. For women undergoing subsequent cesarean, the maternal risks just described are even greater (Cahill, 2006; Marshall, 2011; Silver, 2006). Specifically outlined in Chapter 31 (p. 580), abnormal placentation, wound and uterine infections, adjacent organ injury, cesarean hysterectomy, and blood transfusion are among the morbidity that accrues with multiple subsequent cesarean operations.

As an advantage, cesarean delivery is associated with lower rates of urinary incontinence and pelvic organ prolapse than is vaginal birth (Gyhagen, 2013a,b; Handa, 2011). Rates of anal incontinence appear uninfluenced by a vaginal or cesarean route (Blomquist, 2018; Nelson, 2019). In subgroup evaluation, operative vaginal delivery does carry an overall greater anal incontinence risk, which likely stems from higher sphincter injury rates with these procedures (Chap. 29, p. 535).

Pelvic floor advantages persist to some degree over time, but cesarean delivery is not totally protective. Moreover, longitudinal studies suggest that initial pelvic floor advantages gained from cesarean delivery are lost as women age (Dolan, 2010; MacArthur, 2011, 2013). During their State-of-the-Science Conference, the National Institutes of Health panel (2006) summarized that stress urinary incontinence rates after elective cesarean delivery are lower than those following vaginal delivery. However, the duration of this protection is unclear, particularly in older

and multiparous populations. Defining women who would be at highest long-term risk for pregnancy-related pelvic floor disorders might allow accurate delivery counseling (Jelovsek, 2018).

Neonatal Morbidity

Cesarean delivery is associated with a lower rate of fetal trauma (Linder, 2013; Moczygemba, 2010). Alexander and colleagues (2006) found that fetal injury complicated 1 percent of cesarean deliveries. Skin laceration was most common, but others included cephalohematoma, clavicular fracture, brachial plexopathy, skull fracture, and facial nerve palsy. Cesarean deliveries following a failed operative vaginal delivery attempt had the highest injury rate. The lowest rate—0.5 percent—occurred in the elective cesarean delivery group. That said, Worley and associates (2009) found that approximately a third of women who were delivered at Parkland Hospital entered spontaneous labor at term, and 96 percent of these delivered vaginally without adverse neonatal outcomes.

Cesarean Delivery on Maternal Request

Some women request elective cesarean delivery. Data regarding the true incidence of *cesarean delivery on maternal request (CDMR)* are poor. An older estimate in the United States was 5 percent (Declercq, 2005).

Reasons for the request include protection of pelvic floor support, convenience, fear of childbirth, and reduced risk of fetal injury. One retrospective study of more than 66,000 Chinese parturients compared outcomes of those who elected planned vaginal birth or requested primary cesarean delivery (Liu, 2015). Short-term serious maternal morbidity and neonatal mortality rates were similar. For the newborns, rates of birth trauma, infection, and hypoxic ischemic encephalopathy were low in both groups but statistically lower with cesarean delivery. Respiratory distress syndrome rates were greater in the CDMR cohort. A smaller study comparing these two routes of delivery support these findings (Larsson, 2011).

The debate surrounding CDMR includes two medical points: the concept of informed free choice by the woman, and the autonomy of the physician in offering CDMR. To address this, the National Institutes of Health (2006) held a State-of-the-Science Conference on Cesarean Delivery on Maternal Request. Notably, most of the maternal and neonatal outcomes examined had insufficient data to permit recommendations. Indeed, one of the main conclusions of the conference was that more high-quality research is needed to fully evaluate the issue. Guidelines from the American College of Obstetricians and Gynecologists (2020a) note that CDMR should not be performed before 39 weeks' gestation. It is ideally avoided in women desiring several children because of the earlier-described morbidity from accruing cesarean operations.

PATIENT PREPARATION

Delivery Availability

No nationally recognized standard of care currently dictates the acceptable time interval to begin cesarean delivery. Previously, a 30-minute decision-to-incision interval was recommended. However, Bloom and colleagues (2006) evaluated nearly 3000 cesarean deliveries performed for emergency indications. They reported that failure to achieve a cesarean delivery decision-to-incision time <30 minutes was not associated with a negative neonatal outcome. A subsequent systematic review echoed this finding (Tolcher, 2014). Despite this, when faced with an acute, catastrophic deterioration in fetal condition, cesarean delivery usually is indicated as rapidly as possible, and thus purposeful delays are inappropriate. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) recommend that facilities giving obstetrical care should have the ability to initiate cesarean delivery in a time frame that best incorporates maternal and fetal risks and benefits.

Informed Consent

Informed consent is a process and not merely a medical document. The consenting conversation should enhance a woman's awareness of her diagnosis and contain a discussion of medical and surgical care alternatives, procedure goals and limitations, and operative risks. For women with a prior cesarean delivery, the option of a trial of labor should be included for suitable candidates. For those desiring permanent sterilization or intrauterine device (IUD) insertion, consenting for these can be completed concurrently (Chaps. 38 and 39, pp. 665 and 684).

An informed patient may decline a particular recommended intervention, and a woman's decision-making autonomy must be respected. In the medical record, providers should document the reasons for refusal and should note that the intervention's value and the health consequences of not proceeding with it have been explained.

For Jehovah's Witnesses, informed consent discussions regarding blood products ideally begin early in pregnancy. Acceptable blood products vary widely among individual women, and a preoperative checklist of approved products allows superior preparation (Hubbard, 2015). In general, red cells, white cells, platelets, and plasma are considered primary blood components and are declined. However, certain clotting factors or cell fractions may be acceptable (Lawson, 2015). Before and after surgery, iron, folate, and, if necessary, erythropoietin are accepted agents to help maximize hemoglobin levels. Perioperatively, phlebotomy is limited, and pediatric collection tubes are preferable. Intraoperative options include prompt treatment of atony to limit blood loss and use of topical hemostatic agents, tranexamic acid, and desmopressin to promote clot formation. Red blood cell salvage can provide autologous donation. Normovolemic hemodilution and controlled hypotensive or hypothermic anesthesia can limit red cell losses. To minimize uncontrolled vessel bleeding, uterine artery embolization, occlusive vascular balloons, and other options are described in Chapter 44 (p. 779) (Scharman, 2017).

Timing of Scheduled Cesarean Delivery

With elective delivery before 39 completed weeks, adverse neonatal sequelae from neonatal immaturity are appreciable (Tita, 2009). To avoid these, assurance of fetal maturity before

scheduled elective surgery is essential. Supporting criteria include corroborative ultrasound measurements obtained prior to 20 weeks' gestation, fetal heart tones heard for the past 30 weeks, and passage of 36 weeks since an initial positive pregnancy test result (American Academy of Pediatrics, 2017).

Preoperative Care

Current perioperative care is guided by evidence-based enhanced recovery after surgery (ERAS) recommendations. Among these, solid food intake is stopped at least 6 hours before the procedure. Uncomplicated patients may consume moderate amounts of clear liquids up to 2 hours before surgery (American Society of Anesthesiologists, 2016). Bowel preparation is not recommended (Wilson, 2018).

The woman scheduled for cesarean delivery typically is admitted the day of surgery and evaluated by the obstetrical and anesthesia teams. Recently performed hematocrit and indirect Coombs test are reviewed. If the latter is positive, compatible blood availability must be ensured.

Regional analgesia is preferred for cesarean delivery. To minimize the lung injury risk from rare aspiration, gastric acid is ideally buffered. An oral antacid is consumed shortly before regional analgesia or induction of general anesthesia. One example is Bicitra, 30 mL orally in a single dose. This can be coupled with an intravenous (IV) dose of an H_2-receptor antagonist, which also raises gastric pH (Wilson, 2018).

Once the woman is supine, a wedge beneath the right hip and lower back creates a left lateral tilt to aid venous return and avoid hypotension. Data are insufficient to determine the value of fetal monitoring before scheduled cesarean delivery in women without risk factors. Our practice is to obtain a 5-minute tracing prior to elective cases. At minimum, fetal heart sounds should be documented in the operating room prior to surgery.

Of further preparations, hair removal at the surgical site does not lower surgical site infection (SSI) rates (Kowalski, 2016). However, if hair is obscuring, it is removed the day of surgery by clipping, which is associated with fewer SSIs than shaving (Tanner, 2011). Chemical depilation the night before surgery compared with clipping has similar SSI rates (Lefebvre, 2015). An electrosurgical grounding pad is placed near the surgical incision and typically on the lateral thigh. At Parkland Hospital, we typically insert an indwelling bladder catheter to collapse the bladder away from the hysterotomy incision, to avert urinary retention secondary to regional analgesia, and to allow accurate postoperative urine measurement. Small studies show that catheterization may be withheld in hemodynamically stable women. Catheter-related discomfort can be avoided, but urinary tract infection rates are not lower (Abdel-Aleem, 2014).

The risk of VTE is increased with pregnancy. In the United States in 2014, women with cesarean delivery had a VTE rate of 8 per 10,000, which almost doubled the rate for those with vaginal birth (Abe, 2019). Accordingly, for all women not already receiving thromboprophylaxis, the American College of Obstetricians and Gynecologists (2020c) recommends initiation of pneumatic compression stockings before cesarean delivery. These are usually discontinued once the woman ambulates. Consensus varies among organizations, and the American College of Chest Physicians suggests only early ambulation for women without risk factors who are undergoing cesarean delivery (Bates, 2012). For women already receiving prophylaxis or those with increased risk factors, they support escalation of prophylaxis. Last, the Royal College of Obstetricians and Gynaecologists (2015) is the most conservative and suggest pharmacological prophylaxis for the largest proportion of patients. These various methods and recommendations are discussed in Chapter 55 (p. 989).

Some women scheduled for cesarean delivery have a comorbidity that requires specific management in anticipation of surgery. Among others, these include insulin-requiring diabetes, coagulopathy or thrombophilia, chronic corticosteroid use, and significant reactive airway disease. Surgical preparations are discussed in the respective chapters covering these topics.

Infection Prevention

Antibiotic Prophylaxis

Cesarean delivery is considered a clean contaminated case, and postoperative febrile morbidity is common. Numerous trials show that a single dose of an antibiotic given at the time of cesarean delivery significantly decreases infectious morbidity (Smaill, 2014). Although more obvious for women in active labor who then require cesarean delivery, this practice also pertains to gravidas undergoing elective surgery. Depending on drug allergies, most recommend a single IV dose of a β-lactam antibiotic—either a cephalosporin or extended-spectrum penicillin. A 1-g dose of cefazolin (Ancef) is an efficacious and cost-effective choice. Additional doses are considered in cases with blood loss >1500 mL or with duration longer than 3 hours. Recommendations for a 2- or 3-g cefazolin dose in obese parturients are conflicting (Ahmadzia, 2015; Maggio, 2015; Swank, 2015; Young, 2015). The Centers for Disease Control and Prevention recommends a 2-g dose for weights ≥80 kg and 3 g for those ≥120 kg (Berríos-Torres, 2017). The American College of Obstetricians and Gynecologists (2020d) recognizes either dose as suitable for women ≥80 kg. One pharmacokinetic analysis in obese women showed sufficient tissue levels with a 2-g dose for cesarean deliveries lasting 1.5 hours. Authors recommended consideration for redosing in obese women if surgeries were longer (Grupper, 2017).

Evidence also supports extending the antibiotic spectrum (Markwei, 2021; Tita, 2008). One large randomized trial added azithromycin, 500 mg IV, to standard prophylaxis prior to cesarean delivery for women in labor or with ruptured membranes (Tita, 2016). Rates of SSIs and endometritis were significantly lower in the extended-spectrum group compared with those in the standard prophylaxis cohort.

In pregnant women with a history of infection with methicillin-resistant *Staphylococcus aureus* (MRSA), a single, 15-mg/kg dose of vancomycin can be added to the standard prophylaxis. Decolonization plays a limited role but may be considered prior to a planned cesarean delivery in women with known MRSA colonization (American College of Obstetricians and Gynecologists, 2020d).

Significant β-lactam allergy manifests as anaphylaxis, angioedema, respiratory distress, or urticaria. This merits prophylaxis with a single, 900-mg IV dose of clindamycin combined with a weight-based, 5-mg/kg dose of an aminoglycoside as an alternative. The 900-mg clindamycin dose is also used for obese patients. Some studies link higher SSI rates to regimens that lack a β-lactam (Wilhelm, 2020). Antepartum penicillin-allergy evaluation by a specialist may redefine the significance of the patient's prior reaction. Advantageously, this clarification may remove an allergy label and expanded options (Wolfson, 2021).

Antibiotic administration before surgical incision lowers postoperative infection rates without adverse neonatal effects compared with drug administration after umbilical cord clamping (Mackeen, 2014b; Sullivan, 2007). Prophylaxis is ideally administered within the 60 minutes prior to the start of planned cesarean delivery. For emergent delivery, antibiotics are given as soon as feasible.

Preoperative preparation of the abdominal wall skin immediately prior to surgery can help prevent SSIs. Chlorhexidine-alcohol or povidone-iodine solutions are suitable, but data favor chlorhexidine (Hadiati, 2020; Tolcher, 2019). However, adding a wiping of the skin with chlorhexidine the night before surgery was no better than placebo (Stone, 2020). Once abdominal preparation is completed and dry, surgical drapes cover the patient. One type has a cut-out window in the lower abdomen that is surrounded by an adhesive border. Others are *adhesive incisional drapes*, in which the skin and plastic drape must be incised together. The latter may slightly raise SSI rates (Eckler, 2019; Hadiati, 2020).

Although not our practice, preoperative vaginal cleansing with a 1-percent povidone-iodine scrub lowered endometritis and SSI rates in some studies (Haas, 2020; Roeckner, 2019). With povidone allergy, 4-percent chlorhexidine gluconate solution is an alternative. Last, some early evidence may support extending oral antibiotic prophylaxis for 48 hours postcesarean in obese women to lower SSIs (Valent, 2017).

Antibiotic prophylaxis against infective endocarditis is not recommended for most cardiac conditions. Exceptions are women with repaired or unrepaired cyanotic heart disease, prosthetic valves, or both. Prior infective endocarditis or cardiac transplantation with resulting valve regurgitation are others (American College of Obstetricians and Gynecologists, 2020d). Drug infusion is 30 to 60 minutes prior to expected delivery (Table 52-9, p. 935). Cesarean infection prophylaxis regimens also serve as appropriate endocarditis coverage.

Other Preventions

Glycemic control in diabetics lowers wound infection rates and is emphasized in Chapter 60 (p. 1068). Smoking is another modifiable risk (Avila, 2012). Intraoperative normothermia lowers wound infection rates in general surgery cases (Balki, 2020; Berríos-Torres, 2017). This tenet is logically extrapolated to cesarean delivery (Caughey, 2018).

In children delivered by cesarean, some evidence shows higher asthma and allergy rates (Kristensen, 2016). Gut microbiome differences between vaginal and cesarean birth groups are a suggested cause (Shao, 2019). With the hope to improve neonatal microbiota, swabbing the newborn mouth with a gauze that was incubated in the maternal vagina 1 hour before surgery has been described in preliminary studies. However, the American College of Obstetricians and Gynecologists (2019c) does not encourage this practice due to few data and the potential for transmission of harmful organisms.

Surgical Safety

The Joint Commission (2020) describes a protocol to prevent surgical errors. For cesarean delivery, all relevant documents are verified immediately before surgery, and a "time out" is completed. The "time out" requires attention of the entire team to confirm that the patient, site, and procedure are correct. Important discussions also include introduction of the patient-care team members, verification of prophylactic antibiotics, estimation of procedure length, and communication of anticipated complications. Additionally, requests for special instrumentation should be addressed preoperatively to prevent potential patient compromise and intraoperative delays.

Surgical fires are a specific safety focus. As prevention, surgeons ideally assess the fire risk at the procedure's start, allow adequate drying of alcohol-based skin antiseptics, and keep ignition sources off the patient or drapes when not in use (Food and Drug Administration, 2018; Wolf, 2013).

An instrument, sponge, and needle count before and after surgery is essential. Moreover, active communication during surgery should clearly convey items added to the operative field. At surgery completion, if counts are not reconciled, portable radiographic imaging for retained objects is done.

CESAREAN DELIVERY TECHNIQUE

Laparotomy

As with all surgery, a clear understanding of relevant anatomy is essential (Chap. 2, p. 12). For entry into the abdomen, a suprapubic transverse incision or a midline vertical one is chosen for cesarean delivery. Suitable transverse incisions are Pfannenstiel or Maylard incisions, and the Pfannenstiel type is selected most frequently.

Transverse incisions follow Langer lines of skin tension, and thus exert less stress on the closed wound. Compared with vertical ones, Pfannenstiel incisions offer superior cosmesis and lower incisional hernia rates. The Pfannenstiel incision, however, is often discouraged for cases in which a large operating space is essential or in which access to the upper abdomen may be needed. With transverse incisions, because of the layers created during incision of the internal and external oblique aponeuroses, purulent fluid can collect between these. Therefore, some favor a midline vertical incision for cases with high infection risks. Emergent entry is typically faster with vertical incision during primary and repeat cesarean delivery (Wylie, 2010). Last, neurovascular structures, which include the ilioinguinal and iliohypogastric nerves and superficial and inferior epigastric vessels, are often encountered with transverse incisions. Logically, bleeding, wound hematoma, and neurological disruption may more frequently complicate these incisions compared with vertical ones. The best incision for the morbidly

obese parturient is unclear (Smid, 2016). Our preference for women with morbid obesity is a periumbilical midline vertical incision (Chap. 51, p. 909).

The Maylard incision differs mainly from the Pfannenstiel in that the rectus abdominis muscle bellies and their investing rectus sheath are transected horizontally to widen the operating space. It is technically more difficult due to required muscle cutting and ligation of the inferior epigastric arteries, which lie laterally to these muscle bellies.

Once access is gained, metal handheld retractors provide exposure for hysterotomy. One metaanalysis with nearly 1700 women showed no lowering of postcesarean SSI rates with a disposable plastic barrier retractor (Alexis-O) (Waring, 2018).

Transverse Incisions

With the Pfannenstiel incision, the skin and subcutaneous tissue are incised using a low, transverse, slightly curvilinear incision. This is made at the pubic hairline, which is typically 3 cm above the superior border of the symphysis pubis. The incision is extended laterally to accommodate delivery—12 to 15 cm is typical.

Sharp dissection is continued through the subcutaneous layer to the fascia. The superficial epigastric vessels can usually be identified halfway between the skin and fascia, several centimeters from the midline, and these are coagulated.

The fascia is then incised sharply at the midline. The anterior abdominal fascia is typically composed of two visible layers, the aponeurosis from the external oblique muscle and a fused layer containing aponeuroses of the internal oblique and transverse abdominis muscles. Ideally, the two layers are individually incised during lateral extension of the fascial incision. The inferior epigastric vessels usually lie outside the lateral border of the rectus abdominis muscle and beneath the fused aponeuroses of the internal oblique and transverse abdominis muscles. Thus, although infrequently required, further lateral extension of the fascial incision may encounter these vessels. In this case, vessels ideally are identified and coagulated or ligated to prevent bleeding and vessel retraction.

Once the fascia is incised, the inferior fascial edge is grasped with Kocher clamps and elevated by an assistant as the operator separates the fascial sheath from the underlying rectus abdominis muscle either bluntly or sharply until the superior border of the symphysis pubis is reached. Next, the superior fascial edge is grasped and again, separation of fascia from the rectus muscle is completed. Blood vessels coursing between the sheath and muscles are clamped, cut, and ligated, or they are coagulated with an electrosurgery blade. Meticulous hemostasis is imperative to lower rates of incisional hematoma and infection. The fascial separation progresses cephalad and laterally to create a semicircular area above the transverse incision with a radius of approximately 8 cm. This will vary depending on fetal size. The rectus abdominis and pyramidalis muscles are separated in the midline to expose the transversalis fascia and peritoneum.

The transversalis fascia and preperitoneal fat are bluntly dissected away to reach the underlying peritoneum. The peritoneum near the upper end of the incision is opened carefully, either bluntly or by elevating it with two hemostats placed approximately 2 cm apart. This upper site lowers cystotomy risks. The tented fold of peritoneum between the clamps is examined and palpated to ensure that omentum, bowel, or bladder is not adjacent. The peritoneum is then incised. As the incision is extended cephalad above the arcuate line, the transverse fibers of the posterior rectus sheath are seen and are cut along with the peritoneum. The peritoneal incision is then extended downward to just above the peritoneal reflection over the bladder. Importantly, in women with prior intraabdominal surgery, including cesarean delivery, omentum or bowel may be adhered to the undersurface of the peritoneum. In women with obstructed labor, the bladder may be pushed remarkably cephalad.

Midline Vertical Incision

This incision begins 2 to 3 cm above the superior margin of the symphysis. It should be sufficiently long to allow fetal delivery, and 12 to 15 cm is typical. Sharp or electrosurgical blade dissection through the subcutaneous layers ultimately exposes the anterior rectus sheath. A small opening is made sharply with scalpel in the upper half of the linea alba. Placement here helps avoid potential cystotomy. Index and middle fingers are placed beneath the fascia, and the fascial incision is extended first superiorly and then inferiorly with scissors. Midline separation of the rectus muscles and pyramidalis muscles and peritoneal entry are similar to those just described for the Pfannenstiel incision.

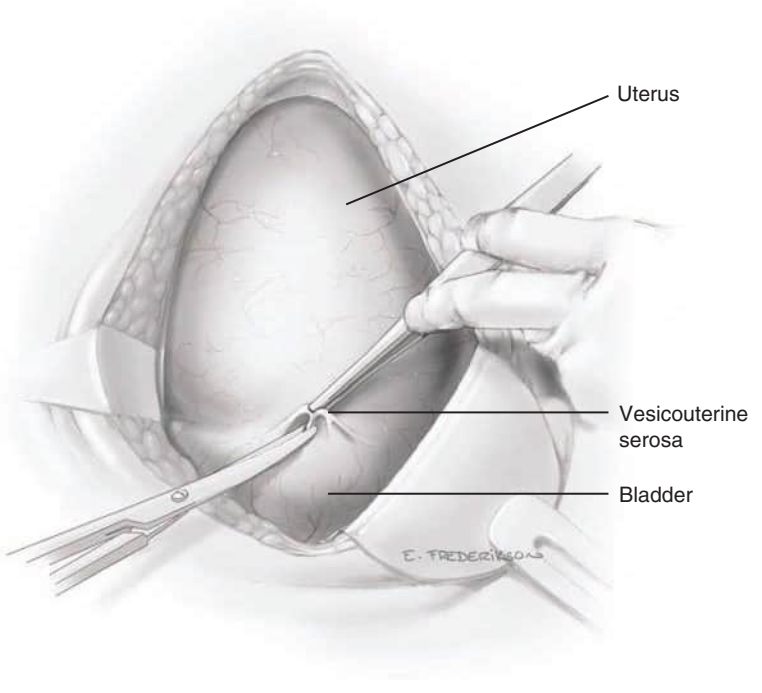

FIGURE 30-1 The loose peritoneum above the bladder reflection is grasped with forceps and incised with Metzenbaum scissors.

Hysterotomy

Most often, the lower uterine segment is incised transversely as described by Kerr in 1921. Occasionally, vertical incision confined solely to the lower uterine segment may be elected (Krönig, 1912). In contrast, a *classical incision* begins as a low vertical incision, which is then extended cephalad into the active portion of the uterine corpus. Last, a fundal or even posterior uterine incision may be selected for cases with placenta accreta syndrome.

Low Transverse Cesarean Incision

For most cesarean deliveries, this incision is preferred. Compared with a classical incision, it repairs easily, causes less incision-site bleeding, and promotes less bowel or omentum adherence to the myometrial incision. Located in the inactive segment, it is also less likely to rupture during a subsequent pregnancy.

Before hysterotomy, the surgeon palpates the fundus to identify degrees of uterine rotation. The uterus may be rotated so that one round ligament is more anterior and closer to the midline (Chap. 3, p. 46). In such cases, the uterus can be manually reoriented and held to permit centering of the incision. This avoids incision extension into and laceration of the adjacent uterine artery. A moist sponge may be used to pack protruding bowel away from the operative field.

The reflection of peritoneum at the upper margin of the bladder and overlying the lower uterine segment is grasped in the midline with forceps and incised transversely with scissors (Fig. 30-1). Following this initial incision, scissors are inserted between peritoneum and lower-uterine-segment myometrium. Open scissors are pushed laterally from the midline on each side. This transverse peritoneal incision extends almost the full length of the lower uterine segment. As the lateral margin on each side is approached, the scissors are directed slightly cephalad (Fig. 30-2). The lower edge of peritoneum is elevated, and the bladder is gently separated from the underlying lower uterine segment with blunt or sharp dissection within this vesicouterine space (Fig. 30-3). This bladder flap creation effectively moves the bladder away from the planned hysterotomy site. It also helps prevent bladder laceration if an unintended inferior hysterotomy extension occurs during fetal delivery. If dense adhesions complicate vesicouterine space dissection, sharp dissection is preferred. If unclear, the bladder and its upper border can be identified by distending or "back filling" it with fluid instilled through a Foley catheter (Saaqib, 2020).

In general, this caudad separation of bladder does not exceed 5 cm and usually is less. However, in instances in which cesarean hysterectomy is planned or anticipated, extended caudad bladder dissection is recommended to aid total hysterectomy and decrease the risk of cystotomy.

Some surgeons do not create a bladder flap. The main advantage is a shorter skin incision-to-delivery time. However, data supporting this practice are currently limited (O'Neill, 2014; Tuuli, 2012).

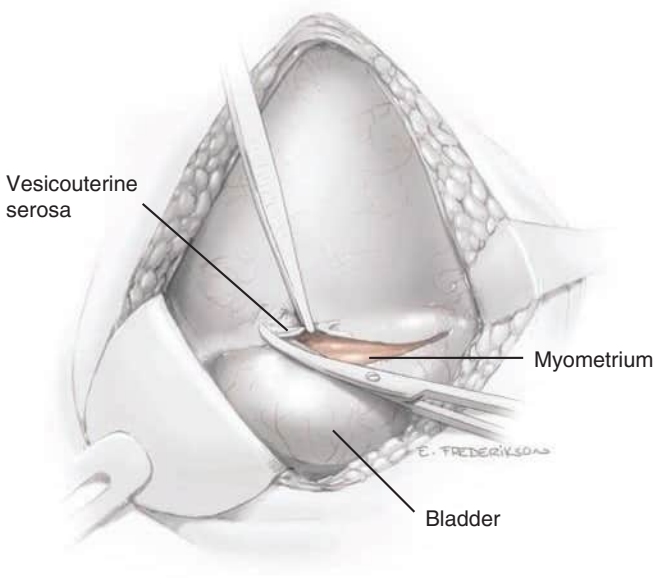

FIGURE 30-2 This peritoneal edge is elevated and incised laterally.

Uterine Incision. The uterus is entered through the lower uterine segment. Digital palpation to find the physiological border between firmer upper segment myometrium and the more flexible lower segment can guide placement. This is often at the level of the bladder flap incision.

For women with advanced or complete cervical dilation, the hysterotomy is placed relatively higher. Failure to adjust increases the risk of lateral extension of the incision into the

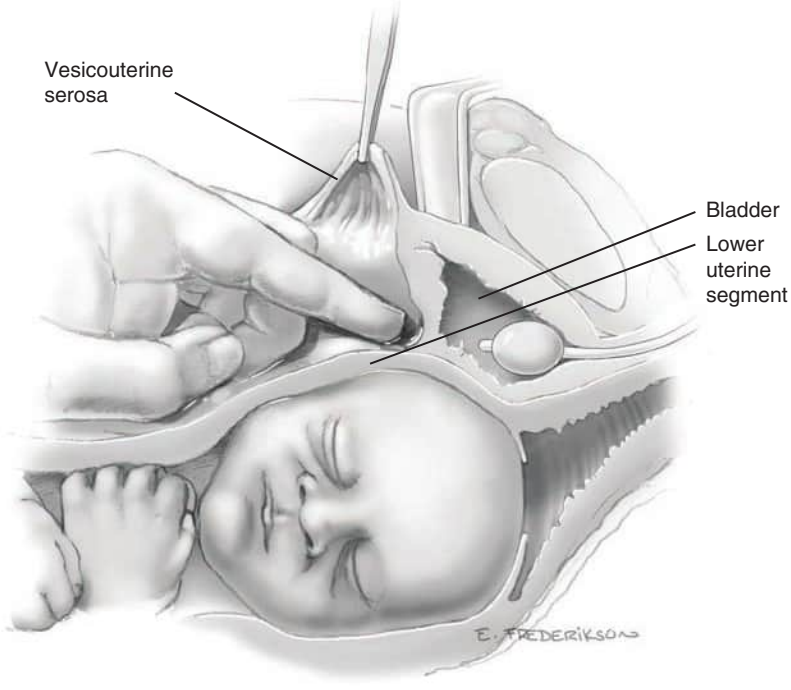

FIGURE 30-3 Cross section shows blunt dissection of the bladder off the uterus to expose the lower uterine segment.

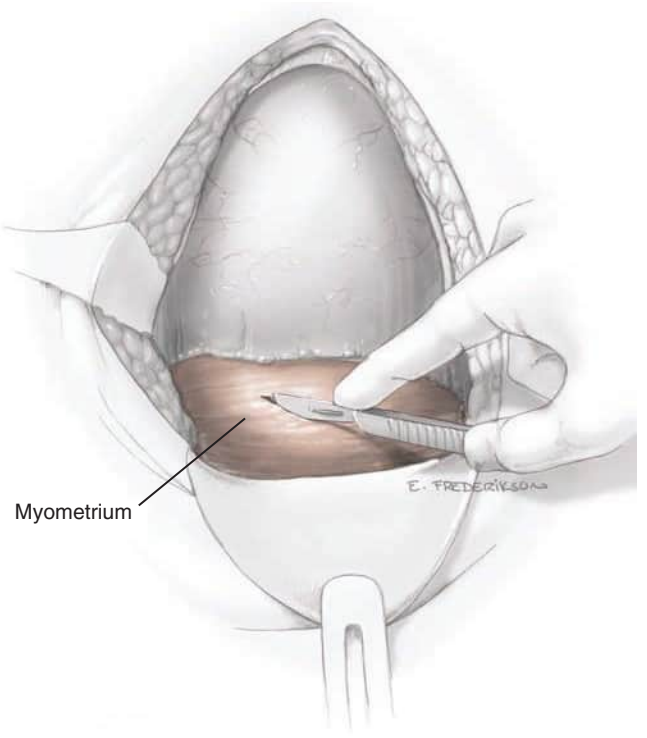

FIGURE 30-4 The myometrium is incised with shallow strokes to avoid cutting the fetal head.

uterine arteries. It may also lead to incision of the cervix or vagina rather than the lower uterine segment. Such incisions into the cervix distort postoperative cervical anatomy.

The uterus can be incised by various techniques. Each is initiated by using a scalpel to transversely incise the exposed lower uterine segment for 1 to 2 cm in the midline (Fig. 30-4). Repetitive shallow strokes help avoid fetal laceration. As the myometrium thins, a fingertip can then bluntly enter the uterine cavity. Once the uterus is entered, the hysterotomy is lengthened by simply spreading the incision, using lateral and slightly upward pressure applied with each index finger (Fig. 30-5). Instead, some evidence supports widening the lower-uterine-segment incision by pulling with fingers in a cephalocaudad direction to help lower hysterotomy extension rates (Morales, 2019; Xodo, 2016).

The goal is to create an incision sufficiently wide to deliver the presenting fetal part yet avoid overextending the incision. Extensions usually tear downward into the lower uterine segment or laterally into the uterine vessels. Extensive inferior tears may include the cervix or vagina. Risk factors for extensions include occiput posterior fetal head position, primary cesarean delivery, and advanced first-stage or second-stage labor (de la Torre, 2006; Karavani, 2020). Specific maneuvers to ameliorate this last high-risk setting are discussed in the next section.

Alternatively, if the lower uterine segment is thick and unyielding, cutting laterally and then slightly upward with bandage scissors will lengthen the incision. Importantly, when scissors are used, the index and middle fingers of the nondominant

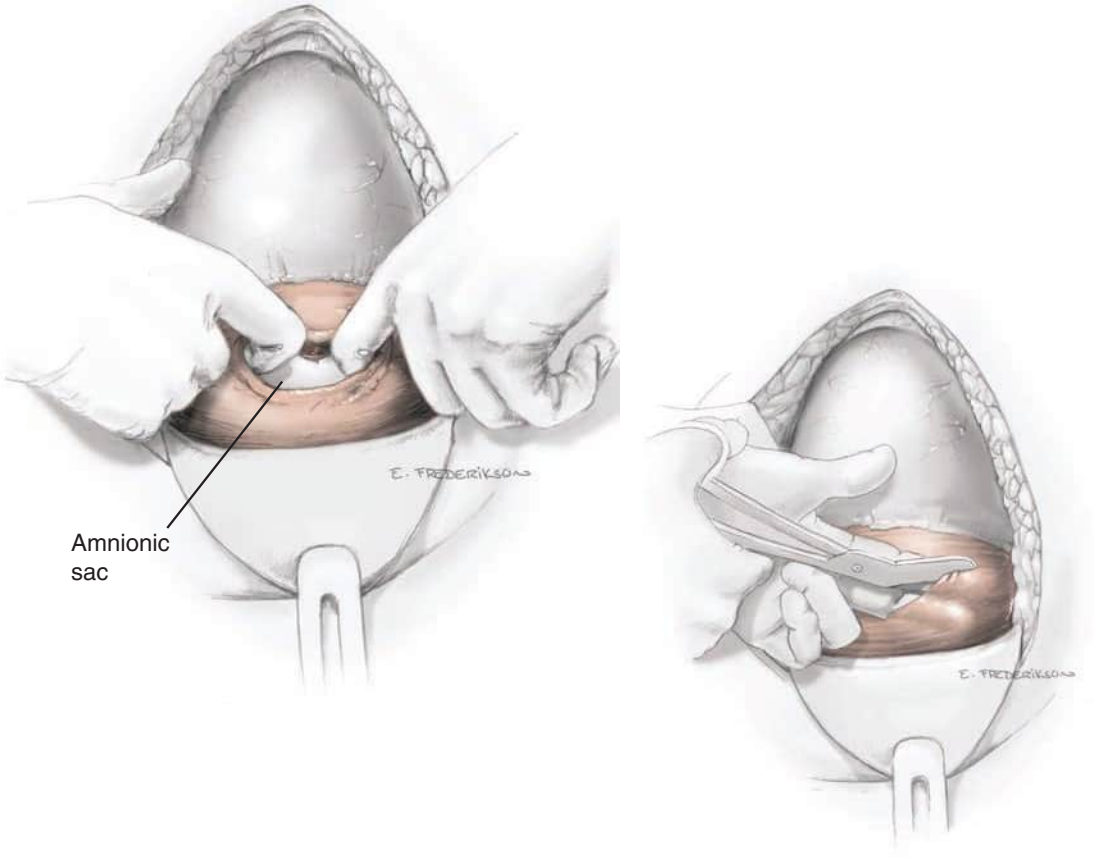

FIGURE 30-5 After entering the uterine cavity, the incision is extended laterally with fingers or with bandage scissors (*inset*).

hand are insinuated beneath the myometrium and above fetal parts to help avert fetal laceration. Comparing blunt and sharp expansion of the initial uterine incision, blunt stretch is associated with fewer unintended incision extensions, shorter operative time, and less blood loss. However, the rates of infection and need for transfusion do not differ (Asıcıoğlu, 2014; Saad, 2014).

During hysterotomy creation, if the placenta lies in the incision line, it must be either detached or incised. Placental function is thereby compromised, and thus delivery is expedited.

At times, a low transverse hysterotomy is selected but provides inadequate room for delivery. In such instances, one corner of the hysterotomy incision is extended cephalad into the contractile portion of the myometrium—a *J incision*. If this is completed bilaterally, a *U incision* is formed. Last, some prefer to extend in the midline—a *T incision*. As expected, these have been linked with higher intraoperative blood loss (Boyle, 1996; Patterson, 2002).

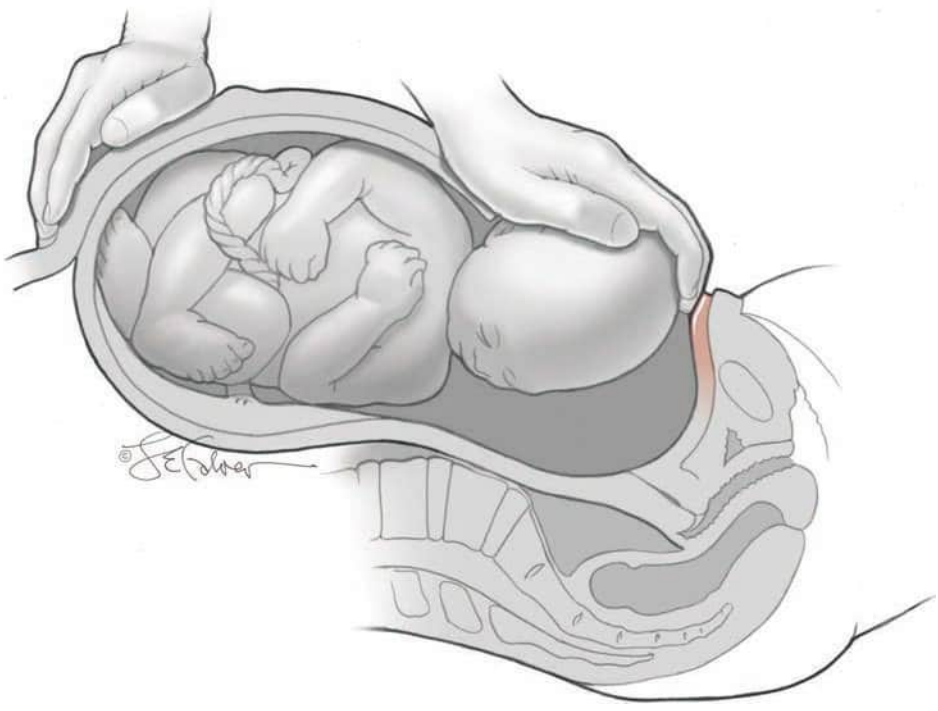

FIGURE 30-6 Delivery of the fetal head. (Figures 30-6 to 30-8: Reproduced with permission from Johnson DD: Cesarean delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

J-, U-, and T-incisions extend into the contractile portion, and a subsequent trial of labor after cesarean (TOLAC) is more likely to be complicated by uterine rupture. Similarly, from limited data, inferior hysterotomy extensions also are associated with higher rupture rates, and in our practice these preclude TOLAC (Goldfarb, 2011). The Royal College of Obstetricians and Gynaecologists (2015) notes insufficient evidence to support the general safety of TOLAC in women with a prior significant uterine extension and cautions for decisions to be individualized. Last, a prior classical incision, described later, or a fundal incision substantially raises the rupture risk during subsequent TOLAC. Thus, following a primary cesarean delivery complicated by these exceptional incision types, a conversation disclosing these events and their significance should ensue with the patient and are carefully described in the operative report.

Delivery of the Fetus.

With a cephalic presentation, a hand is slipped into the uterine cavity between the symphysis and fetal head. The head is elevated gently with the fingers and palm through the incision. Once the head enters the incision, delivery may be aided by modest fundal pressure (Fig. 30-6).

After a long labor with cephalopelvic disproportion, the fetal head may be tightly wedged in the birth canal. This situation raises the risk of hysterotomy extension, of associated blood loss, and of fetal skull fracture. First, a "push" method may be used. With this, upward pressure exerted by a hand in the vagina by an assistant will help to dislodge the head and push it cephalad. If this is anticipated, a patient in frog-leg position may allow easier vaginal access.

Second, as an alternative, a "pull" method grasps the fetal legs and brings them through the hysterotomy. The fetus is then delivered as one would complete a breech extraction. Support for this latter approach comes from small randomized trials and retrospective cohort studies (Berhan, 2014; Jeve, 2016). The main advantage appears to be lower uterine extension rates.

Another pull method attempts to free the head by placing a palm on each fetal shoulder and gently elevating them. Last, a least-common method uses a "fetal pillow." This is a distensible intravaginal balloon that is positioned below the head and then inflated to elevate the fetal head. Evidence for its superiority to the push method is limited and conflicting (Sacre, 2021; Seal, 2016).

Conversely, in women without labor, the fetal head may be unmolded and lack a leading cephalic point. The round head may be difficult to lift through the uterine incision in a relatively thick lower segment that is unattenuated by labor. In such instances, either forceps or a vacuum device may be used to deliver the fetal head. For this, the fetal head is manually grasped and turned to an occiput transverse position. In this example, the head is left OT (LOT) position. Two or more fingers of the right hand are introduced inside the hysterotomy and behind the fetal head (Fig. 30-7). Fingers of the left hand grasp the handle of the forceps. The blade's toe is gently introduced between the hand and fetal head. It is curved inward between the fetal head and the palmar surface of the fingers. For the upper blade, two or more fingers of the left hand are inserted into the right posterolateral aspect of the hysterotomy. The forceps handle is grasped by the right hand. The blade toe

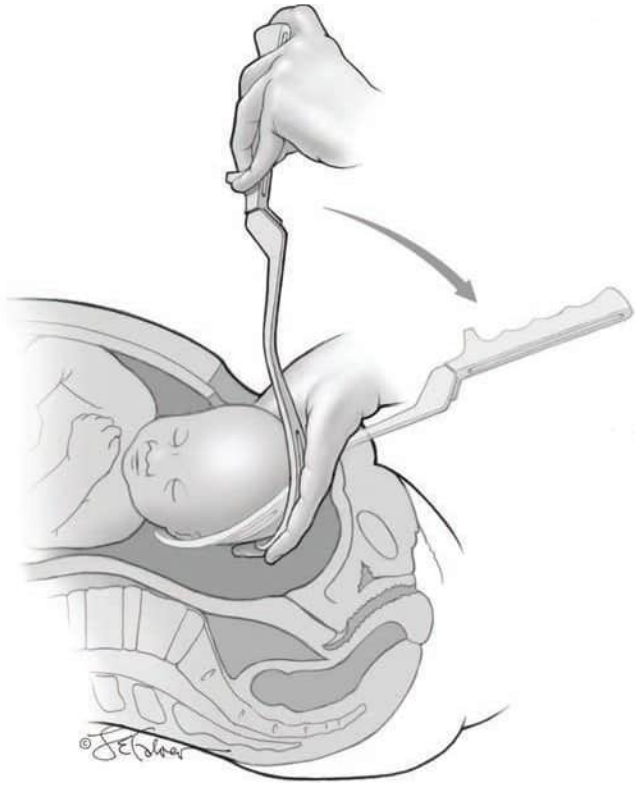

FIGURE 30-7 To place the first forceps blade, the operator's palm is slipped beneath the head. It is guided along the palm to ultimately lie across the fetal malar and lower parietal bone as in vaginal forceps application.

is then gently introduced along the posterior left lower uterine segment wall. It is curved inward between the fetal face and the palmar surface of the fingers (Fig. 30-8A). The fingers of the left hand are moved beneath the lower edge of this blade. Upward pressure against this edge will sweep or wander the blade into position. As the blade reaches its final position, the shank and handle come to rest in the midline, and the two handles are articulated (Fig. 30-8B). Traction is up and out to guide the occiput through the hysterotomy. Concurrent, gentle fundal pressure can be applied by an assistant.

After head delivery, a finger is passed across the fetal neck to determine whether it is encircled by one or more umbilical cord loops. If present, these are slipped over the head. The head is rotated to an occiput transverse position, which aligns the fetal bisacromial diameter vertically. The sides of the head are grasped with two hands, and gentle axial traction is applied until the anterior shoulder enters the hysterotomy incision. Next, by upward axial traction, the posterior shoulder is delivered. During delivery, abrupt or powerful lateral force is avoided to avert brachial plexus injury. With steady outward traction, the rest of the body then readily follows. Gentle fundal pressure may aid this.

With some exceptions, current American Heart Association recommends against routine neonatal suctioning immediately after birth, even with meconium present (Wyckoff, 2015). A fuller discussion of this and delayed umbilical cord clamping is found in Chapter 27 (p. 500). Specific to cesarean delivery, delayed clamping does not lower maternal hemoglobin levels on the first postoperative day (Jenusaitis, 2020; Purisch, 2019).

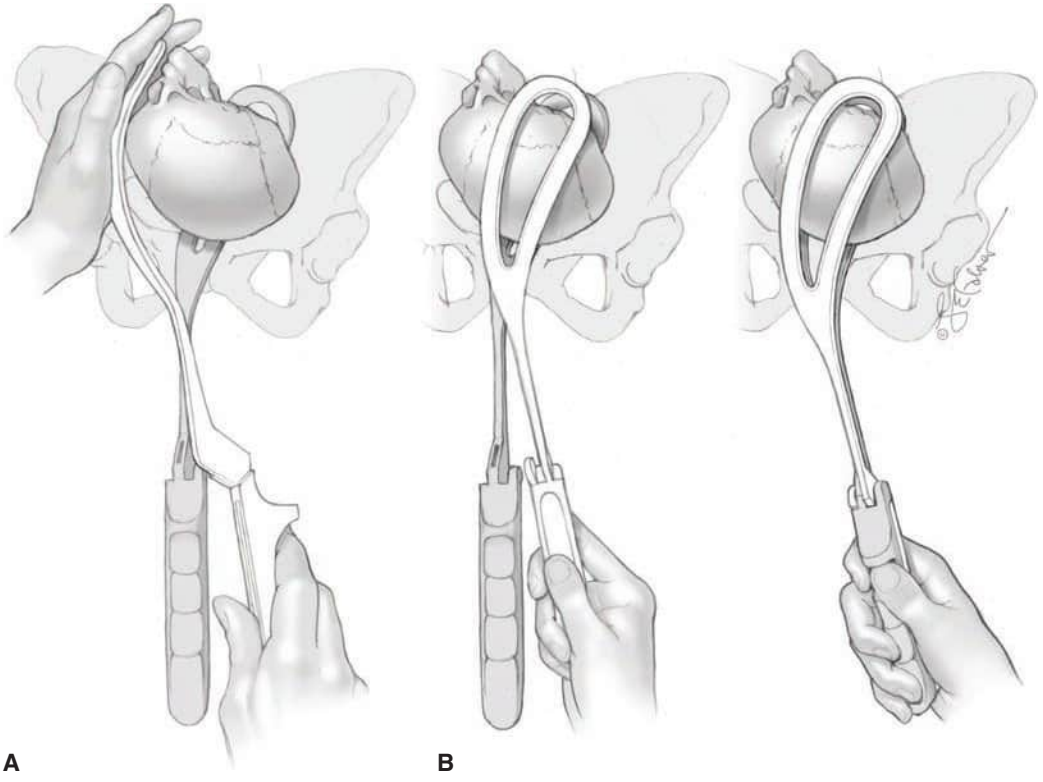

FIGURE 30-8 **A.** To apply the second blade, the operator's hand is inserted into the posterolateral aspect of the hysterotomy. The forceps blade is slipped inward across the palm. This hand then guides the blade to overlie the upper malar and parietal bones. **B.** Once positioned, the handles are interlocked. Slight upward and outward traction is used to lift the head through the incision.

After the umbilical cord is clamped, the newborn is given to the team member who will conduct care.

Comparing elective cesarean under neuraxial anesthesia and spontaneous vaginal deliveries, studies show that the need for neonatal resuscitation is not practically different between the two (Gordon, 2005). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) recommend that "a qualified person who is skilled in neonatal resuscitation should be in the delivery room." At Parkland Hospital, pediatric nurse practitioners attend uncomplicated, scheduled cesarean deliveries. Notably, as anticipated neonatal risks rise, so too should the resuscitative skills of the attendants (Wyckoff, 2015).

To promote breastfeeding, the American College of Obstetricians and Gynecologists (2020b) recommends skin-to-skin contact between newborn and mother in the delivery room. Although most randomized trials focus on vaginal birth, several small studies support such contact following cesarean delivery, and this is our practice (Frederick, 2020; Moore, 2016). Breastfeeding can be initiated the day of surgery.

Delivery of the Placenta. The uterine incision is observed for any vigorously bleeding sites. These should be quickly clamped with Pennington or ring forceps. Although some surgeons may prefer manual removal of the placenta, spontaneous delivery prompted by some gentle steady cord traction may reduce the risk of operative blood loss and infection (Anorlu, 2008; Baksu, 2005). Traction is coupled with fundal massage to hasten placental separation and delivery (Fig. 30-9).

Immediately after delivery and quick gross inspection of the placenta for missing portions, the uterine cavity is suctioned and wiped out with a gauze sponge to remove avulsed membranes, vernix, and clots. In the past, double-gloved fingers or ring forceps placed through the hysterotomy incision were used to dilate a closed cervix. This does not reduce infection or postpartum hemorrhage rates and is not our practice (Kirscht, 2017; Liabsuetrakul, 2018).

To help prevent uterine atony after birth, an IV infusion containing two ampules or 20 units of oxytocin per liter of crystalloid is infused at 10 mL/min. Some prefer higher infusion rates, however, nondilute boluses are avoided because of associated hypotension (Roach, 2013). Once the uterus contracts satisfactorily, the rate can be reduced. Although not available in the United States, an alternative is *carbetocin*, which is a longer-acting oxytocin derivative. It provides suitable, albeit more expensive, hemorrhage prophylaxis (Kalafat, 2021). Other choices for hemorrhage prophylaxis include misoprostol (Cytotec) and the ergots, namely methylergonovine (Methergine) and ergonovine (Ergotrate). A combination agent of oxytocin plus ergonovine (Syntometrine) is used outside the United States. Of agents, the World Health Organization (2018) recommends oxytocin for first-line use. Last, tranexamic acid (TXA) can be added to a standard oxytocin infusion to help prevent blood loss. Despite early encouraging evidence, methodology flaws have been cited (Franchini, 2018; Ker, 2016). With TXA in one large trial, rates of estimated blood loss >1000 mL or red-cell transfusion were lower than with placebo. But, TXA did not lower rates of common blood loss–related secondary clinical outcomes (Sentilhes, 2021). In contrast to prevention, treatment of atony is found in Chapter 42 (p. 734).

Uterine Repair. After placental delivery, the uterus is lifted through the incision and onto the draped abdominal wall. We favor exteriorizing and believe a relaxed, atonic uterus can be recognized quickly and massage applied. Incision and bleeding points are more easily visualized and repaired, especially if extensions were torn or the patient is obese. Adnexal exposure is superior, and thus, tubal sterilization is easier. In contrast, some clinicians prefer to close the hysterotomy with the uterus in situ. Comparing these two approaches, the Coronis Collaborative Group (2013) trial randomly assigned nearly 5000 parturients and found no differences in the endometritis or transfusion rate. In one large metaanalysis, nausea and vomiting and associated pain rates were comparable with either method (Zaphiratos, 2015).

Before hysterotomy closure, IUD insertion, if planned, is completed (Chap. 38, p. 668). Our practice is to perform a primary needle and sponge count prior to uterine incision closure completion. For closure, one end of the uterine incision is grasped to stabilize and maneuver the incision. The uterine incision is then closed with one or two layers of continuous 0- or no. 1 absorbable suture (Fig. 30-10). Chromic catgut suture is used by many, but some prefer synthetic delayed-absorbable polyglactin 910 (Vicryl). In subsequent pregnancy,

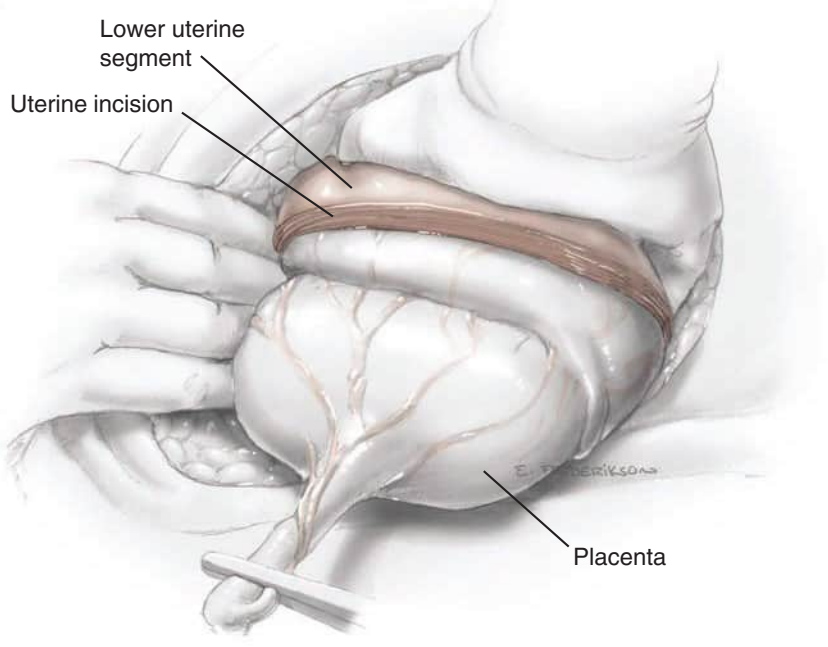

FIGURE 30-9 Placenta bulging through the uterine incision as the uterus contracts. A hand gently massages the fundus to help aid spontaneous placental separation.

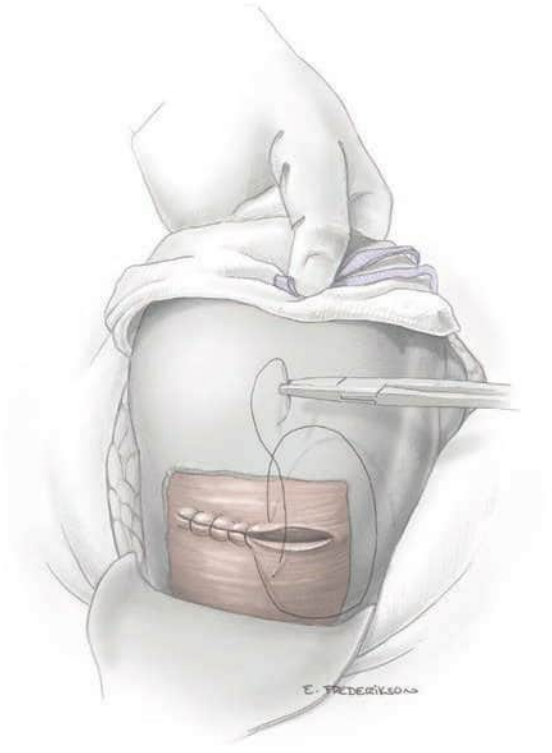

FIGURE 30-10 The cut edges of the uterine incision are approximated with a running, locking suture.

neither suture type is superior in mitigating against greater rates of adverse pregnancy outcomes such as uterine incision rupture (CORONIS Collaborative Group, 2016).

Single-layer closure is typically faster and is not associated with higher rates of infection or transfusion (CAESAR Study Collaborative Group, 2010; Dodd, 2014; Roberge, 2014). Moreover, most studies observed that the number of layers does not significantly affect complication rates in the next pregnancy (Chapman, 1997; CORONIS Collaborative Group, 2016; Durnwald, 2003). One randomized trial with nearly 1600 parturients found a slightly greater formation rate of cesarean scar niches at 3 months after double-layer closure (Stegwee, 2021).

At Parkland Hospital, we use a one-layer uterine closure with chromic catgut. The initial suture is placed just beyond one end of the uterine incision. A continuous, locking suture line for hemostasis is performed, and each suture penetrates the full myometrial thickness. The suture line then extends to a point just beyond the incision's opposite end. If bleeding sites or defects persist after a single layer, more sutures are required. Another layer of running suture or individually targeted figure-eight or mattress stitches are options.

Although not our routine practice, the peritoneum in the anterior cul-de-sac can be approximated with a continuous 2-0 chromic catgut suture line. Multiple randomized trials suggest that omission of this step causes no postoperative complications (Grundsell, 1998; Irion, 1996; Nagele, 1996). If tubal sterilization is planned, it is completed as described in Chapter 39 (p. 683).

Adhesions

Following cesarean delivery, adhesions commonly form within the vesicouterine space or between the anterior abdominal wall and uterus. With each successive pregnancy, the percentage of affected women and adhesion severity rise (Morales, 2007; Tulandi, 2009). Adhesions can significantly lengthen incision-to-delivery time and total operative time (Rossouw, 2013; Sikirica, 2012). Rates of cystotomy and bowel injury also are raised because of adhesive disease (Rahman, 2009; Silver, 2006).

Intuitively, scarring can be reduced by handling tissues delicately, achieving hemostasis, and minimizing tissue ischemia, infection, and foreign-body reaction. Most recent data on short- and long-term outcomes show no benefit to peritoneal closure (CAESAR Study Collaborative Group, 2010; CORONIS Collaborative Group, 2013, 2016; Kapustian, 2012). Similarly, most studies show no benefit from placement of an adhesion barrier at the hysterotomy site (Edwards, 2014; Kiefer, 2016).

Abdominal Closure

Any laparotomy sponges are removed, and the paracolic gutters and cul-de-sac are gently suctioned of blood and amniotic fluid. Some surgeons irrigate the gutters and cul-de-sac, especially in the presence of infection or meconium. Routine irrigation in low-risk women, however, leads to greater intraoperative nausea but not to lower postoperative infection rates (Eke, 2016; Viney, 2012).

Prior to abdominal closure, correct sponge and instrument counts are verified. The rectus abdominis muscle bellies are allowed to fall into place. The overlying rectus fascia is closed by a continuous, nonlocking technique with a delayed-absorbable suture. In patients with a higher risk for infection, monofilament suture may be preferable to braided material.

The subcutaneous tissue usually need not be closed if it is <2 cm thick. With thicker layers, however, closure is recommended to minimize seroma and hematoma formation, which can lead to wound infection, disruption, or both (Bohman, 1992; Chelmow, 2004). Adding a subcutaneous drain does not prevent significant wound complications (Hellums, 2007; Ramsey, 2005).

Skin is closed with a running subcuticular stitch of 4-0 delayed-absorbable suture, with adhesive glue, or with staples. In comparison, final cosmetic results and infection rates appear similar, skin suturing takes longer, but wound separation rates are higher with metal staples (Basha, 2010; Figueroa, 2013; Mackeen, 2014a, 2015). Poliglecaprone 25 (Monocryl) or polyglactin 910 (Vicryl) are both suitable (Tuuli, 2016). Outcomes with 2-octyl cyanoacrylate adhesive (Dermabond) were equivalent to sutures for Pfannenstiel incisions (Daykan, 2017; Siddiqui, 2013). A sterile thin abdominal wound dressing is sufficient. In obese women, most evidence favors against a negative-pressure wound vacuum atop the closed skin incision compared with a standard wound dressing to lower wound infection rates (Gillespie, 2021; Hussamy, 2019; Tuuli, 2020).

Joel-Cohen and Misgav Ladach Techniques

The Pfannenstiel-Kerr technique just described has been used for decades. Others include the more recent Joel-Cohen and Misgav Ladach techniques (Holmgren, 1999). These differ from traditional Pfannenstiel-Kerr entry mainly by their initial incision placement and greater use of blunt dissection.

The Joel-Cohen technique creates a straight 10-cm transverse skin incision 3 cm below the level of the anterior superior

iliac spines (Olofsson, 2015). The subcutaneous tissue layer is opened sharply 2 to 3 cm in the midline. This is carried down, without lateral extension, to the fascia. A small transverse incision is made in the fascia, and curved Mayo scissors are pushed laterally on each side and beneath intact subcutaneous fat to incise the fascia. With this incision completed, an index finger from each hand is inserted between the rectus abdominis muscle bellies and beneath the fascia. One finger is moved cranially and the other caudally, in opposition, to separate the bellies and further open the fascial incision. Then, a finger from each hand hooks under each belly to stretch the muscles laterally. The peritoneum is entered sharply, and this incision is sharply extended cephalocaudad. Entry with the Misgav Ladach technique differs in that the peritoneum is entered bluntly (Holmgren, 1999).

Modifications to the Joel-Cohen method abound. For emergency delivery, we begin along a line somewhat lower on the abdomen and similar to that for Pfannenstiel incision. For speed, we extend the initial fascial incision bluntly by hooking index fingers in the fascial incision's lateral corners and pulling laterally (Hofmeyr, 2009; Oloffson, 2015). Index fingers insinuated between the rectus bellies then move cephalocaudad in opposition to separate the muscle bellies. Blunt index-finger dissection enters the peritoneum, and again, cranial and caudad opposing stretch lengthens the peritoneal incision. Last, all the layers of the abdominal wall are grasped together and pulled laterally in opposition to further open the operating space.

These techniques have been associated with shorter operative times and with lower rates of intraoperative blood loss and postoperative pain (Mathai, 2013). They may, however, prove difficult for women with preexisting anterior rectus fibrosis and peritoneal adhesions (Bolze, 2013).

Classical Cesarean Incision

Indications. This incision is usually avoided because it encompasses the active upper uterine segment and thus is prone to rupture with subsequent pregnancies. Some indications stem from difficulty in exposing or safely entering the lower uterine segment. For example, a densely adhered bladder from previous surgery is encountered; a *leiomyoma* occupies the lower uterine segment; or the cervix is currently invaded by cancer. Women with prior radical trachelectomy for cervix cancer are usually delivered by classical incision. Massive maternal obesity can preclude safe access to the lower uterine segment. A classical incision is also preferred for placenta previa with anterior implantation, especially those complicated by placenta accreta syndrome. In extreme cases of this, the typical classical hysterotomy may be placed even higher in the uterine body or posteriorly to avoid the placenta. Fetuses with cephalic presentation are then delivered in a manner similar to total breech extraction.

In other instances, fetal indications dictate the need. *Transverse lie of a large fetus*, especially if the membranes are ruptured and the shoulder is impacted in the birth canal, usually requires a classical incision. Second, with a fetus presenting as a back-down transverse lie, the back precludes easy grasping of a leg through a transverse uterine incision for breech delivery. Here, a classical incision provides superior room. Third, in instances when the fetus is very small and breech, a classical incision may be preferable (Osmundson, 2013). In such cases, the poorly developed lower uterine segment provides inadequate space for the manipulations required for breech delivery. Or, less commonly, the small fetal head may become entrapped by a contracting uterine fundus following membrane rupture. With multiple fetuses, a classical incision again may provide needed room for extraction of fetuses that may be malpositioned or preterm (Osmundson, 2015). A large fetal malformation or conjoined twins may require the added space afforded by a classical incision.

Uterine Incision and Repair. A vertical uterine incision is initiated with a scalpel beginning as low as possible and preferably within the lower uterine segment (Fig. 30-11). If adhesions, insufficient exposure, a tumor, or placenta percreta preclude development of a bladder flap, then the incision is made above the level of the bladder. Described earlier (p. 553), back filling the bladder may aid this.

Once the uterus is entered with a scalpel, the incision is extended cephalad with bandage scissors until it is long enough to permit fetal delivery. With scissor use, the fetus can be better protected from laceration. Fingers of the surgeon's nondominant hand are insinuated between the myometrium and fetus to prevent scissor cuts. As the incision is opened, numerous large vessels that bleed profusely are commonly encountered within the myometrium. The remainder of fetal and placental delivery mirrors that with a low transverse hysterotomy.

For incision closure, one method employs a layer of 0- or no. 1 chromic catgut with a running stitch to approximate the

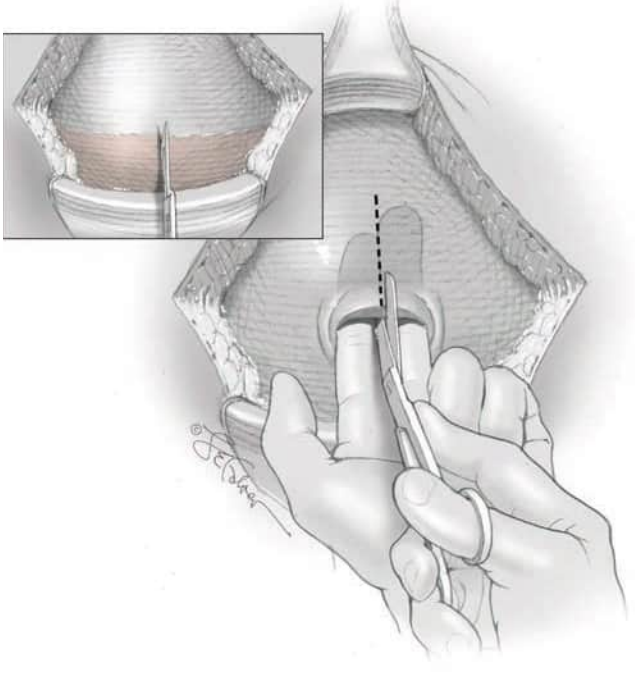

FIGURE 30-11 An initial small vertical hysterotomy incision is made in the lower uterine segment. Fingers are insinuated between the myometrium and fetus to avoid fetal laceration. Scissors extend the incision cephalad as needed for delivery. (Figures 30-11 and 30-12: Reproduced with permission from Johnson DD: Cesarean delivery. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

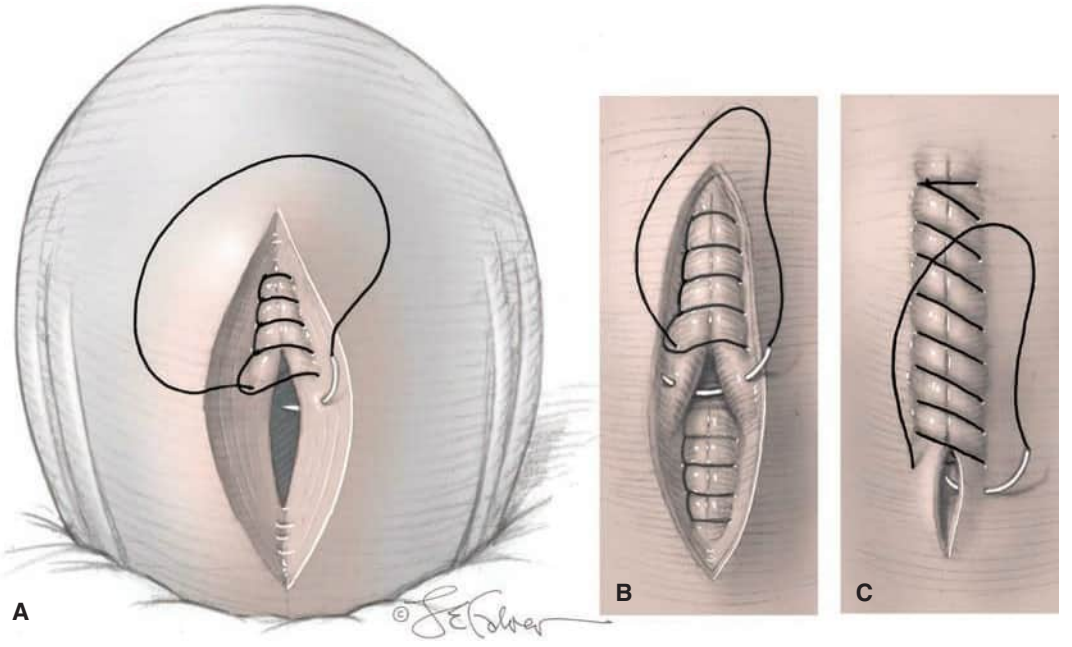

FIGURE 30-12 Classical incision closure. The deeper half (**A**) and superficial half (**B**) of the incision are closed in a running fashion. The serosa is then closed (**C**).

deeper length of the incision (Fig. 30-12). The outer layer of myometrium is then closed along its length with similar suture and with a running suture line. To achieve good approximation and to prevent the suture from tearing through the myometrium, it is helpful to have an assistant relieve tension by compressing the uterus on each side of the wound toward the midline as each stitch is placed.

PERIPARTUM HYSTERECTOMY

Indications

Hysterectomy is most commonly performed to arrest or prevent hemorrhage from intractable uterine atony, surgical trauma/tears, or abnormal placentation (Bateman, 2012; Kallianidis, 2020). It is more often completed during or after cesarean delivery but may be needed following vaginal birth. Among all deliveries, the peripartum hysterectomy rate in the United States approximates 1 per 1000 births and has risen significantly during the past few decades (Bateman, 2012; Govindappagari, 2016). During a 25-year period, the rate of peripartum hysterectomy at Parkland Hospital was 1.7 per 1000 births (Hernandez, 2012). Most of this rise is attributed to the increasing rates of cesarean delivery and its associated complications in subsequent pregnancy (Flood, 2009; Orbach, 2011). Of hysterectomies, approximately one half to two thirds are total, whereas the remaining cases are supracervical (Rossi, 2010; Shellhaas, 2009).

Major complications of peripartum hysterectomy include greater blood loss and risk of urinary tract damage. Blood loss is usually appreciable because hysterectomy is being performed for hemorrhage that frequently is torrential, and the procedure itself is associated with substantial bleeding. Although many cases with hemorrhage cannot be anticipated, those with abnormal implantation are often identified antepartum. Preparations for placenta accreta syndrome are discussed in Chapter 43 (p. 763) and are outlined by the American College of Obstetricians and Gynecologists (2018).

An important factor affecting the cesarean hysterectomy complication rate is whether the operation is performed electively or emergently. With anticipated or planned cesarean hysterectomy, rates of blood loss, blood transfusion, and urinary tract complications are lower those with emergent procedures (Briery, 2007; Glaze, 2008).

Hysterectomy Technique

Total or supracervical hysterectomy is performed using standard operative techniques. Adequate exposure is essential, but initially, placement of a self-retaining retractor such as a Balfour is not necessary. Rather, satisfactory exposure is obtained with cephalad traction on the uterus by an assistant, along with handheld Richardson or Deaver retractors. The bladder flap is deflected caudad to the level of the cervix if possible to permit total hysterectomy. In cases in which cesarean hysterectomy is planned or strongly suspected, extended bladder flap dissection is ideally completed before initial hysterotomy. Later attempts at bladder dissection may be obscured by bleeding, or excess blood may be lost during this dissection.

After cesarean delivery, the placenta is typically removed. In cases of placenta accreta syndrome for which hysterectomy is already planned, the placenta is usually left undisturbed in situ. If the hysterotomy incision is bleeding appreciably, it can be quickly reapproximated with full-thickness sutures, or Pennington or sponge forceps can be applied for hemostasis. If bleeding is minimal, neither maneuver is necessary.

The round ligament is divided close to the uterus between clamps, and each pedicle is ligated (Fig. 30-13). Either 0 or no.

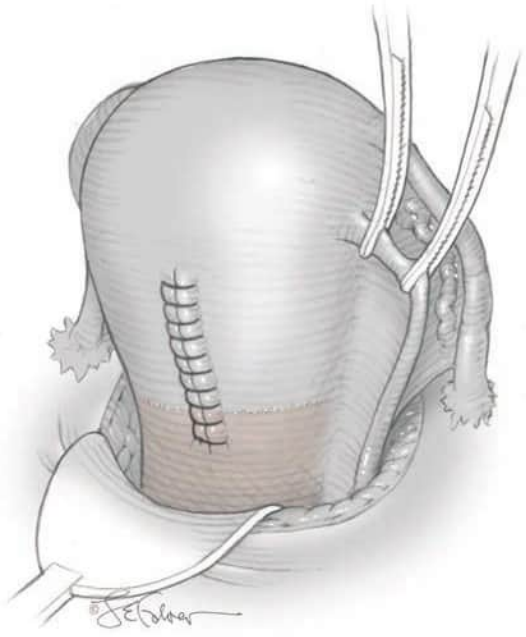

FIGURE 30-13 The round ligaments are clamped, ligated, and transected bilaterally. (Figures 30-13 to 30-21: Reproduced with permission from Cunningham FG, Gilstrap LC III: Peripartum hysterectomy. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

1 suture can be used in either chromic gut or delayed-absorbable material. Division of the round provides access to the anterior leaf of the broad ligament, which is incised downward to meet the former bladder flap incision. The posterior leaf of the broad ligament adjacent to the uterus is bluntly or sharply perforated at a point beneath the fallopian tube, uteroovarian ligament, and ovarian vessels (Fig. 30-14). These structures together are then divided between sturdy clamps placed close to the uterus (Fig. 30-15). The lateral pedicle is doubly ligated. The medial clamp remains and is removed later with the entire uterine specimen. The posterior leaf of the broad ligament

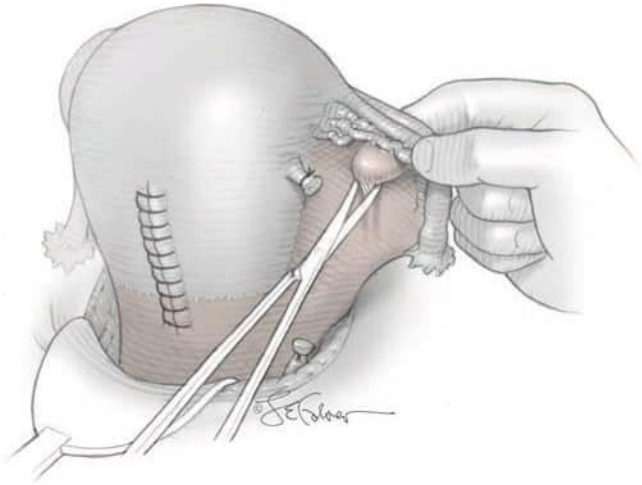

FIGURE 30-14 The posterior leaf of the broad ligament adjacent to the uterus is perforated just beneath the fallopian tube, uteroovarian ligaments, and ovarian vessels.

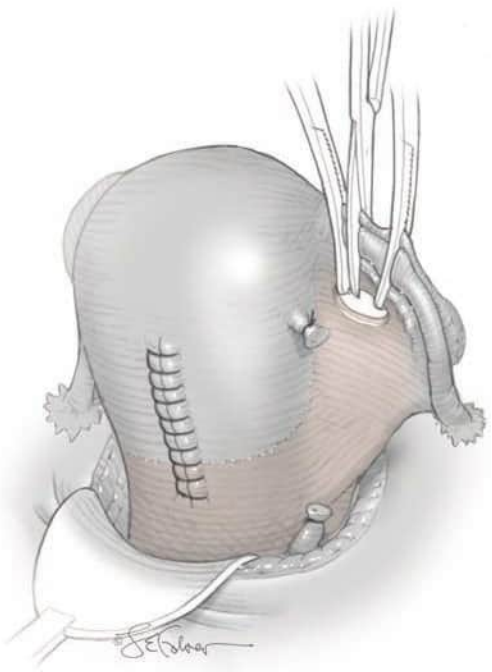

FIGURE 30-15 The uteroovarian ligament and fallopian tube are clamped and cut. The lateral pedicle is doubly ligated.

is then incised caudad toward the uterosacral ligaments (Fig. 30-16). The bladder and attached peritoneal flap are further deflected and dissected as needed. If the bladder flap is densely adhered, as it may be after previous hysterotomy incisions, careful sharp dissection is employed (Fig. 30-17).

Special care is required from this point on to avoid injury to the ureters, which pass beneath the uterine arteries. To help accomplish this, an assistant places constant traction to pull the

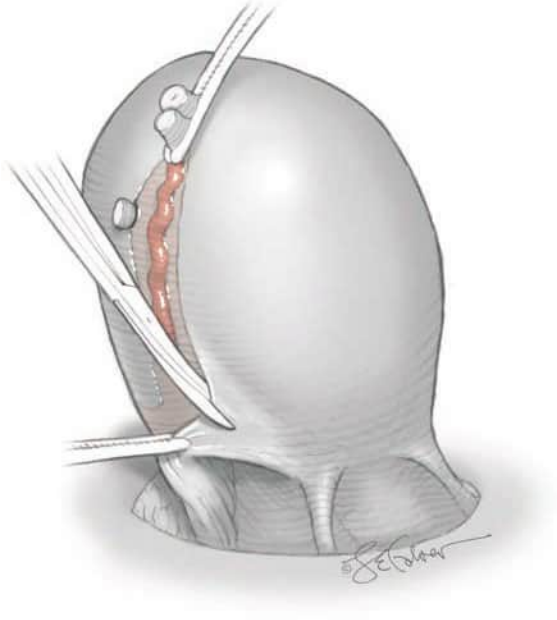

FIGURE 30-16 The posterior leaf of the broad ligament is divided inferiorly toward the uterosacral ligament.

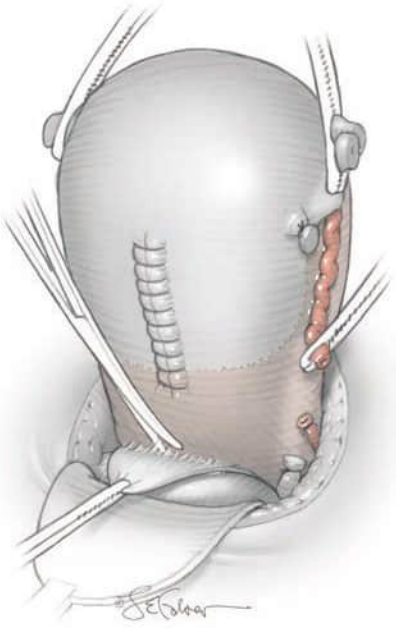

FIGURE 30-17 The bladder is dissected sharply from the lower uterine segment.

uterus in the direction away from the side on which the uterine vessels are being ligated. The ascending uterine artery and veins on either side are identified. These vessels are then clamped adjacent to the uterus (Fig. 30-18). For security, some may prefer two lateral clamps. The medial-most clamp helps prevent back bleeding from the uterus. The uterine vessels are divided, and the lateral tissue pedicle is doubly suture ligated. The medial clamp remains for later removal with the specimen. After securing the uterine vessels on one side, the round ligament, adnexal pedicle, and uterine vessels are then addressed on the contralateral side.

In cases with profuse hemorrhage, time and rapid hemostasis can be gained by quickly clamping and dividing all of the just-described pedicles. Once all are clamped, the surgical team can then return to ligate each pedicle individually.

Total Hysterectomy

Even if total hysterectomy is planned, we find it technically easier in many cases to finish the operation after amputating the uterine fundus and placing Ochsner or Kocher clamps on the cervical stump for traction and hemostasis. Self-retaining retractors also may be placed at this time. To remove the cervix, the bladder is mobilized further if needed. This carries the ureters caudad as the bladder is retracted beneath the symphysis. Bladder retraction can also help prevent laceration or suturing of the bladder during cervical excision and vaginal cuff closure.

The cardinal ligament, the uterosacral ligaments, and the many large vessels within these ligaments are clamped systematically with sturdy Heaney-type curved or straight clamps (Fig. 30-19). The clamps are placed as close to the cervix as possible, taking care not to include excessive tissue in each clamp. The tissue between the pair of clamps is incised, and the lateral pedicle is suture ligated. These steps are repeated caudally and bilaterally until the level of the lateral vaginal fornix is reached on each side. In this way, the descending branches of the uterine vessels are clamped, cut, and ligated as the cervix is separated from the cardinal ligaments.

If the cervix is effaced and dilated considerably, its softness may obscure palpable identification of the cervicovaginal junction. The junction location can be ascertained either through the open hysterotomy incision or through a vertical uterine incision made anteriorly in the midline at the level of the ligated uterine vessels. A finger is directed inferiorly through the incision to identify the free margin of the dilated, effaced cervix. The contaminated glove is replaced. Another useful method to

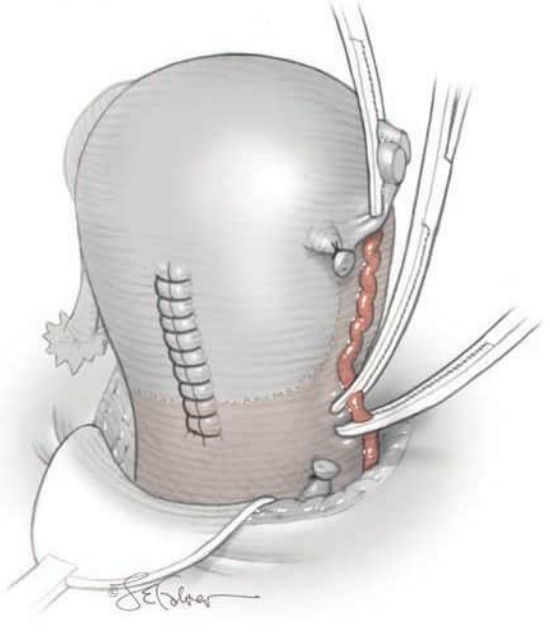

FIGURE 30-18 The uterine vessels are clamped. Once divided, the lateral vascular pedicle is doubly ligated to ensure hemostasis.

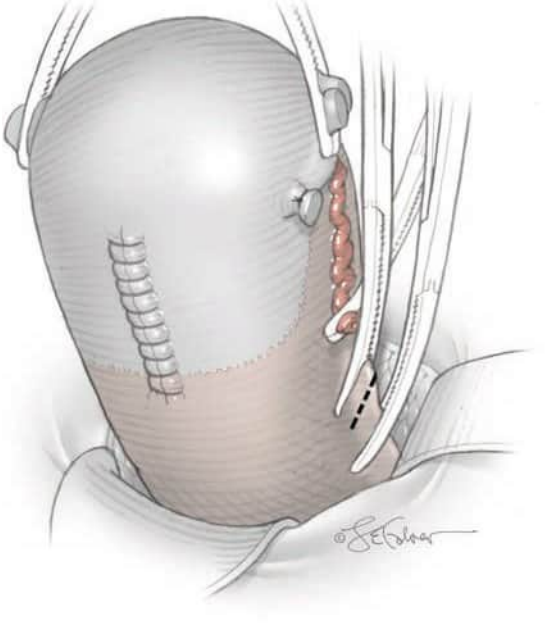

FIGURE 30-19 The cardinal ligaments are clamped, incised, and ligated.

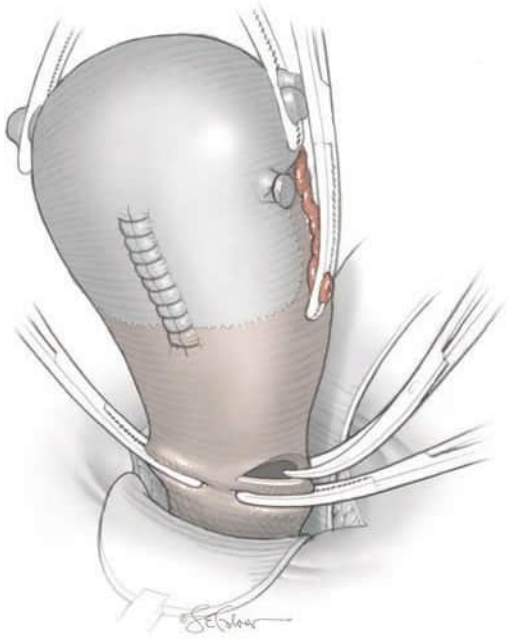

FIGURE 30-20 A curved clamp is placed across the lateral vaginal fornix below the level of the cervix, and the tissue incised medially to the point of the clamp.

identify the cervical margins in cases of planned hysterectomy is to transvaginally place four metal skin clips or brightly colored sutures at 12, 3, 6, and 9 o'clock positions on the cervical edges.

Immediately below the level of the cervix, a curved clamp is placed across the lateral vaginal fornix on each side, and the vagina is incised above the clamp (Fig. 30-20). The cervix is inspected to ensure that it has been completely removed. A transfixing suture is used for vaginal cuff closure as each clamp is removed. Interrupted stitches may be added to approximate the middle portion of the cuff (Fig. 30-21). Each lateral vaginal fornix is secured to the uterosacral ligaments to mitigate later vaginal prolapse. For cuff closure, some surgeons instead prefer to close the vagina by apposing the anterior and posterior vaginal walls with interrupted figure-eight sutures or running suture line.

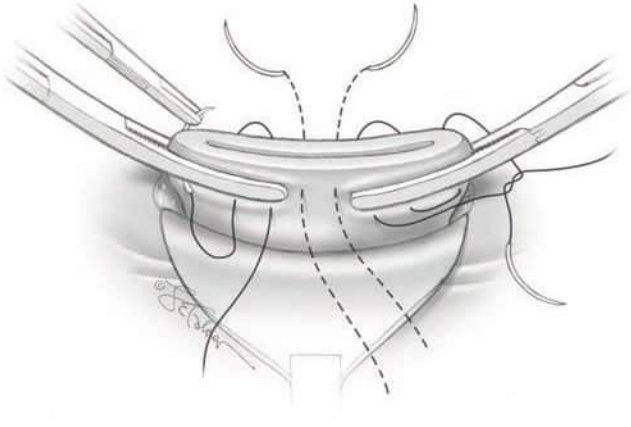

FIGURE 30-21 A transfixing stitch is placed on each side to close the lateral vaginal cuff. Interrupted stitches (dotted lines) may be needed to close any midline gap.

All sites are examined carefully for bleeding. One technique is to perform a systematic bilateral survey from the fallopian tube and ovarian ligament pedicles to the vaginal vault and bladder flap. Bleeding sites are ligated with care to avoid the ureters. The abdominal wall normally is closed in layers, as previously described for cesarean delivery (p. 558).

Supracervical Hysterectomy

To perform a subtotal hysterectomy, the uterine body is amputated immediately above the level of uterine artery ligation. The cervical stump may be closed with a continuous or interrupted suture line of chromic catgut or delayed-absorbable material. Subtotal hysterectomy is often all that is necessary to stop hemorrhage. It may be preferred for women who would benefit from a shorter surgery or for those with extensive adhesions that threaten significant urinary tract injury.

Salpingo-oophorectomy

Because of the large adnexal vessels and their close proximity to the uterus, it may be necessary to remove one or both adnexa to obtain hemostasis. Briery and colleagues (2007) reported unilateral or bilateral oophorectomy in a fourth of cases. Preoperative counseling for anticipated hysterectomy should include this possibility.

■ Urinary Tract or Bowel Injury

These injuries are rare during cesarean delivery. The bladder laceration rate approximates 2 injuries per 1000 cesarean deliveries, whereas that for ureteral trauma nears 0.3 events per 1000 cases (Güngördük, 2010; Oliphant, 2014). Bowel is damaged in about 1 in 1000 cesarean deliveries (Silver, 2006).

Cystotomy

Bladder laceration most commonly occurs during blunt or sharp dissection in the vesicouterine space to create the bladder flap, during peritoneal cavity entry, and during hysterotomy (Phipps, 2005; Rahman, 2009). Risks are prior cesarean delivery; comorbid adhesive disease; emergency cesarean delivery; cesarean hysterectomy, especially cases with morbidly adherent placenta; and surgery in second-stage labor compared with first-stage (Alexander, 2007; Salman, 2017; Silver, 2006).

Bladder injury is typically identified intraoperatively, and a clear-fluid gush or the Foley bulb are indicators. In suspected cases, cystotomy can be confirmed with retrograde instillation of fluid through a Foley catheter and into the bladder. Dilute sterile infant formula is a common, available option. Methylene blue–stained saline is another. Leakage of the indicator fluid aids laceration identification and delineation of its borders. The dome is lacerated most often, and trigone injuries make up the remainder (Phipps, 2005; Salman, 2017).

Prior to cystotomy repair, ureters are examined, and urine jets from each orifice are sought. Inspection can be done directly through the cystotomy, if at the dome. A separate diagnostic extraperitoneal cystotomy may be preferable if the laceration nears the trigone. To aid viewing, urine jets can be colored by IV dye, as described in the next section.

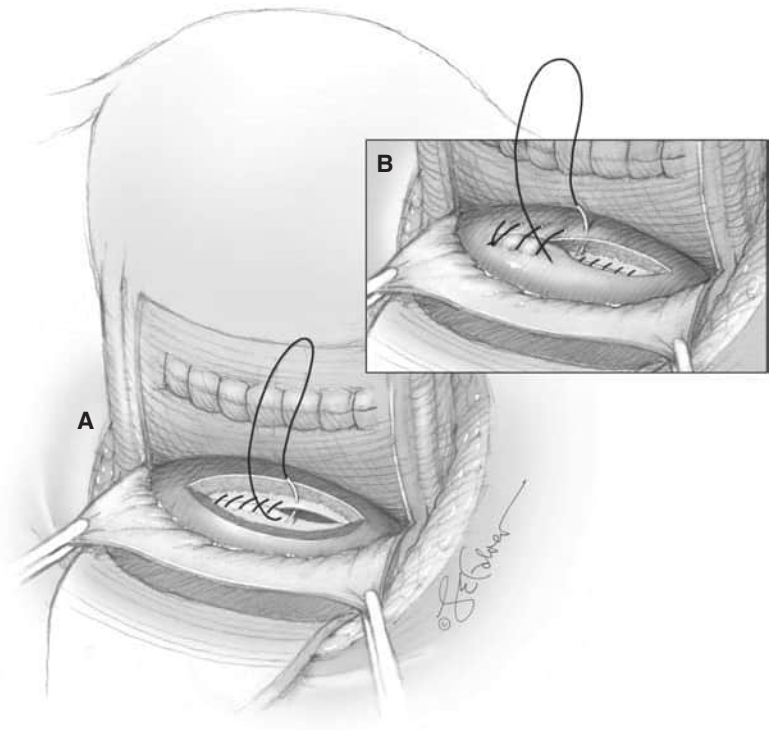

FIGURE 30-22 Cystotomy repair. **A.** The primary layer inverts the bladder mucosa with running or interrupted sutures of 3-0 delayed-absorbable or absorbable suture. **B.** Second and possibly a third layer approximate the bladder muscularis to reinforce the incision closure. (Reproduced with permission from Balgobin S: Urologic and gastrointestinal injuries. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

Once ureteral patency is confirmed, the bladder can be closed with a two- or three-layer running closure using a 3-0 absorbable or delayed-absorbable suture (Fig. 30-22). The first layer inverts the mucosa into the bladder. Subsequent layers reapproximate the bladder muscularis. After the final layer, the bladder is filled with a marker fluid to demonstrate repair integrity. Leaking defects are closed with interrupted reinforcing stitches.

Postoperative care requires continuous bladder drainage for 7 to 14 days to permit healing and minimize the risk of fistula formation. Uropathogen prophylaxis during this drainage is not required. Prior to catheter removal, cystourethrography may not be needed for a simple, single laceration measuring under 1 cm (Glaser, 2019).

Larger lacerations in or near the trigone require careful attention. Specialists may be consulted, and in preparation, ureteral catheters, described in the next section, can be assembled. Ureteral orifices are directly inspected to document jets from both. If not seen, a ureteral catheter may be passed through the cystotomy and into each orifice to confirm patency. Once this is confirmed, repair should not disrupt the ureteral orifices, and stents may remain to ensure their patency.

Unrecognized cystotomy can manifest postoperatively as hematuria, oliguria, abdominal pain, ileus, ascites, peritonitis, fever, urinoma, or fistula. For diagnosis, retrograde cystography or abdominal computed tomography (CT) with cystography can be used (Tarney, 2013). Cystoscopy is also an option but may require a procedural room. Once cystotomy is identified, prompt repair is indicated (Balgobin, 2017).

Ureteral Injury

The ureter may be at risk during cesarean hysterectomy, especially those complicated by placenta accreta syndrome. (Woldu, 2014). Although not our practice, some advocate preoperative ureteral catheter placement to aid intraoperative ureter identification (Eller, 2009; Matsubara, 2013). Organization guidelines recommend individualization of this practice depending on anticipated placenta accreta syndrome complexity (American College of Obstetricians and Gynecologists, 2018; Collins, 2019). Further, initial dorsal lithotomy positioning of the patient for these cases can permit cystoscopy. Aside from hysterectomy, the ureter is also at risk during repair of hysterotomy extensions into the broad ligament or vagina (Safrai, 2020).

If ureteral injury is suspected, IV dye is administered, and the pelvis is directly inspected for extravasation. Of options, 50 mg of IV methylene blue may be given over 5 minutes. However, methylene blue carries the potential for inciting methemoglobinemia in patients with glucose-6-phosphate dehydrogenase deficiency. Another option is 25 or 50 mg of IV 10-percent sodium fluorescein, which stains bright yellow (Espaillat-Rijo, 2016; Grimes, 2017).

Next, brisk dye-stained urine jets are sought from each orifice to exclude ureteral kinking or ligation. Orifice viewing may be via cystoscopy, if available; through a comorbid traumatic cystotomy; or through an intentional diagnostic cystotomy. For the last, a midline extraperitoneal cystotomy in the bladder dome gives excellent exposure. Sluggish or absent jets may reflect patient hypovolemia, and ongoing volume resuscitation may yield expected orifice jets. If not, consultation with a specialist is typically requested to exclude ureteral injury.

While waiting, catheters and stents can be assembled. Semantically, *ureteral catheters* are diagnostic tools, and typically are inserted and removed in the same therapeutic intervention. Most stents are designed to remain indwelling for prolonged ureteral drainage. Both types are hollow to permit radiopaque medium injection and to allow urine egress through or around them (Corton, 2020).

To exclude ureteral obstruction, a 4F to 6F open-ended or whistle-tip catheter is threaded into one orifice. Once inserted, the catheter is advanced to the level of suspected obstruction. If the tool threads easily up toward the renal pelvis, obstruction is unlikely. In most, ureteral injury occurs at or below the pelvic brim, and the distance from the ureteral orifice to the brim approximates 13 cm (Jackson, 2019). Failure to easily advance the catheter may indicate ureteral kinking, ligation, or crush injury. The appearance of the catheter in the abdominal cavity indicates partial or complete transection (Balgobin, 2017).

Repair of ureteral injuries is dependent upon the type of injury and location.

First, kinked or ligated ureters can be relieved by release of ensnaring sutures. Crush injuries are inspected to ensure vital tissue. In these cases, stents are left to avert ureteral stricture. Ureteral stents range from 4F to 7F. Stents vary in length from 20 to 30 cm, and a 24-cm or 26-cm length is appropriate for most adults. Double-pigtail or double-J stents describe their tip shape, and the ends coil within the renal pelvis and bladder, respectively, to prevent stent migration (Corton, 2020). A Foley catheter remains for 7 to 10 days, and the ureteral stents are removed via cystoscopy after 14 days. Intravenous pyelography (IVP) is usually not necessary before removal of the stent if it was placed as a precautionary measure after relatively minor injury (Davis, 1999).

Crush injuries with devascularization, thermal injury, or transection require more extensive repair. If a healthy-appearing ureter can be reimplanted into the bladder without undue tension, then ureteroneocystostomy is preferable. For more proximal injuries, a ureteroureterostomy, a psoas hitch, or a Boari flap may be needed. An explanation of these more extensive procedures is found in *Cunningham and Gilstrap's Operative Obstetrics*, 3rd edition (Balgobin, 2017).

Unrecognized ureteral injury can mimic that of cystotomy with the addition of possible costovertebral angle tenderness. CT urography is a preferred initial diagnostic tool (Sharp, 2016). The duration of time from injury to identification directs repair. Those identified early are often suitable for immediate repair.

Bowel Injury

Serosal tears represent weak points in the small bowel. If obstruction develops postoperatively, these weak spots may perforate, leading to peritonitis. If serosal tears are few, they can be oversewn with either a fine absorbable or nonabsorbable suture (Davis, 1999). More significant lacerations are often repaired in consultation with a general surgeon or gynecologic oncologist.

POSTOPERATIVE CARE

Euvolemia Evaluation

During and after cesarean delivery, requirements for IV fluids can vary considerably. Current ERAS strategies aim for euvolemic replacement (Caughey, 2018). Administered fluids consist of either lactated Ringer solution or a similar crystalloid solution with 5-percent dextrose. Blood loss with uncomplicated cesarean delivery approximates 1000 mL. The average-sized woman with a hematocrit of 30 percent or more and with a normally expanded blood and extracellular fluid volume most often will tolerate blood loss up to 2000 mL without difficulty. Unappreciated bleeding through the vagina during the procedure, bleeding concealed in the uterus after its closure, or both commonly lead to underestimation.

Blood loss averages 1500 mL with elective cesarean hysterectomy, although this is variable (Pritchard, 1965). Most peripartum hysterectomies are unscheduled, and blood loss in these cases is correspondingly greater. Thus, in addition to close monitoring of vital signs and urine output, the hematocrit should be determined intra- or postoperatively as indicated.

Recovery Suite

The amount of vaginal bleeding is closely monitored for at least an hour in the immediate postoperative period. The uterine fundus is also identified frequently by palpation to ensure that the uterus remains firmly contracted. Criteria for transfer to the postpartum ward include minimal bleeding, stable vital signs, and adequate urine output.

Hospital Care until Discharge

Analgesia, Vital Signs, Intravenous Fluids

Several schemes are suitable for postoperative pain control. First, adding intrathecal opioid or epidural opioid such as morphine to neuraxial analgesia can provide 12 to 24 hours of postoperative relief (American College of Obstetricians and Gynecologists, 2019a; Caughey, 2018). Sedation and respiratory depression rise with increasing intrathecal opioid doses. Postoperative monitoring protocols reflect this and are outlined in Chapter 25 (p. 472) (Bauchat, 2019). Other potential side effects include pruritus, nausea, or vomiting (Sultan, 2016). Despite these, long-acting neuraxial analgesia is recommended instead of intermittent parental opioid dosing (American Society of Anesthesiologists, 2016). For additional relief, nonsteroidal antiinflammatory drugs (NSAIDs) can alternate with acetaminophen (Ong, 2010). Breakthrough pain can be relieved by oxycodone 2.5 to 5 mg every 4 hours (Bollag, 2021). Neonatal sedation is a concern, and total oxycodone doses higher 30 mg/d are not recommended (American College of Obstetricians and Gynecologists, 2019a). Instead, for severe breakthrough pain, intramuscular (IM) meperidine, 50 to 75 mg every 3 to 4 hours, or IM morphine, 10 to 15 mg every 3 to 4 hours, is an option.

For those without neuraxial anesthesia, a transversus abdominis place (TAP) block can be considered (Fig. 2-2, p. 14). Patient-controlled analgesia (PCA) also is reasonable. One PCA regimen uses IV morphine given as needed as a 1-mg dose with a 6-minute lockout interval and maximum dose of 30 mg in 4 hours. An additional 2-mg booster dose is permitted for a maximum of two doses.

After transfer to her room, the woman is assessed at least hourly for 4 hours, and thereafter at intervals of 4 hours. Deep breathing and coughing are encouraged to prevent atelectasis. Vital signs, uterine tone, urine output, and vaginal and incisional bleeding are evaluated. The hematocrit is routinely measured the morning after surgery. It is checked sooner if blood loss was significant or if postoperative hypotension, tachycardia, oliguria, or other evidence suggests hypovolemia. If the hematocrit is significantly lower than the preoperative level, the measurement is repeated and a search for the cause is instituted. Clinical and objective thresholds for transfusion are described fully in Chapter 44 (p. 771). If ongoing blood loss is not expected, iron therapy is preferred to transfusion.

Postpartum, the patient begins to mobilize and excrete her physiologically expanded extravascular volume. Thus, maintenance IV fluid proves adequate after surgery until consistent oral intake is reestablished. If urine output falls below 30 mL/hr, however, a woman should be reevaluated promptly. The cause of the oliguria may range from unrecognized blood loss to an antidiuretic effect from infused oxytocin.

Women undergoing unscheduled cesarean delivery may have pathological retention or constriction of the extracellular fluid compartment caused by severe preeclampsia, sepsis syndrome, vomiting, prolonged labor without adequate fluid intake, or increased blood loss. Women with these complications are generally observed in the recovery room until improved.

Bladder and Bowel Function

A Foley catheter is often required to accurately assess urinary output. For women not needing such monitoring, organizations differ in their recommendations. The Society for Obstetric Anesthesia and Perinatology suggests removal after 6 to 12 hours and cites the urinary retention risks associated with long-acting neuraxial anesthesia (Bollag, 2021). The ERAS Society recommends immediate postoperative removal (Macones, 2019). The prevalence of urinary retention following cesarean delivery approximates 5 percent (Chap. 36, p. 643). Failure to progress in labor and postoperative narcotic analgesia are identified risks (Chai, 2008; Liang, 2007).

In uncomplicated cases, liquids or solid food may be offered within hours of surgery and advanced as tolerated (Guo, 2015; Macones, 2019). Some degree of adynamic ileus follows virtually every laparotomy but is negligible after most cesarean deliveries. Postoperative ileus symptoms include abdominal distention, colic, and an inability to pass flatus or stool. With persistent nausea and vomiting or with prolonged bowel function delay, radiological imaging may help exclude bowel obstruction. A plain abdominal radiograph is a frequent first choice. However, in the general population, this study is diagnostic in only 50 to 60 percent of small-bowel obstruction (SBO) cases (Maglinte, 1997). Thus, a radiograph may best serve as a triage tool in cases in which ileus is the suspected diagnosis. Notably, an enlarged postpartum uterus can compress the rectosigmoid and prevent it from filling with gas. Thus, findings suggesting a distal colonic obstruction may confuse true cases of transient ileus (Kammen, 2000). CT with IV and oral contrast provides greater accuracy for SBO diagnosis. Last, although uncommon, an unrecognized bowel injury may underlie otherwise unexplained fever and bowel dysfunction. Again, CT would be the more diagnostic examination.

For treatment of ileus, IV fluids compensate for poor oral intake and losses from emesis. Electrolyte imbalances are corrected to improve bowel motility and avoid bowel edema. Nasogastric decompression is necessary only with persistent vomiting or severe distention.

For prevention, surgical goals strive to minimize bowel manipulation, avoid excess IV fluids or profound hypovolemia, and limit surgery length (Bragg, 2015). After surgery, gum chewing enhances early bowel function recovery (Ciardulli, 2018). Among studies, chewing was initiated immediately or up to 12 hours later, lasted 15 to 60 minutes, and was repeated in at least three sessions daily (Pereira Gomes Morais, 2016).

Ambulation and Wound Care

As discussed earlier, women undergoing cesarean delivery have an increased VTE risk compared with those delivering vaginally (Chap. 55, p. 989). Early ambulation lowers this risk. Walking to the bathroom begins, initially with assistance. Brief walks are encouraged. For women with marked abdominal laxity, an abdominal binder can aid comfortable deep coughing and ambulation. Evidence supporting routine application for all parturients is limited and conflicting (Chankhunaphas, 2020; Gillier, 2016).

Although not evidence based, we remove the surgical dressing after 24 hours and inspect the incision daily. One small randomized trial showed no wound healing effects if removed at 6 hours (Peleg, 2016). By the third postpartum day, showering does not harm the incision. Prior to this, a plastic covering can maintain dryness during showers. If used, staples are often removed on the fourth postoperative day. In their place, tape strips can remain for 1 week to reinforce skin edge integrity. If potential superficial wound separation, without infection, is a concern, staples can remain for 7 to 10 days.

Hospital Discharge

For uncomplicated cesarean delivery, the average hospitalization length is 3 to 4 days (Buie, 2010). Data from studies suggest that earlier discharge is feasible for properly selected women and newborns (Bayoumi, 2016; Tan, 2012). Protocols ideally include earlier reevaluation for neonatal jaundice. However, discharge before 96 hours leads to a greater neonatal readmission rate (Jones, 2020).

Activities during the first week are limited to self-care and newborn care with assistance. Driving can be resumed when pain does not limit the ability to brake quickly and when narcotic medications are not in use. In women with cesarean delivery, intercourse was resumed in 44 percent by 6 weeks postpartum, 81 percent by 3 months, and 97 percent at 1 year (McDonald, 2013). After the puerperium, the quality of sexual functioning does not differ between those undergoing spontaneous vaginal birth or cesarean delivery (Chang, 2015; Fehniger, 2013; Rogers, 2014). Return to work is variable. Six weeks is commonly cited, although many women use the Family and Medical Leave Act to allow up to 12 weeks for recovery and newborn bonding.

CHAPTER 31

Prior Cesarean Delivery

By the beginning of the 20th century, cesarean delivery had become a relatively safe procedure. However, rupture of the uterine scar with subsequent labor was appreciated early. This danger resulted in the oft-quoted remark by Cragin (1916) that "Once a cesarean, always a cesarean." During the intervening 50 years, enthusiasm developed to allow many of these women to be delivered vaginally. But, as chronicled next, this support has waned during the past three decades. So, as we reach the 100-year mark of Cragin's pronouncement, the issue remains largely unsettled.

100 YEARS OF CONTROVERSY

Despite Cragin's early philosophy, some practitioners did allow labor in a subsequent pregnancy after a cesarean delivery. Eastman (1950) described a 30-percent postcesarean vaginal delivery rate at Johns Hopkins Hospital. He also reported a 2-percent uterine rupture rate and associated 10-percent maternal mortality rate. As modern techniques made cesarean delivery safer, observational studies during the 1960s suggested that postcesarean vaginal delivery was a reasonable option (Pauerstein, 1966, 1969). Germane to this is that through the 1960s, the overall cesarean delivery rate approximated only 5 percent. Since then, as the primary cesarean rate has escalated, the repeat cesarean delivery rate followed (Rosenstein, 2013).

During the 1980s, a National Institutes of Health (NIH) Consensus Development Conference on Vaginal Birth After Cesarean (1981) was convened, and the participants questioned the necessity of routine repeat cesarean delivery. With support and encouragement from the American College of Obstetricians and Gynecologists (1988, 1994), enthusiastic attempts were begun to increase the practice rate of *vaginal birth after cesarean—VBAC*. These attempts were highly successful, and VBAC rates rose from 3.4 percent in 1980 to a peak of 28.3 percent in 1996. This rate and a concomitant decline in total cesarean delivery rate for the United States, are shown in Figure 31-1. Also, a new lexicon was developed to describe these practices and outcomes (Table 31-1).

However, with the higher postcesarean vaginal delivery rate, reports of uterine rupture-related maternal and perinatal morbidity and mortality began to appear (McMahon, 1996; Sachs, 1999). These complications dampened prevailing enthusiasm for a *trial of labor after cesarean section (TOLAC)*. They also prompted the American College of Obstetricians and Gynecologists (1998) to caution that such trials should be attempted only in appropriately equipped institutions with physicians *readily available* to provide emergency care. Less than a year later, the College (1999) recommended that physicians should be *immediately available* when pursuing a TOLAC. Many believe that this one-word change—from *readily* to *immediately* available—was an impetus for the resulting decade-long decline in national VBAC rates illustrated in Figure 31-1 (Cheng, 2014; Leeman, 2013).

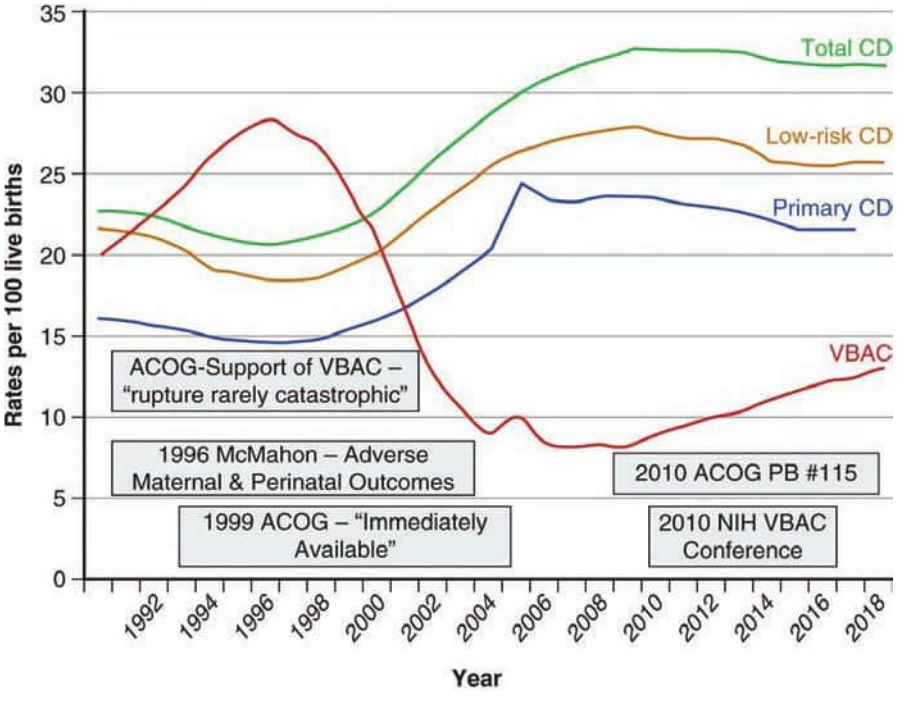

FIGURE 31-1 Total, primary, and low-risk cesarean delivery (CD) rates and vaginal birth after previous cesarean (VBAC) rates in the United States, 1989–2018. Epochs denoted within rectangles represent contemporaneous ongoing events related to these rates. ACOG = American College of Obstetricians and Gynecologists; NIH = National Institutes of Health; PB = practice bulletin. (Data from Hamilton, 2015, 2016; Martin, 2019; National Institutes of Health: NIH Consensus Development Conference, 2010.)

Using birth certificate data for 2013, Curtin and associates (2015) reported that only 1 in 5 women with one prior cesarean delivery attempted a TOLAC. In women with two or more prior cesarean deliveries, less than 1 in 10 women attempt a TOLAC, and half resulted in successful vaginal deliveries. At Parkland Hospital, although only 15 percent of women choose a TOLAC, the VBAC rate is 86 percent.

Thus, multiple interrelated factors—both medical and nonmedical—undoubtedly contributed to declining VBAC rates. Because of this, in 2010 the NIH convened a Consensus Development Conference Panel to study the issue. The panel report included a contemporaneous summary concerning the risks and benefits of repeat cesarean versus vaginal delivery. These findings were subsequently described and coupled with current recommendations by various professional organizations. As shown in Figure 31-1, it would seem that this report was followed by a slight rise in the VBAC rate.

In a cross-sectional analysis between 1990 and 2009, the proportion of women with a prior cesarean delivery who underwent a TOLAC peaked in 1995, and slightly more than half of these women chose this option (Fig. 31-2). After this, the proportion of women *attempting* TOLAC declined to a nadir of 16 percent in 2006 and subsequently rose to 21 percent through 2009. Additionally, the percentage of VBACs reached its peak of 70 percent in 2000 but subsequently declined to a nadir of 38 percent in 2006 (Uddin, 2013).

TABLE 31-1. Acronyms Used to Describe Management of Women with a Prior Cesarean Delivery

CD: cesarean delivery
TOL: trial of labor
VBAC: vaginal birth after CD
TOLAC: trial of labor after CD
Failed TOLAC: resulting in CD
Successful TOLAC: resulting in VBAC
ERCD: elective repeat cesarean delivery
Scheduled ERCD: CD planned before labor
Unscheduled ERCD: planned scheduled CD but indications for early delivery, e.g., spontaneous labor, abruption, etc.
Uterine rupture:
Complete: all uterine wall layers separated
Incomplete: uterine dehiscence with uterine muscle separated but peritoneum intact

INFLUENCING FACTORS

For the woman with a prior cesarean delivery, planning for future pregnancies and delivery route should begin with preconceptional counseling and be addressed again early in prenatal care. Importantly, decisions made throughout pregnancy regarding delivery mode are subject to continuing revisions as dictated by exigencies that arise during pregnancy. Assuming no mitigating circumstances, there are two basic choices. First,

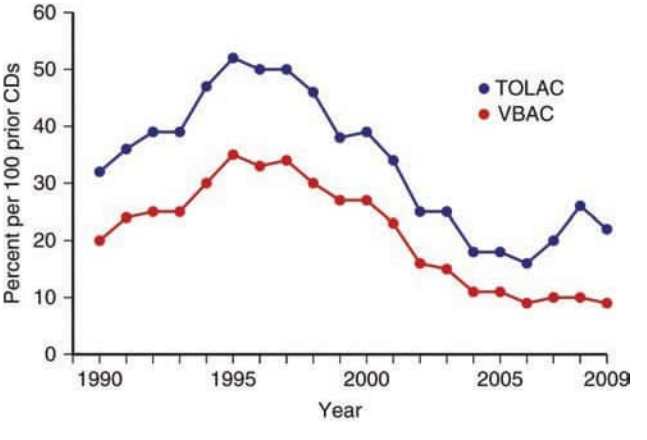

FIGURE 31-2 Percentage of women with a prior cesarean delivery who attempted a trial of labor (TOLAC) compared with the successful vaginal delivery (VBAC) rate for the United States 1990–2009. (Data from Centers for Disease Control and Prevention; National Center for Health Statistics; Curtin, 2015; Simon, 2013; Uddin, 2013).

TABLE 31-2. Some Factors That Influence a Successful Trial of Labor in a Woman with Prior Cesarean Delivery (CD)

Low-Risk	Favors Success	Increased Failure Rate	High-Risk[a]
Transverse incision	Teaching hospital	Single mother	Classical or T incision
Prior vaginal delivery	White race	Advanced maternal age	Prior uterine rupture
Appropriate counseling	Spontaneous labor	Macrosomic fetus	Patient refusal
Sufficient personnel and equipment	Prior indication of fetal malpresentation	Obesity	Transfundal surgery
	1 or 2 prior low transverse incisions	Current breech	Obstetrical contraindication, e.g., previa
	Nonrecurrent indication	Multifetal pregnancy	Prior open maternal–fetal surgery
	Current preterm pregnancy	Preeclampsia	Inadequate obstetrical or anesthesia staff coverage
		EGA >40 weeks	
		Low vertical incision	
		Unknown incision	
		Labor induction	
		Medical disease	
		Multiple prior CDs	
		Education <12 years	
		Short interdelivery interval	
		Liability concerns	

[a]Most consider these absolute contraindications.
EGA = estimated gestational age.

a *TOLAC* offers the goal of achieving a *VBAC*. If cesarean delivery becomes necessary during the trial, it is a *failed TOLAC*. A second choice is *elective repeat cesarean delivery (ERCD)*. This includes scheduled cesarean delivery as well as unscheduled but planned cesarean delivery for spontaneous labor or another delivery indication.

The decision regarding delivery mode should weigh clinical factors known to influence TOLAC success as well as benefits and risks (Table 31-2). As expected, TOLAC rates vary between institutions and providers. Last, economics, staffing, and medicolegal factors also may shape the decision to offer TOLAC.

DELIVERY ROUTE RISKS

As evidence mounted that the uterine rupture risk might be greater than expected, the American College of Obstetricians and Gynecologists (1988, 1994, 1998, 1999, 2015, 2019a,d) issued updated bulletins supporting TOLAC but also urging a more cautious approach. *It is problematic that both options have risks and benefits to mother and fetus but that these are not always congruent.*

Maternal Risks

Rates of uterine rupture and associated complications clearly are increased with TOLAC. As shown in Table 31-1, uterine rupture typically is classified as either: (1) *complete*, when all uterine wall layers are separated, or (2) *incomplete*, when the uterine muscle is separated but the visceral peritoneum is intact. Incomplete rupture is also commonly referred to as *uterine dehiscence* (Chap. 42, p. 742). It is these risks that underpin most of the angst in attempting TOLAC. Despite this, some argue that these factors should weigh only minimally in the decision because their absolute risk is low. For example, a systematic review by Guise and coworkers (2010) concludes that the uterine rupture risk was significantly elevated in women undergoing TOLAC—absolute risk of 0.47 percent and relative risk of 20.7—compared with women choosing ERCD.

The Maternal-Fetal Medicine Units (MFMU) Network conducted a prospective study at 19 medical centers (Landon, 2004). Shown in Table 31-3 are outcomes of nearly 18,000 women attempting TOLAC that were compared with those of more than 15,000 gravidas undergoing ERCD. The absolute risk of uterine rupture was 0.7 percent compared with no reported uterine ruptures in the ERCD cohort. Various reports suggest either no or an increased mortality risk for ERCD compared with attempted TOLAC (Guise, 2010; Wen, 2004).

Maternal morbidity estimates also are conflicting. The review by Guise and coworkers (2010) observed no significant differences in hysterectomy or transfusion risk. But, another metaanalysis reported that women undergoing TOLAC were approximately half as likely to require transfusion or hysterectomy compared with those undergoing ERCD (Mozurkewich, 2000). Conversely, in the MFMU Network study, the risks for transfusion and infection were significantly greater for women attempting TOLAC (Landon, 2004). A recent large retrospective Canadian cohort study compared maternal and neonatal outcomes (Young, 2018). The absolute rates of severe maternal morbidity and mortality were low. However, women attempting TOLAC had significantly higher adjusted risk ratios of uterine rupture (6.41), severe postpartum hemorrhage with transfusion (2.80), and composite maternal morbidity (1.96) compared with women who underwent ERCD. This disparity is also found among other studies. Importantly, compared with a successful TOLAC, the risk of these major complications was fivefold greater with a failed TOLAC (Rossi, 2008).

TABLE 31-3. Complications in Women with a Prior Cesarean Delivery Enrolled in the Study by the NICHD MFMU, 1999–2002

Complication	TOLAC n = 17,898 No. (%)	ERCD n = 15,801 No. (%)	Odds Ratio (95% CI)	*p* value
Maternal				
Uterine rupture	124 (0.7)	0	NA	<.001
Uterine dehiscence	119 (0.7)	76 (0.5)	1.38 (1.04–1.85)	.03
Hysterectomy	41 (0.2)	47 (0.3)	0.77 (0.51–1.17)	.22
Thromboembolic disease	7 (0.04)	10 (0.1)	0.62 (0.24–1.62)	.32
Transfusion	304 (1.7)	158 (1.0)	1.71 (1.41–2.08)	<.001
Uterine infection	517 (2.9)	285 (1.8)	1.62 (1.40–1.87)	<.001
Death	3 (0.02)	7 (0.04)	0.38 (0.10–1.46)	.21
Perinatal				
Antepartum stillbirth[a]				
37–38 weeks	18 (0.4)	8 (0.1)	2.93 (1.27–6.75)	.008
≥39 weeks	16 (0.2)	5 (0.1)	2.70 (0.99–7.38)	.07
Intrapartum stillbirth[a]	2	0	NA	NS
Term HIE[a]	12 (0.08)	0	NA	<.001
Term neonatal death[a]	13 (0.08)	7 (0.05)	1.82 (0.73–4.57)	.19

[a]Denominator is 15,338 for the TOLAC group and 15,014 for the ERCD group.
CD = cesarean delivery; CI = confidence interval; ERCD = elective repeat cesarean delivery; HIE = hypoxic ischemic encephalopathy; NA = not applicable; MFMU = Maternal–Fetal Medicine Units Network; NICHD = National Institute of Child Health and Human Development; NS = not significant; TOLAC = trial of labor after cesarean delivery.

Perinatal Risks

In the Canadian study cited previously, rates of composite severe neonatal morbidity and mortality were higher among women delivering after an attempted VBAC compared with those delivering by ERCD—adjusted odds ratio (aOR) 1.49 (Young, 2018). In this study failed VBAC was also associated with a significantly increased rate of neonatal death—aOR 3.22. Both the prospective MFMU Network study shown in Table 31-3 and review by Guise (2010) found significantly higher *perinatal mortality* rates with TOLAC compared with ERCD. In the latter review, the perinatal mortality rate with TOLAC was 0.13 percent compared with 0.05 percent for ERCD. In the Canadian study cited previously, adjusted risk ratios for neonatal death (3.22) and for composite severe neonatal morbidity and mortality (1.49) were significantly higher among women delivering after an attempted TOLAC compared with those delivering by ERCD (Young, 2018). In another study of nearly 25,000 women with a prior cesarean delivery, the TOLAC-related perinatal death rate was 1.3 per 1000 among 15,515 women (Smith, 2002). Although this absolute risk is small, it is 11 times greater than the perinatal risk found in 9014 women with ERCD.

TOLAC also appears to be associated with a higher risk of *hypoxic ischemic encephalopathy (HIE)* compared with that for ERCD. The MFMU Network study reported the incidence of encephalopathy at term to be 46 per 100,000 TOLACs compared with zero cases in women undergoing ERCD (Landon, 2004). In the review by Guise (2010), the absolute risk of *transient tachypnea of the newborn* was slightly higher with ERCD compared with TOLAC—4.2 versus 3.6 percent. But, neonatal bag and mask ventilation was used more often in newborns delivered following TOLAC than in those delivered by ERCD—5.4 versus 2.5 percent. The 5-minute Apgar scores or neonatal intensive care unit admission rates for newborns delivered by TOLAC did not differ from those delivered by ERCD.

TRIAL OF LABOR SELECTION CONSIDERATIONS

Both patients and providers ideally would like individualized risks when counseling regarding the chance of successful TOLAC. However, few high-quality data guide selection of suitable TOLAC candidates. Several TOLAC/VBAC calculators can be used at entry to prenatal care and again at the time of labor to assist in successful TOLAC prediction. However, these have not been validated as predictors of adverse maternal outcomes, such as uterine rupture. Similarly, algorithms and nomograms to aid prediction fail to demonstrated reasonable prognostic value (Grobman, 2007b, 2008, 2021; Metz, 2013; Wyckoff, 2020). Lipschuetz and colleagues (2020) applied newer statistical analysis techniques to help improve prognostic accuracy.

Despite the limitations of these predictive tools, several points are pertinent to candidate evaluation and are described subsequently. Current recommendations of the American College of Obstetricians and Gynecologists (2019d) are that most

TABLE 31-4. Types of Prior Uterine Incisions and Estimated Risks for Uterine Rupture

Prior Incision	Estimated Rupture Rate (%)
One low transverse	0.2–0.9
Multiple low transverse	0.9–1.8
Low-vertical[a]	1–7
Classical	2–9
T-shaped	4–9
Prior preterm CD	"Increased"
Prior uterine rupture	
Lower segment	2–6
Upper uterus	9–32

[a]See text for definition.
CD = cesarean delivery.
Data from the American College of Obstetricians and Gynecologists, 2017; Cahill, 2010b; Chauhan, 2002; Landon, 2006; Macones, 2005a,b; Martin, 1997; Miller, 1994; Sciscione, 2008; Society for Maternal-Fetal Medicine, 2012; Tahseen, 2010.

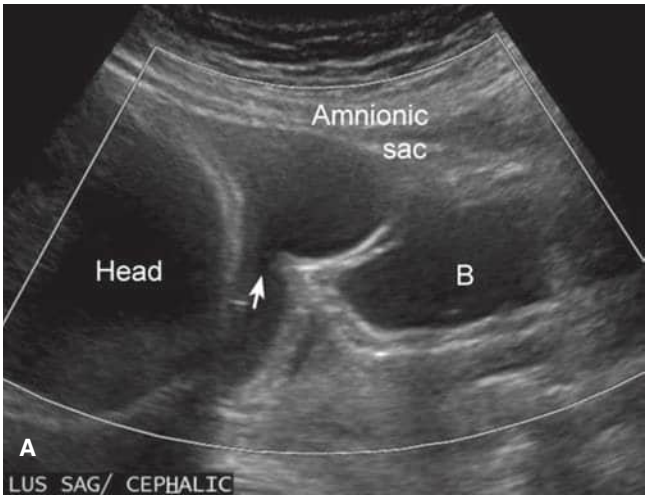
women with one prior low transverse hysterotomy are candidates, and if appropriate, they should be counseled regarding both TOLAC and ERCD options. It is further recommended that home birth is a contraindication for TOLAC.

■ Prior Uterine Incision

Prior Incision Type

The type and number of prior cesarean deliveries are overriding factors in recommending TOLAC (see Table 31-2). And these caveats aim to avoid intrapartum uterine rupture. As shown in Table 31-4, women with one prior low transverse hysterotomy have the lowest risk of symptomatic scar separation. However, asymptomatic dehiscence or complete rupture is still a concern in these women (Fig. 31-3). The uterine rupture risk in women with a prior vertical incision that did not extend into the fundus is unclear. Martin (1997) and Shipp (1999) and their associates reported that these low vertical uterine incisions do not have a higher risk for rupture compared with low transverse incisions. The American College of Obstetricians and Gynecologists (2015) concluded that although evidence is limited, women with a prior vertical incision in the lower uterine segment without fundal extension may be candidates for TOLAC. This is in contrast to prior classical or T-shaped uterine incisions, which are considered by most as contraindications to labor.

The highest risks are with prior vertical incisions extending into the fundus. Importantly, women with a classical uterine scar may rupture before labor onset, and this may even occur before term. Chauhun and colleagues (2002) reviewed 157 women with a prior classical cesarean incision. They used a policy of fetal lung maturity assessment at 36 weeks and then delivery if mature. With a mean gestational age of 35.6 weeks at delivery, they reported one uterine rupture at 29 weeks that resulted in fetal death; 9-percent uterine dehiscence rate; and 25-percent risk of maternal morbidity. For a woman with a



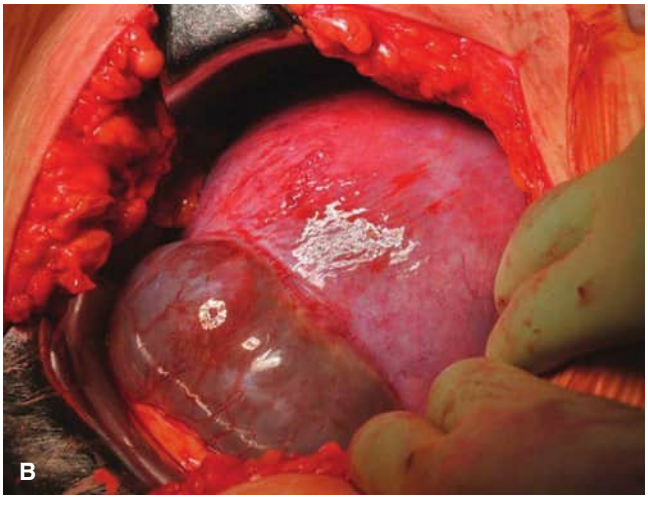


FIGURE 31-3 Extensive "uterine window" in a woman at term with one prior low transverse cesarean delivery. **A.** Transabdominal sonogram shows the uterine defect (*arrow*), bulging amnionic sac, and adjacent anatomy. B = Bladder. **B.** At the time of cesarean delivery, the amnionic sac is seen protruding through the defect and is visible beneath the thin vesicocervical peritoneum. (Reproduced with permission from Dr. Angela Seasley.)

prior classical cesarean delivery, the authors concluded that uterine rupture and dehiscence are neither predictable nor preventable despite early delivery. The risk for earlier rupture is even greater in women who have undergone open maternal-fetal surgery (Chmait, 2019; Goodnight, 2019). The American College of Obstetricians and Gynecologists (2021) recommends delivery between $36^{0/7}$ and $37^{0/7}$ weeks for a prior classical incision.

Although few indications dictate a primary classical incision, 53 percent of women undergoing cesarean delivery between $24^{0/7}$ weeks and $25^{6/7}$ weeks have such an incision (Osmundson, 2013). By 28 weeks' gestation, the risk drops to 35 percent and declines to <10 percent by 32 weeks. The likelihood of classical uterine incision is also increased by noncephalic presentations. In those instances—for example, preterm breech fetus with an undeveloped lower segment—the "low vertical" incision almost invariably extends into the active segment. From their review, Moramarco and colleagues (2020) reported that prior preterm

classical cesarean delivery was associated with a 1-percent risk for rupture. Lannon and coworkers (2015) compared 456 women with a prior periviable cesarean delivery with more than 10,000 women whose prior cesarean delivery was done at term. The uterine rupture rate was 1.8 percent in the prior periviable group and 0.4 percent in the prior term group. Of the uterine ruptures in the periviable group, half were in women whose prior uterine incision was described as low transverse. Harper and associates (2009) did not confirm these findings.

The type of uterine incision cannot be confirmed in all women. Unless clinical circumstances raise concern for a prior classical uterine incision, the American College of Obstetricians and Gynecologists (2019d) consider these women as potential TOLAC candidates.

Special consideration is given to women with uterine malformations who have undergone cesarean delivery. Earlier reports suggested that the uterine rupture risk in a subsequent pregnancy was greater than the risk in those with a normal uterus and a prior low transverse hysterotomy (Ravasia, 1999). However, in a study of 103 women with müllerian duct anomalies, there were no cases of uterine rupture (Erez, 2007).

Prior Incision Closure

As discussed in Chapter 30 (p. 558), the low transverse uterine incision can be sutured in either one or two layers. One metaanalysis compared single- versus double-layer closure and locking versus nonlocking suture for uterine closure (Roberge, 2014). The uterine dehiscence or rupture rates for these closures did not differ significantly. Both single-layer closure and closure that locked the first layer, however, were associated with a reduced myometrial thickness during subsequent sonographic measurement. In contrast, Bennich and coworkers (2016) reported that a double-layer closure did not increase the residual myometrial thickness when saline contrast sonography was done several months postpartum. Our practice at Parkland Hospital is to routinely suture the lower-segment incision with one running, locking suture line.

Number of Prior Cesarean Incisions

At least three studies report a doubling or tripling of the uterine rupture rate in women with two compared with one prior transverse hysterotomy (Macones, 2005a; Miller, 1994; Tahseen, 2010). In contrast, an analysis of the MFMU Network database did not confirm this (Landon, 2006). Namely, in 975 women with multiple prior cesarean deliveries, the rupture rate was 0.9 percent and not significantly different from the 0.7-percent rate in 16,915 women with a single prior operation.

Imaging of Prior Incision

Sonographic measurement of a prior hysterotomy incision has been used to predict rupture risk. Large defects in a nonpregnant uterus forecast a greater risk (Osser, 2011). Naji and coworkers (2013a,b) found that the *residual myometrial thickness* decreased as pregnancy progressed and that rupture risk correlated positively with a thinner scar.

Jastrow and colleagues (2010a) did a systematic review of women with a prior low transverse hysterotomy incision who underwent third-trimester sonographic evaluation. They concluded that a uterine scar defect was strongly predicted by a thin lower uterine segment. They defined this segment as the smallest measurement between urine in the maternal bladder and amniotic fluid. That said, they could not find an ideal threshold value to recommend safe TOLAC. This same group subsequently recruited 1856 women contemplating vaginal birth after a single low transverse incision, and they sonographically measured lower uterine segment thickness between $34^{0/7}$ and $38^{6/7}$ weeks (Jastrow, 2016). Women were grouped into three risk categories for uterine rupture during TOLAC based on measurements: high risk <2.0 mm; intermediate risk 2.0 to 2.4 mm; and low risk ≥2.5 mm. The TOLAC rates were 9, 42, and 61 percent in the three categories, respectively. Of the 984 TOLACs, there were no symptomatic uterine ruptures. At Parkland Hospital, we do not assess the lower uterine segment in women with a prior cesarean delivery.

Prior Uterine Rupture

Women who have previously sustained a uterine rupture are at greater risk for recurrence. As shown in Table 31-4, those with a prior lower-segment rupture have up to a 6-percent recurrence risk, whereas prior upper-segment rupture confers a 9- to 32-percent risk (Reyes-Ceja, 1969; Ritchie, 1971). Sheth (1968) described outcomes of 21 subsequent pregnancies in 13 women who underwent uterine rupture repair. Rupture recurred in four pregnancies—approximately 20 percent. Usta and colleagues (2007) reported similar results. Fox and associates (2014) reported 14 women with prior uterine rupture and 30 women with prior uterine dehiscence. In 60 subsequent pregnancies, they noted no uterine ruptures or severe complications if women underwent ERCD prior to labor onset or immediately at the onset of preterm labor. Delivery is recommended between $36^{0/7}$ and $37^{0/7}$ weeks' gestation (American College of Obstetricians and Gynecologists, 2021).

Interdelivery Interval

Magnetic resonance imaging studies of myometrial healing suggest that complete uterine involution and restoration of anatomy may require at least 6 months (Dicle, 1997). As a potential risk for uterine rupture, the relationship between interdelivery interval and uterine rupture in 2409 women with one prior cesarean delivery was examined (Shipp, 2001). There were 29 women with a uterine rupture—1.4 percent. Interdelivery intervals ≤18 months were associated with a threefold greater risk of symptomatic rupture during a subsequent TOLAC compared with intervals >18 months. Similarly, Stamilio and associates (2007) noted a threefold augmented risk of uterine rupture in women with an interpregnancy interval <6 months compared with one ≥6 months.

Prior Vaginal Delivery

Prior vaginal delivery, either before or after a cesarean birth, significantly improves the prognosis for a successful TOLAC (Grinstead, 2004; Hendler, 2004; Mercer, 2008). Prior vaginal delivery also lowers the TOLAC-related risk of subsequent uterine rupture and other morbidities (Cahill, 2006; Hochler, 2014; Zelop, 1999).

Prior Cesarean Delivery Indication

Women with a nonrecurring indication—for example, breech presentation—have the highest successful TOLAC rate—nearly 90 percent (Wing, 1999). Those with a prior cesarean delivery for fetal compromise have an approximately 80-percent VBAC rate, and for those done for labor arrest, VBAC rates approximate only 60 percent (Bujold, 2001; Peaceman, 2006).

Prior second-stage cesarean delivery can be associated with second-stage uterine rupture in a subsequent pregnancy (Jastrow, 2013). A secondary analysis of the MFMU Cesarean Registry revealed that a prolonged second stage of labor—exceeding 3 hours—during TOLAC will often lead to VBAC. However, adverse maternal outcomes including uterine rupture or dehiscence were observed to be more common as the second stage lengthens (Hehir, 2018).

Fetal Size and Lie

Most studies show that increasing fetal size is inversely related to VBAC rates. The risk for uterine rupture is less robustly linked. Zelop and colleagues (2001) studied outcomes of almost 2750 women undergoing TOLAC, and the uterine rupture rate increased—albeit not significantly—with rising fetal weight. The rate was 1.0 percent for fetal weight <4000 g, 1.6 percent for >4000 g, and 2.4 percent for >4250 g. Similarly, others have found associated increased risks for uterine rupture with fetuses >4000 g (Jastrow, 2010b). With preterm fetuses, compared with term ones, women who attempt a TOLAC have similar or higher VBAC rates and lower uterine rupture rates (Durnwald, 2006; Quiñones, 2005).

Few studies address the choice of TOLAC for a singleton term breech fetus. Very limited data suggest a possible link with adverse perinatal outcome (Azria, 2012; Macharey, 2017). Data supporting external cephalic version for breech presentation with a prior cesarean scar also are limited and are derived from small studies (Impey, 2018; Weill, 2017). From these, version success and adverse event rates appear comparable with women without a prior cesarean delivery. The American College of Obstetricians and Gynecologists (2020) does not consider a prior uterine incision to be a contraindication for attempted version. At Parkland Hospital, we do not attempt version or vaginal breech delivery in these women.

Multifetal Gestation

Twin pregnancy does not appear to increase the risk of uterine rupture. In one study of 1850 women with twins, the VBAC rate was 45 percent, and the rupture rate was 0.9 percent (Ford, 2006). Similar studies by Cahill (2005) and Varner (2007) and their coworkers reported rupture rates of 0.7 to 1.1 percent and VBAC rates of 75 to 85 percent. According to the American College of Obstetricians and Gynecologists (2019d), women with twins and a prior low transverse hysterotomy can safely undergo TOLAC.

Maternal Obesity

Multiple studies have reported an inverse relationship between prepregnancy body mass index (BMI) and successful TOLAC rates (Juhasz, 2005; Wu, 2019). Hibbard and associates (2006) reported the following rates: 85 percent with a normal BMI, 78 percent with a BMI between 25 and 30, 70 percent with a BMI between 30 and 40, and 61 percent with a BMI ≥40.

Fetal Death

Most women with a prior cesarean delivery and fetal death in the current pregnancy would prefer a vaginal delivery. Although fetal concerns are obviated, available data suggest that maternal risks are increased. Nearly 46,000 women with a prior cesarean delivery in the MFMU Network database had a total of 209 fetal deaths at an average gestational age of 32.8 weeks (Ramirez, 2010). Of the 158 women who elected TOLAC, the VBAC rate was 87 percent. In the entire TOLAC group, the uterine rupture rate was 2.4 percent, and in 116 women who underwent an induction of labor, the rupture rate was 3.4 percent. Labor induction for second-trimester fetal demise has a low complication rate (Bahar, 2021).

LABOR AND DELIVERY CONSIDERATIONS

Timing

The American College of Obstetricians and Gynecologists (2019a) recommends delaying nonmedically indicated deliveries until 39 completed weeks of gestation or beyond. Data from Tita and colleagues in Figure 31-4 show significant and appreciable adverse neonatal morbidity has been reported with ERCD before 39 completed weeks (Chiossi, 2013; Clark, 2009). Thus, if ERCD is planned, it is essential that the fetus be mature. Conversely, delaying delivery beyond 40 weeks is associated with higher neonatal morbidity rates.

Accurate pregnancy dating is paramount prior to ERCD. The American College of Obstetricians and Gynecologists (2019c) offers guidelines to assist in accurate pregnancy dating using a combination of last menstrual period and sonography. The most accurate method to confirm or establish gestational age is by sonographic measurement of an early embryo-fetus.

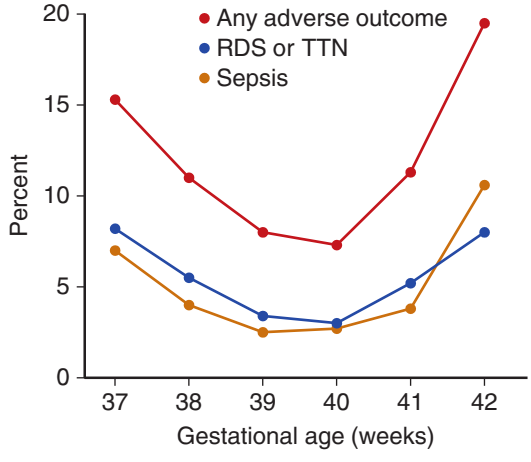

FIGURE 31-4 Neonatal morbidity rates seen with 13,258 elective repeat cesarean deliveries. Any adverse outcome includes death. Sepsis includes suspected and proven. RDS = respiratory distress syndrome; TTN = transient tachypnea of the newborn.

Intrapartum Care

Because uterine rupture during TOLAC may be unpredictable, the American College of Obstetricians and Gynecologists (2019d) recommends that labor in women attempting TOLAC should be undertaken in facilities that can provide emergency cesarean delivery for situations associated with immediate threats to the life of the women or her fetus. If those resources are not available, the College recommends discussion of the hospital's resources and availability of providers with the patient considering TOLAC. Ultimately, the best alternative may be referral to an institution with resources appropriate for TOLAC.

Some argue that these provisions deny women full access to choices. For example, in an earlier survey of Ohio hospitals, 15 percent of Level I, 63 percent of Level II, and 100 percent of Level III institutions met these requirements (Lavin, 2002). Moreover, an obstetrical anesthesia workforce survey reported that due to staffing limitations, TOLAC was allowed in only 88 percent of hospitals with ≥1500 annual deliveries, in 59 percent of those with 500 to 1499 deliveries, and in 43 percent of those with <500 deliveries (Traynor, 2016).

Cervical Ripening and Labor Stimulation

Labor induction is associated with a higher TOLAC failure rate compared with spontaneous labor. The risks for uterine rupture, however, are less clear with induction or augmentation, with the exception of prostaglandin E_1 (PGE_1)—misoprostol—which is contraindicated (American College of Obstetricians and Gynecologists, 2019d). Of other considerations, induction or augmentation is ideally avoided in women with an unknown prior incision type, an unfavorable cervix, or pregnancy >40 weeks. At Parkland Hospital we do not induce or augment labor pharmacologically in women electing TOLAC. Instead, we attempt induction only by amniotomy.

Oxytocin

Use of oxytocin for labor induction or augmentation has been *implicated* in increased uterine rupture rates in women undergoing TOLAC (Zelop, 1999). In the MFMU Network study reported by Landon (2004), uterine rupture was more frequent in women induced with oxytocin alone—1.1 percent—compared with those presenting in spontaneous labor—0.4 percent. Labor augmentation was associated with uterine rupture in 0.9 percent. Among women in this cohort without a prior vaginal delivery, the uterine rupture risk associated with oxytocin induction was 1.8 percent—a fourfold greater risk compared with spontaneous labor (Grobman, 2007a). In contrast, in one case-control study, induction was not associated with a higher rupture risk (Harper, 2012a). Cahill (2008) and Goetzl (2001) and their coworkers reported a dose-related risk of rupture with oxytocin.

Prostaglandins

Various prostaglandin preparations commonly employed for cervical ripening or labor induction are discussed in Chapter 26 (p. 489). Wing and colleagues (1998) compared misoprostol versus oxytocin for labor induction in women with a prior cesarean delivery. They terminated their trial after two of the first 17 women assigned to misoprostol developed a uterine rupture. Other studies confirmed this. The American College of Obstetricians and Gynecologists (2019d) recommends that misoprostol should not be used for cervical ripening or labor induction in women at term with a prior cesarean delivery or major uterine surgery.

Studies using other prostaglandin agents for labor induction are contradictory. Ravasia and coworkers (2000) compared uterine rupture rates in 172 women given PGE_2 gel with 1544 women in spontaneous labor. The rupture rate of 2.9 percent was significantly greater in women treated with PGE_2 gel compared with 0.9 percent in those with spontaneous labor. Lydon-Rochelle and associates (2001) found similar results. In the MFMU Network study cited previously, however, the uterine rupture rate was 1.4 percent when any prostaglandin was used in combination with oxytocin (Landon, 2004). But, in the subgroup of 227 women in whom labor was induced with a prostaglandin alone, there were no ruptures. Similar findings were reported with intravaginal prostaglandins, which were not associated with a greater uterine rupture risk (Macones, 2005b). These latter investigators, along with Kayani and colleagues (2005), found that sequential use of a prostaglandin followed by oxytocin was associated with a threefold greater rupture risk compared with spontaneous labor.

Mechanical Methods

In a retrospective study of 2479 women with a prior cesarean delivery, the uterine rupture risk using a transcervical Foley catheter for labor induction (1.6 percent) was not significantly greater than that with spontaneous labor (1.1 percent)—or with amniotomy with or without oxytocin (1.2 percent) (Bujold, 2004). In 101 women induced with a balloon catheter, a 50-percent successful TOLAC rate and no uterine ruptures was reported (Sarreau 2020). In contrast, Hoffman and coworkers (2004) described 138 women who underwent preinduction cervical ripening with a Foley catheter compared with 536 women who entered labor spontaneously. The inordinately high intrapartum uterine rupture rate of 6.5 percent following Foley catheter cervical ripening was greater than the 1.9-percent rate with spontaneous labor.

Epidural Analgesia

Concerns that epidural analgesia for labor might mask the pain of uterine rupture have not been verified. Fewer than 10 percent of women with scar separation experience pain and bleeding, and fetal heart rate decelerations are the most likely sign of rupture (Kieser, 2002). That said, Cahill and associates (2010a) documented that more frequent episodes of epidural catheter dosing were associated with increasing uterine rupture rates. VBAC rates are similar, and in some cases higher, among women with labor epidural analgesia compared with those using other analgesia forms (Landon, 2005). Perhaps related, almost a fourth of VBAC deliveries were completed with either forceps or vacuum (Inbar, 2017). The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) have concluded that epidural analgesia may safely be used during TOLAC.

Uterine Scar Exploration

Following VBAC, some clinicians routinely document the integrity of a prior scar by placing a hand through the dilated cervix and along the inner surface of the lower uterine segment. But, routine uterine exploration is considered by others to be unnecessary. In a longitudinal study of 3469 women who had a VBAC, seven uterine dehiscences and one uterine rupture yielded an overall event rate of 0.23 percent (Silberstein, 1998). These investigators concluded that transcervical evaluation need only be performed for those with severe third-stage bleeding.

Currently, the benefits of routine scar evaluation in the asymptomatic woman are unclear, however, surgical correction of a dehiscence is necessary for associated significant bleeding. At Parkland Hospital, we routinely examine the lower uterine segment following a VBAC and document its integrity. A large tear, a breach into the peritoneal cavity, and presence of active bleeding favor a decision for laparotomy and repair.

UTERINE SCAR RUPTURE

Diagnosis

Progress of labor in women attempting TOLAC is similar to normal labor, and no specific pattern presages uterine rupture (Graseck, 2012; Harper, 2012b). Before hypovolemic shock develops, symptoms and physical findings in women with uterine rupture may appear bizarre unless the possibility is kept in mind. For example, hemoperitoneum from a ruptured uterus may result in diaphragmatic irritation with pain referred to the chest. This may suggest a diagnosis of pulmonary or amnionic fluid embolism instead of uterine rupture. As the example shown in Figure 31-5, the most common sign of uterine rupture is a nonreassuring fetal heart rate pattern with variable decelerations that may evolve into late decelerations and bradycardia. In one report of 36 cases during TOLAC, fetal signs of uterine rupture were evident in 24, maternal signs in eight, and a combination of maternal and fetal in three (Holmgren, 2012). Few women experience cessation of contractions following uterine rupture, and the use of intrauterine pressure catheters does not assist reliably in the diagnosis (Rodriguez, 1989).

The clinical appearance of uterine rupture associated with a TOLAC may mirror that of placental abruption but with little appreciable pain or tenderness. Also, because most women in labor are treated for discomfort with either narcotics or epidural analgesia, pain and tenderness may not be readily apparent. Ultimately, the diagnosis of uterine rupture becomes evident because of fetal distress and occasionally because of maternal hypovolemia from concealed hemorrhage.

If the fetal presenting part has already entered the pelvis with labor, loss of station may be detected by pelvic examination. If the fetus is partly or totally extruded from the uterine rupture site, abdominal palpation or vaginal examination may be helpful to identify the presenting part, which will have moved away from the pelvic inlet. A firm contracted uterus may at times be felt alongside the fetus. Emergent sonography in the labor unit may be helpful.

Management

With rupture and expulsion of the fetus into the peritoneal cavity, the chances for intact fetal survival are poor. *Fetal condition depends on the degree to which the placental implantation remains intact, although this can change within minutes.* The only chance of intact fetal survival is afforded by immediate delivery—most often by laparotomy—otherwise, hypoxia is inevitable. If rupture is followed by total placental separation, very few neurologically intact fetuses will be salvaged.

Thus, even in the best of circumstances, some fetal outcomes will be impaired. The Utah experiences are instructive here (Holmgren, 2012). Of the 35 laboring patients with uterine rupture, the decision-to-delivery time was <18 minutes in 17, and none of these infants had an adverse neurological outcome. Of the 18 born >18 minutes from decision time, the three infants with long-term neurological impairments were delivered at 31, 40, and 42 minutes. There were no deaths, but severe neonatal neurological morbidity developed in 8 percent of this group of 35 women with uterine rupture. Importantly, delivery within 30 minutes did not prevent every case of low cord pH or low 5-minute Apgar score. When uterine rupture was identified and delivery was accomplished is less than 30 minutes, there was no long-term neonatal morbidity. In the MFMU Network study cited earlier, seven of the 114 uterine ruptures associated with TOLAC—6 percent—were complicated by development of neonatal encephalopathy (Spong, 2007).

Neonatal mortality rate is likewise increased several fold. In a study using the Swedish Birth Registry, the risk of neonatal death following uterine rupture was 5 percent (Kaczmarczyk, 2007).

Maternal deaths from uterine rupture are uncommon. Of 2.5 million women who gave birth in Canada between 1991 and 2001, there were 1898 cases of uterine rupture, and four of these—0.2 percent—resulted in maternal death (Wen, 2005). In other regions of the world, however, maternal mortality rates are

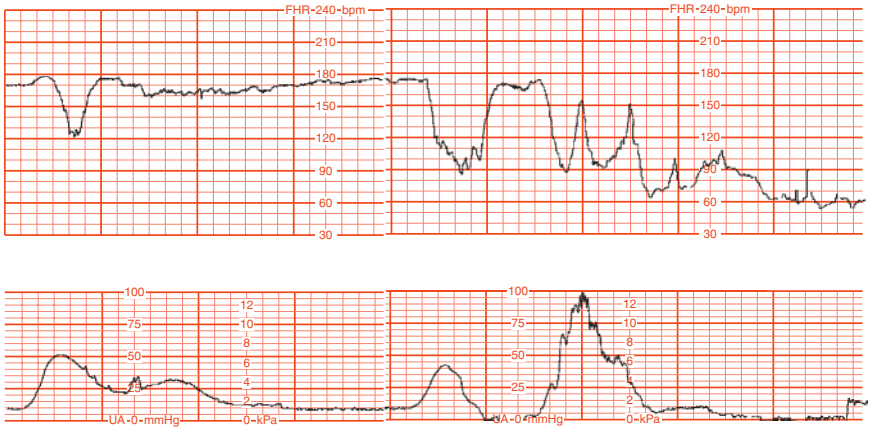

FIGURE 31-5 Fetal heart rate tracing in a woman whose uterus ruptured during labor while pushing. The rupture apparently stimulated a reflex push, after which uterine tone diminished and fetal bradycardia worsened.

much higher. From rural India, the maternal mortality rate associated with uterine rupture was 30 percent (Chatterjee, 2007).

Following complete rupture during TOLAC, hysterectomy may be required. In selected cases, however, suture repair with uterine preservation may be performed. Subsequent pregnancy following such repair was described earlier (p. 576). Bladder injury may be comorbid, and interrogation of its integrity is prudent (Chap. 30, p. 563) (Phipps, 2005; Webb, 2000).

MULTIPLE REPEAT CESAREAN DELIVERIES

The incidences of some common complications for women with a prior transverse cesarean delivery who undergo an ERCD were shown in Table 31-3 (Landon, 2004). Rates of these complications and of other serious maternal morbidity rise with the number of prior cesarean deliveries (Marshall, 2011).

First, the incidence of *placenta accreta spectrum (PAS)*, which includes placenta accreta, increta, or percreta increases markedly with the number of previous hysterotomies. In an MFMU Network cohort of 30,132 women who had from one to six repeat cesarean deliveries, a significant association between an accruing number of cesarean deliveries and PAS in women with placenta previa was noted (Fig. 31-6) (Silver, 2006). The PAS rate grew from 11 percent for women with a placenta previa undergoing their second cesarean delivery to 67 percent for women undergoing their fifth (Fig. 43-12, p. 761). Indeed, almost half of cesarean

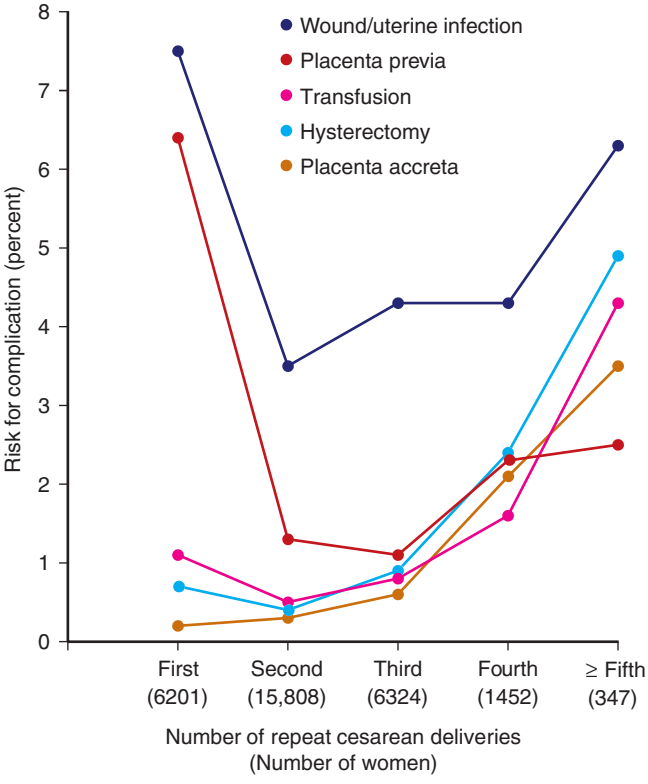

FIGURE 31-6 Maternal-Fetal Medicine Units Network: rates of some complications with increasing number of repeat cesarean deliveries.

TABLE 31-5. Some Recommendations of Professional Societies Concerning TOLAC

	Counseling	Facilities	Other
ACOG (2019d)	Offer to most women with 1 prior LTCD; consider for 2 prior LTCDs	Safest with ability for immediate CD; patients should be allowed to accept increased risk when not available	Not precluded: twins, macrosomia, prior low vertical or unknown incision type
SOGC	Offer to women with 1 prior LTCS; with >1 prior CD then VBAC likely successful but increased risks	Should deliver in hospital in which timely CD is available; the woman and provider must be aware of hospital resources and availability of obstetrical, anesthetic, pediatric, and operating room staff	Oxytocin or Foley catheter induction safe, but PGs not recommended; macrosomia, diabetes, postterm pregnancy, twins are not contraindications
RCOG (2015)	Offer to most women with singleton, cephalic fetus at ≥37 weeks with 1 prior LTCD; with >1 prior CD then VBAC likely successful but increased risks, offer after counseling by senior obstetrician, VBAC checklists should be considered	Suitable delivery suite with continuous intrapartum care and monitoring; immediate cesarean delivery and advanced neonatal resuscitation	Uncertainty about safety and efficacy with postterm, twin gestation, macrosomia, and advanced maternal age; induction and augmentation associated with two- to threefold increased risk of uterine rupture

ACOG = American College of Obstetricians and Gynecologists; CD = cesarean delivery; LTCS = low transverse cesarean delivery; PG = prostaglandins; RCOG = Royal College of Obstetricians and Gynaecologists; SOGC = Society of Obstetricians and Gynaecologists of Canada; TOLAC = trial of labor after cesarean delivery; VBAC = vaginal birth after cesarean.

TABLE 31-6. Conservative Approach to TOLAC

Review and follow ACOG guidelines
Education and counseling
Preconceptionally
Provide ACOG patient pamphlet
Prenatal care: early counseling and delivery planning
Develop preliminary delivery plan
Revisit delivery plan at least each trimester
Be willing to alter decision
Confirm facility capabilities
Risk assessment
Review and document operative note(s)
Review relative/absolute contraindications
Reconsider risks as pregnancy progresses
Careful consideration and counseling if:
>1 prior transverse CD, unknown incision, twins, macrosomia
Labor and delivery
Review previous medical records/operative notes
Cautions for induction: unfavorable cervix, high station
Consider AROM
Avoid prostaglandins
Respect oxytocin and know when to quit
Continuous EFM
Beware of abnormal labor progress
Respect EFM pattern abnormalities
Be ready to abandon TOLAC
Recommend against home birth

ACOG = American College of Obstetricians and Gynecologists; AROM = artificial rupture of membranes; CD = cesarean delivery; EFM = electronic fetal monitoring; TOLAC = trial of labor following cesarean delivery.

hysterectomies done at Parkland Hospital are in women with one or more prior cesarean deliveries (Hernandez, 2013).

Other maternal morbidity data come from the same MFMU Network cohort and are shown in Figure 31-6 (Silver, 2006). In addition, rates of bowel or bladder injury, admission to an intensive care unit or need for ventilator therapy, maternal mortality, and length of surgery and hospitalization showed significantly rising trends. Similar results have been reported by others (Nisenblat, 2006; Usta, 2005). More difficult to quantify are risks for bowel obstruction and pelvic pain from peritoneal adhesive disease, both of which increase after each successive cesarean delivery (Andolf, 2010; Mankuta, 2013).

From the United Kingdom Obstetric Surveillance System (UKOSS), adverse sequelae in women with five or more cesarean deliveries were described (Cook, 2013). These women had significantly higher rates of morbidity compared with those with one prior operation. Specifically, the major hemorrhage rate increased 18-fold; visceral damage, 17-fold; critical care admissions, 15-fold; and delivery <37 weeks, sixfold. Much of this morbidity was in the 18 percent who had a placenta previa or PAS. This same study showed higher neonatal complication rates stemming mainly from indicated premature delivery.

VAGINAL BIRTH AFTER CESAREAN—2021

Unfortunately for women and their providers, no large randomized trials compare maternal or neonatal outcomes in those pursuing either TOLAC or ERCD. Most studies have compared *actual* routes of delivery rather than the *intended* route of delivery. Thus, we agree with Scott (2011) regarding a common-sense approach. The woman—and if she wishes, her partner—are encouraged to actively participate with the provider in an informed-consent discussion. Patient decision aids often assist shared decision making (Poprzenczny, 2020). Although the absolute rates of adverse maternal and neonatal outcomes are low, TOLAC is associated with a higher rate of both maternal and neonatal morbidity and mortality compared with ERCD.

Counseling should include documentation of the prior uterine incision and discussion of risks, benefits, and probable outcomes associated with TOLAC or ERCD. This includes consideration of risks involving future pregnancies. Ideally, counseling begins preconceptionally and continues throughout pregnancy, with flexible options extending up to delivery. For women who desire TOLAC despite a factor that increases their specific risk, additions to the consent form are recommended by the American College of Obstetricians and Gynecologists (2019d). Bonanno and colleagues (2011) have provided such an example. Tsakiridis and coworkers (2018) have compared national guidelines of societies in the United States, Canada, and the United Kingdom. A composite of these recommendations of professional society guidelines is shown in Table 31-5 (Dy, 2019). Guidelines that tend to be more conservative are shown in Table 31-6.

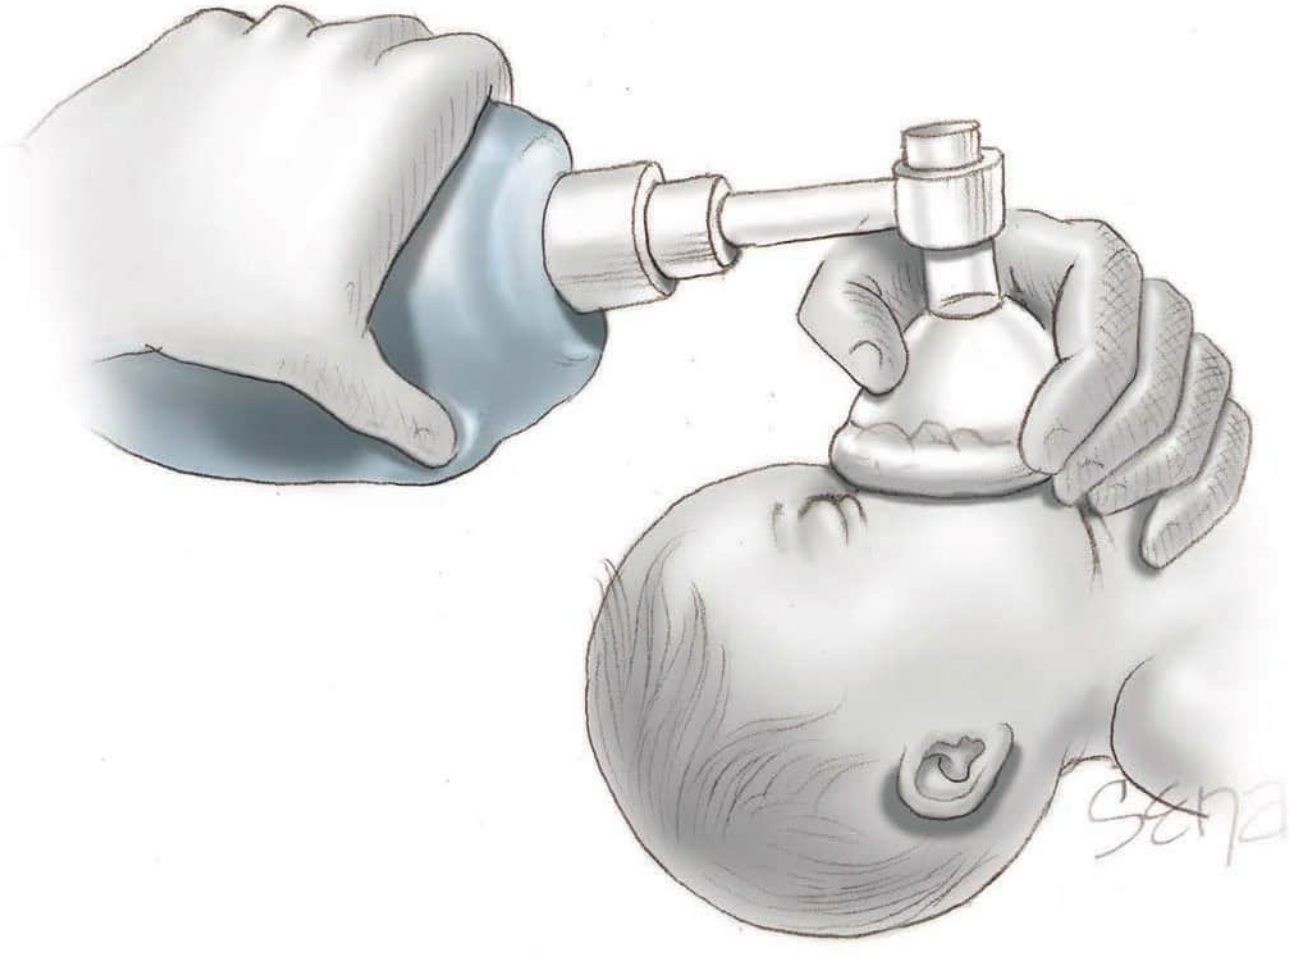
SECTION 9

THE NEWBORN



CHAPTER 32

The Newborn

In most instances at delivery, the newborn is healthy and vigorous, but at times, special care may be needed. For this reason, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017a) recommend that every birth should be attended by at least one qualified individual. This person should be skilled in the initial steps of newborn care and positive-pressure ventilation, and their only responsibility is management of the newborn. This usually is a pediatrician, nurse practitioner, anesthesiologist, nurse anesthetist, or specially trained nurse. However, in their absence, the responsibility for neonatal resuscitation falls to the obstetrical attendant. Thus, obstetricians should be well versed in measures for immediate care of the newborn.

The number and qualifications of personnel who attend the delivery will vary depending on the anticipated risk, the number of babies, and the hospital setting. A qualified team with full resuscitation skills should be present for high-risk deliveries and immediately available for every resuscitation. This team should not be on call at home or in a remote area of the hospital. Moreover, team training through frequent simulation practice is recommended for all who may be called to attend deliveries (Aziz, 2020).

TRANSITION TO AIR BREATHING

Immediately following birth, the newborn must promptly convert from placental to pulmonary gas exchange. Pulmonary vascular resistance must fall, pulmonary perfusion must rapidly rise, and unique fetal vascular shunts must begin to close to separate the systemic and pulmonary circulations. These shunts include the patent ductus arteriosus and patent foramen ovale, described in Chapter 7 (p. 128). Lung aeration is not only critical for pulmonary gas exchange. Specifically, recent studies suggest that it is responsible for initiating cardiovascular changes at birth (Hooper, 2019).

In utero, the fetal lungs are filled with amnionic fluid, which must be cleared quickly for air breathing. Various means contribute, and these mechanisms may depend on gestational age and mode of delivery. First, in term fetuses, a large release of fetal adrenaline late in labor stimulates pulmonary epithelial cells to stop secreting and instead to start reabsorbing lung liquid due to sodium-channel activation (te Pas, 2008). This mechanism is likely a minor one, as blockade of the receptors for sodium-channel activation reduces or delays but does not prevent liquid clearance from the lungs at birth (Buchiboyina, 2017).

As a second method, mechanical forces aid lung fluid clearance. Early reports described expulsion of lung liquid by compression of the fetal thorax and abdomen as they passed through the birth canal (Karlberg, 1962; Saunders, 1978). By this mechanism, up to a third of lung liquid is expelled in a jet of fluid from the nose and mouth once the respiratory tract is exposed to the lower outside pressure. However, it appears that uterine contractions force a change in fetal posture, which compresses the thorax and raises intrathoracic pressures. This expels lung liquid early in labor more so than the "vaginal squeeze" theory (Hooper, 2019; te Pas, 2008; Vyas, 1981).

In a third mechanism, a significant amount of lung liquid is cleared after birth (Hooper, 2019). In animal studies, most lung aeration occurs during inspiration—within three to five

breaths after birth (Hooper, 2007). The transpulmonary pressure gradient during inspiration promotes movement of fluid into the interstitial tissue. No liquid clears between breaths. From the interstitium, fluid is gradually cleared, probably by the pulmonary circulation and lymphatic vessels. It is possible for lung interstitial tissue pressure to rise to a point that fluid can actually move back into the airspaces during expiration unless positive end-expiratory pressure opposes liquid reentry (Siew, 2009). This may contribute to development of *transient tachypnea of the newborn*.

As fluid is replaced by air, compression of the pulmonary vasculature is reduced considerably, and in turn, resistance to blood flow is lowered. With the fall in pulmonary arterial blood pressure, the ductus arteriosus normally closes.

High, negative intrathoracic pressures are required to permit the initial entry of air into the fluid-filled alveoli. Normally, from the first breath after birth, progressively more residual air accumulates in the lung. With each successive breath, lower pulmonary opening pressure is required. In the normal mature newborn, by approximately the fifth breath, pressure-volume changes achieved with each respiration are very similar to those of the adult. Thus, the breathing pattern shifts from shallow episodic inspirations characteristic of the fetus to regular, deeper inhalations.

As a last mechanism, surfactant is synthesized by type II pneumocytes. It lowers alveolar surface tension and helps maintain lung inflation by preventing alveolar collapse. Insufficient surfactant, which is common in preterm neonates, leads promptly to respiratory distress syndrome (Chap. 34, p. 615).

In utero, umbilical venous return is the main source of preload for the left ventricle. Namely, the fetal pulmonary blood flow is very low due to high pulmonary vascular resistance and is unable to provide sufficient venous return to maintain left ventricular output (Hooper, 2019).

Clamping the umbilical cord reduces preload for the left ventricle and thus reduces cardiac output. Until the lungs aerate and pulmonary blood flow increases, the reduced cardiac output will manifest as bradycardia. If cord clamping is delayed until after the lungs have aerated, the transition is smoother and cardiac output does not fall (Bhatt, 2013). This understanding has led to interest in delayed (physiological) cord clamping, especially if it can be done after successful inflation of the lung. Specialized resuscitation trolleys have been developed to aid this practice, and several international randomized trials are underway.

CARE IN THE DELIVERY ROOM

The International Liaison Committee on Resuscitation (ILCOR) updated its scientific review for neonatal delivery room care and resuscitation (Wyckoff, 2020). This review is used by the American Academy of Pediatrics and the American Heart Association to develop the neonatal resuscitation guidelines for North America (Aziz, 2020).

Immediate Care

Before and during delivery, several determinants of neonatal well-being are carefully considered. Risk factors can include: (1) poor maternal health status; (2) prenatal complications, including any suspected fetal malformations; (3) preterm gestational age; (4) labor complications; (5) long duration of labor and ruptured membranes; (6) anesthesia that may affect placental perfusion; (7) difficult delivery; and (8) various medications given during labor and their dosages, administration routes, and timing.

When risk factors are present, neonatal resuscitation providers should be present for the delivery. This team readies equipment, ensures that adequate personnel are present, delegates roles and responsibilities, and considers contingency plans to stabilize the newborn. In preparation, a neonatal provider will ask the delivery provider regarding expected gestational age, amnionic fluid color, additional maternal and fetal risk factors, and the management plan for umbilical cord clamping (Weiner, 2021). Several neonatal conditions are associated with a nonvigorous presentation. These may include immaturity, hypoxemia or acidosis from any cause, sepsis, recent drugs administered to the mother, meconium-stained amnionic fluid, and central nervous system developmental abnormalities. Those related to the respiratory tract are lung abnormalities, upper airway obstruction, pneumothorax, and meconium aspiration.

Umbilical Cord Management

Obstetrical and pediatric care teams should ideally discuss plans regarding umbilical cord management prior to delivery. Deferred cord clamping provides transfusion of placental blood to the newborn. In term neonates, delaying cord clamping by 30 to 60 seconds raises hemoglobin levels at birth and improves iron stores during infancy. The only reported negative outcome is hyperbilirubinemia and a higher subsequent rate of phototherapy (Gomersall, 2021). In preterm neonates, deferred cord clamping may reduce rates of blood transfusion, intraventricular hemorrhage, and necrotizing enterocolitis and improves survival rates (Seidler, 2021).

Delayed cord clamping should be performed in preterm and term newborns who do not require resuscitation at birth. There should be no delay if a newborn requires resuscitation or if placental abruption, cord avulsion, or bleeding placenta previa or vasa previa complicates delivery. Cord milking is a reasonable alternative to immediate cord clamping for late preterm and term newborns. It should be avoided in neonates <28 weeks' gestation (American College of Obstetricians and Gynecologists, 2020a; Gomersall, 2021; Seidler, 2021).

Newborn Resuscitation

Approximately 10 percent of newborns require some degree of active resuscitation to stimulate breathing, and 1 percent need extensive care. Perhaps not coincidentally, the neonatal death rate with home birth in the United States is small but still fourfold greater than attended hospital births (Grünebaum, 2020).

When deprived of adequate gas exchange, either before or after birth, neonates demonstrate a well-defined sequence of events leading to apnea (Fig. 32-1). With oxygen deprivation and carbon dioxide (CO_2) elevation, there is a transient period of rapid breathing, and if it persists, breathing stops, which

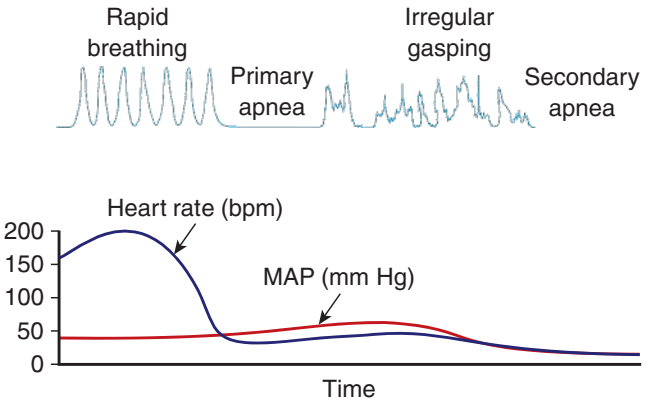


FIGURE 32-1 Physiological changes associated with primary and secondary apnea in the newborn. bpm = beats per minute; HR = heart rate; MAP = mean arterial pressure. (Reproduced with permission from Kattwinkel J: Textbook of Neonatal Resuscitation, 6th ed. Elk Grove Village, American Academy of Pediatrics and American Heart Association, 2010.)

is termed *primary apnea*. This stage is accompanied by a fall in heart rate and loss of neuromuscular tone. Simple stimulation will usually reverse primary apnea. If oxygen deprivation and asphyxia persist, however, the newborn will develop deep gasping respirations, followed by *secondary apnea*. This latter stage is associated with a further decline in heart rate, fall in blood pressure, and loss of neuromuscular tone. Neonates in secondary apnea will not respond to stimulation and will not spontaneously resume respiratory efforts. Unless ventilation is assisted, death follows.

Clinically, primary and secondary apneas are initially indistinguishable. When a response to stimulation is not immediate, resuscitation with effective ventilation of the apneic newborn must begin quickly. Effective positive-pressure ventilation is the most critical intervention in neonatal resuscitation.

Resuscitation Protocol

Initial Assessment

Immediately after birth and usually during the delay for umbilical cord clamping, newborn tone, respiratory effort, and heart rate are evaluated (Fig. 32-2). Most term neonates are vigorous by 10 to 30 seconds after birth (Ersdal, 2012). For these, initial steps of warming the newborn can be done on the mother's chest or abdomen. Direct skin-to-skin contact with the mother and drying and covering the newborn with a warm blanket will help maintain euthermia (36.5 to 37.5°C). A vigorously crying newborn does not require routine oral suctioning (Aziz 2020; Foster, 2017). Instead, bulb suctioning to remove secretions is best reserved for those who cannot clear secretions on their own due to apnea or copious secretions. Additional routine care steps include drying, gentle stimulation by rubbing the newborn's back, and continued observation during the transition period.

If not vigorous or if preterm, the neonate is carried to a prewarmed radiant warmer for initial newborn care steps. The initial wet birth blanket is removed to allow newborn drying. Cold stress is associated with multiple neonatal morbidities and

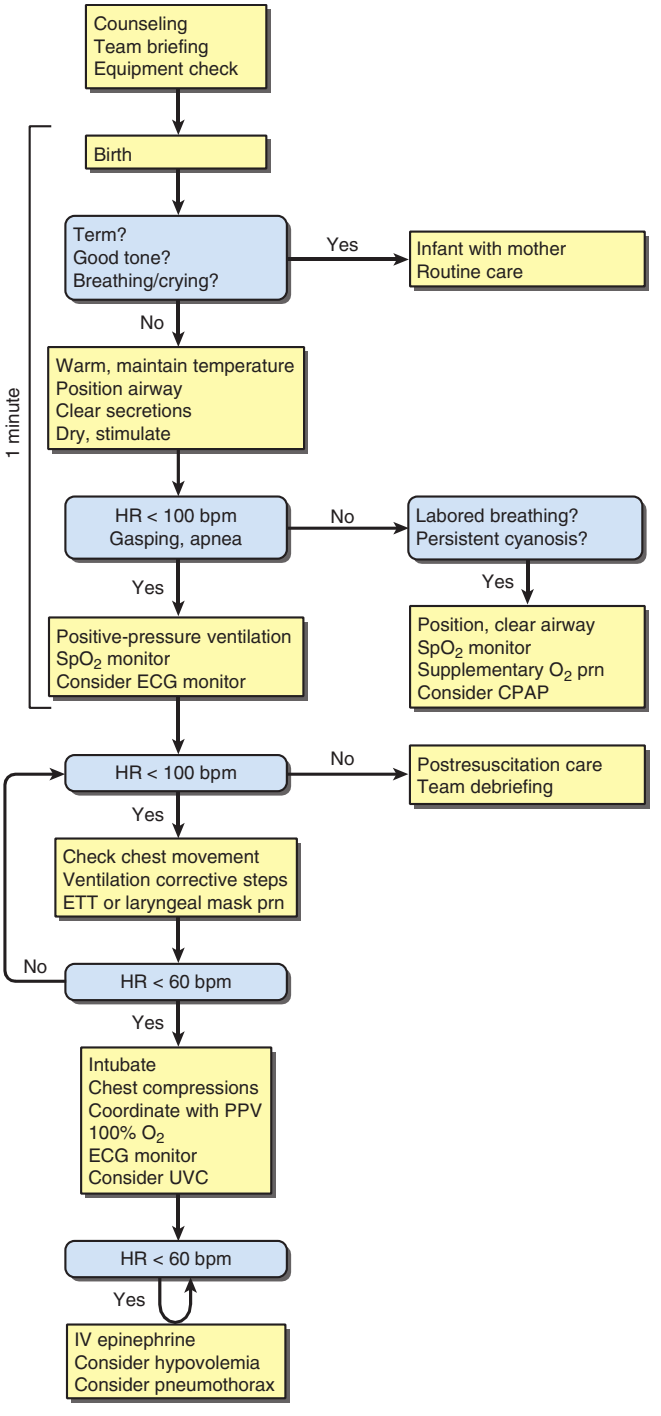

FIGURE 32-2 Algorithm for resuscitation of the newborn based on the International Liaison Committee on Resuscitation scientific review and recommended by the American Academy of Pediatrics and American Heart Association (Aziz, 2020; Wyckoff, 2020). bpm = beats per minute; CPAP = continuous positive airway pressure; ECG = electrocardiogram; ETT = endotracheal tube; HR = heart rate; IV = intravenous; PPV = positive-pressure ventilation; SpO_2 = peripheral oxygen saturation; UVC = umbilical venous catheter.

mortality. Preterm infants are particularly vulnerable, and special steps can help maintain euthermia. These are providing a warm delivery room (>25°C), covering the neonatal head with either a plastic or wool hat, applying polyethylene plastic "ponchos" or wraps to slow evaporative heat losses, using chemically

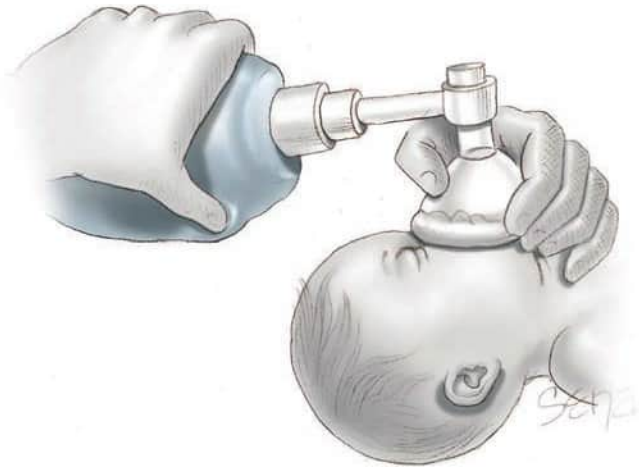

FIGURE 32-3 Correct use of bag-and-mask ventilation. The head should be in a sniffing position with the tip of the nose pointing to the ceiling. The neck should not be hyperextended.

activated thermal mattresses to reduce conductive heat loss, and administering warm, humidified respiratory gases during respiratory stabilization (Aziz, 2020; Wyckoff, 2020).

At the radiant warmer, newborns are positioned with mild neck extension to maximally open the airway. If the newborn is apneic or has copious secretions that obstruct the airway, then a bulb syringe or suction catheter can help clear the mouth and the nose. Routine intubation and suctioning of meconium-stained amnionic fluid is not recommended for the nonvigorous newborn (American College of Obstetricians and Gynecologists, 2021a; Wyckoff, 2020). Intubation and suction are reserved for suspected airway obstruction. Meconium-stained amnionic fluid is a significant risk factor for the need for advanced resuscitation. In rare circumstances, the meconium-stained fluid can obstruct the newborn's airway and necessitate intubation and tracheal suctioning (Aziz, 2020; Wyckoff, 2020).

After completion of the initial stabilization steps, persisting apnea, gasping respirations, or heart rate ≤100 beats per minute (bpm) should prompt immediate administration of positive-pressure ventilation with room air (Fig. 32-3). This should be started by 60 seconds of life, if not sooner, once the initial steps are completed.

Mask Ventilation

Assisted ventilation by facemask at a rate of 40 to 60 breaths per minute is recommended as an initial resuscitation step. Oxygen saturation is monitored by pulse oximetry. Supplemental oxygen can be given in graduated, rising percentages to maintain oxygen saturation values within a normal range. Percentage goals rise progressively with accruing minutes of life (Table 32-1) (Weiner, 2021). Adequate ventilation is best indicated by an improved heart rate. A colorimetric end-tidal carbon dioxide ($ETCO_2$) monitor that lies between the positive-pressure device and facemask serves as a helpful adjunct to detect successful gas exchange during mask ventilation.

TABLE 32-1. Oxygen Saturation Goals per Minute of Life

1 min	60–65%
2 min	65–70%
3 min	70–75%
4 min	75–80%
5 min	80–85%
10 min	85–95%

If the heart rate remains ≤100 beats per minute after 5 to 10 positive pressure breaths, and the attempted ventilation is inadequate, then further corrective steps should begin. These can be remembered by the mnemonic MR. SOPA (Table 32-2) (Weiner, 2021). The two most common problems are mask leak due to an ineffective seal and malposition of the airway (Schmölzer, 2019). Mask positioning should maintain an open mouth. This provides a superior conduit for gas transfer than the narrow-caliber nares. If the other corrective steps do not raise the heart rate, either intubation with an endotracheal tube or placement of a supraglottic airway is required.

Alternative Airway

If mask ventilation is ineffective or prolonged, an alternative airway is placed. For tracheal intubation, a laryngoscope with a straight blade—size 0 for a preterm newborn and size 1 for a term neonate—is used. Gentle cricoid pressure may be useful. An increasing heart rate and $ETCO_2$ detection after several breaths are the primary methods to confirm intubation of the trachea and not the esophagus. One can also look for symmetrical chest wall motion; auscultate for equal breath sounds, especially in the axillae; and auscultate for the absence of breath sounds or gurgling over the stomach.

Once in place, the tube is used for tracheal suctioning only for a suspected obstructed airway. Otherwise, an appropriate positive-pressure device (self-inflating bag, flow-inflating bag, or T-piece resuscitator) is attached to the endotracheal tube (Roehr, 2021). Ventilation breaths are delivered at a rate of 40 to 60 per minute with a force adequate to stabilize the heart

TABLE 32-2. Ventilation Corrective Steps (MR. SOPA)

M—Mask adjustment	Check the mask seal and reapply if needed
R—Reposition airway	Ensure the newborn is truly in the open airway position with mild neck extension
S—Suction mouth and nose	Remove obstructing secretions
O—Open the mouth	Avoid closing the mouth during efforts to achieve a good mask seal
P—Pressure increase	Increase the inflation pressure
A—Advanced airway	If all prior steps fail to achieve chest rise, then intubate or place a laryngeal mask or other supraglottic airway

rate. In term newborns, opening pressures of 30 to 40 cm H_2O typically will expand the alveoli without causing barotrauma. Once the lung is inflated, less pressure is typically needed (20 to 25 cm H_2O). For preterm neonates, pressures of 20 to 25 cm H_2O are typically used. Increases in heart rate and peripheral oxygen saturation (SpO_2) levels to acceptable ranges reflect a positive response.

Chest Compressions

Most commonly, effective ventilation is all that is required to stabilize the newborn in the delivery room. If the heart rate remains <60 bpm despite ventilation corrective steps, including placement of an endotracheal tube, chest compressions are initiated. Once the endotracheal tube is secured, compressions are done from the head of the bed rather than the side so that space is opened up for a provider to have umbilical venous access. When compressions are initiated, the oxygen concentration is increased to 100 percent. With the two-thumb compression method, hands encircle the chest, while the thumbs depress the sternum. Compressions are delivered on the lower third of the sternum at a depth sufficient to generate a palpable pulse. This is typically one third of the anterior-posterior diameter of the chest. Compared with other techniques, this method offers less provider fatigue over time, yields higher generated perfusion pressures, and lessens hand malpositioning that could cause traumatic injury (Kapadia, 2012).

A 3:1 compressions-to-ventilation ratio is recommended, and 90 compressions and 30 breaths achieve approximately 120 events each minute. Coordinated chest compressions and ventilations should continue until the spontaneous heart rate is ≥60 bpm (Wyckoff, 2020).

If the heart rate remains ≤60 bpm after adequate ventilation and chest compressions, intravenously administered epinephrine is indicated. The recommended intravenous dose is 0.01 to 0.03 mg/kg. Epinephrine may be given through the endotracheal tube if venous access has not been established, but its action is less reliable (Isayama, 2020). If given through the endotracheal tube, higher doses are employed—0.05 to 0.1 mg/kg.

Resuscitation Discontinuation

ILCOR concludes that it is reasonable to discontinue resuscitative efforts for a neonate who remains without a heartbeat despite at least 20 minutes of continuous and adequate resuscitative efforts (Wyckoff, 2020). Notably, the decision to continue or discontinue resuscitative efforts must be individualized. The time was recently lengthened due to reports of some newborns enrolled in therapeutic hypothermia trials who had a 10-minute Apgar score of 0 yet survived without disability. This suggests the need for caution in limiting resuscitation to 10 minutes (Foglia, 2020).

EVALUATION OF NEWBORN CONDITION

■ Apgar Score

The scoring system described by Dr. Virginia Apgar in 1953 remains a useful clinical tool to classify newborn health immediately after birth and to assess the effectiveness of resuscitative measures (American College of Obstetricians and Gynecologists, 2021b). During scoring, each of five easily identifiable characteristics—heart rate, respiratory effort, muscle tone, reflex irritability, and color—is assessed and assigned a value of 0, 1, or 2 (Table 32-3). In the currently recommended expanded form, concurrent resuscitation interventions also are recorded over time. The total score, based on the sum of the five components, is determined in all neonates at 1 and 5 minutes after delivery. In those with a score <7, the score may be calculated at further 5-minute intervals until a 20-minute Apgar score is assigned or resuscitation efforts are halted (Weiner, 2021).

In an analysis of more than 150,000 newborns delivered at Parkland Hospital, Casey and associates (2001b) assessed the significance of the 5-minute score for predicting survival during the first 28 days of life. They found that in term neonates, the

TABLE 32-3. 20-Minute Expanded Apgar Score

CPAP = continuous positive airway pressure; ETT = endotracheal tube; PPV = positive-pressure ventilation.

risk of neonatal death was approximately 1 in 5000 for those with Apgar scores of 7 to 10. This risk compares with a mortality rate of 25 percent for term newborns with 5-minute scores ≤3. Low 5-minute scores were comparably predictive of neonatal death in preterm neonates. Similarly, an analysis of more than 113,000 preterm neonates ranging from 22 to 36 weeks' gestation found that Apgar scores at 5 and 10 minutes provided prognostic information for neonatal survival rates across gestational-age strata (Cnattingius, 2020). Thus, the Apgar scoring system remains relevant for the prediction of neonatal survival.

Apgar scores alone are not predictive of hypoxic ischemic encephalopathy (HIE). However, in cohorts of babies diagnosed with HIE based on umbilical cord blood pH and standardized neurologic examinations, low 10-minute Apgar scores are significantly associated with school-age outcomes (Natarajan, 2013).

Previously, many groups established erroneous definitions of asphyxia based solely on low Apgar scores. These prompted the American College of Obstetricians and Gynecologists and American Academy of Pediatrics (2021b) to issue a series of joint opinions with important caveats regarding Apgar score limitations. Certain elements of the Apgar score are partially dependent on the physiological maturity of the newborn, and a healthy, preterm neonate may receive a low score only because of immaturity. Other influencing factors include fetal malformations, maternal medications, and infection. Thus, it is inappropriate to use an Apgar score alone to diagnose asphyxia. Moreover, the Apgar score alone cannot establish hypoxia as the cause of cerebral palsy, as discussed in Chapter 33 (p. 604).

Umbilical Cord Blood Acid–Base Studies

Blood taken from umbilical vessels may be used for acid–base studies to assess the metabolic status of the neonate. Blood collection is performed following delivery by immediately isolating a 10- to 20-cm segment of cord with two clamps placed near the neonate and another two clamps positioned nearer the placenta. The cord is then cut between the two proximal clamps and then the two distal clamps (Blickstein, 2007).

Arterial blood is drawn from the isolated cord segment into a 1- to 2-mL commercially prepared plastic syringe containing lyophilized heparin or a similar syringe that has been flushed with a heparin solution containing 1000 U/mL. Once sampling is completed, the needle is capped and the syringe transported, on ice, to the laboratory. Although efforts should be made for prompt transport, neither the pH nor partial pressure of CO_2 (P_{CO_2}) values change significantly in blood kept at room temperature for up to 60 minutes (Lynn, 2007). Mathematical models have been developed that allow reasonable prediction of birth acid–base status in properly collected cord blood samples analyzed as late as 60 hours after delivery (Chauhan, 1994). Notably, acid–base measurements can show significant variances between different analyzing devices (Mokarami, 2012).

Fetal Acid–Base Physiology

The fetus produces both carbonic and organic acids. Carbonic acid (H_2CO_3) forms from oxidative metabolism of CO_2. The fetus usually rapidly clears CO_2 through the placental circulation. If CO_2 clearance drops, carbonic acid levels rise. This often follows impaired placental exchange. When H_2CO_3 accumulates in fetal blood and organic acids do not concurrently rise, the result is *respiratory acidemia*.

In contrast, organic acids primarily include lactic and β-hydroxybutyric acids. Levels of these increase with persistent placental exchange impairment, and they result from anaerobic glycolysis. These organic acids are cleared slowly from fetal blood. When they accumulate, without a concurrent increase in H_2CO_3, the result is *metabolic acidemia*. With the development of metabolic acidemia, bicarbonate (HCO_3^-) levels drop because it is used to buffer the organic acid. A rise in H_2CO_3 concentrations accompanied by greater organic acid levels, reflected by decreased HCO_3^- levels, causes *mixed respiratory-metabolic acidemia*.

In the fetus, respiratory and metabolic acidemia and ultimately tissue acidosis are most likely part of a progressively worsening continuum. This is different from adult pathophysiology, in which distinct conditions result either in respiratory acidosis—for example, pulmonary disease, or in metabolic acidosis—for example, diabetes. In the fetus, the placenta serves as both the lungs and, to a certain degree, the kidneys. One principal cause of fetal acidemia is a drop in uteroplacental perfusion. This creates retention of CO_2, that is, respiratory acidemia, and if protracted and severe enough, yields a mixed or metabolic acidemia.

Assuming that maternal pH and blood gases are normal, the actual pH of fetal blood depends on the proportion of carbonic and organic acids and the amount of bicarbonate, which is the major buffer in blood. This can best be illustrated by the Henderson–Hasselbalch equation:

$$\text{pH} = \text{pK} + \log \frac{[\text{base}]}{[\text{acid}]} \text{ or, } \text{pH} = \text{pK} + \log \frac{HCO_3^-}{H_2CO_3}$$

For clinical purposes, HCO_3^- represents the metabolic component and is reported in mEq/L. The H_2CO_3 concentration reflects the respiratory component and is reported as the P_{CO_2} in mm Hg. Thus:

$$\text{pH} = \text{pK} + \log \frac{\text{metabolic } (HCO_3^- \text{ mEq/L})}{\text{respiratory } (P_{CO_2} \text{ mm Hg})}$$

The result of this equation is a pH value. Because pH is a logarithmic term, it does not give a linear measure of acid accumulation. For example, a change in hydrogen ion concentration associated with a fall in pH from 7.0 to 6.9 is almost twice that which is associated with a fall in pH from 7.3 to 7.2. For this reason, the change in base—termed *delta base*—offers a more linear measure of the degree of accumulation of metabolic acid (Armstrong, 2007). The delta base is a calculated number used as a measure of the change in buffering capacity of bicarbonate (HCO_3^-). The formula for calculating the base excess (BE) is as follows:

$$\text{BE} = 0.02786 \times P_{CO_2} \times 10^{(\text{pH} - 6.1)} \times 13.77 \times \text{pH} - 124.58$$

Shown in Figure 32-4 is a nomogram from which these can be calculated if only two parameters are known. For example, the HCO_3^- concentration declines with a metabolic acidemia as it is consumed to maintain a normal pH. A base deficit develops when the HCO_3^- concentration drops below normal levels, and a

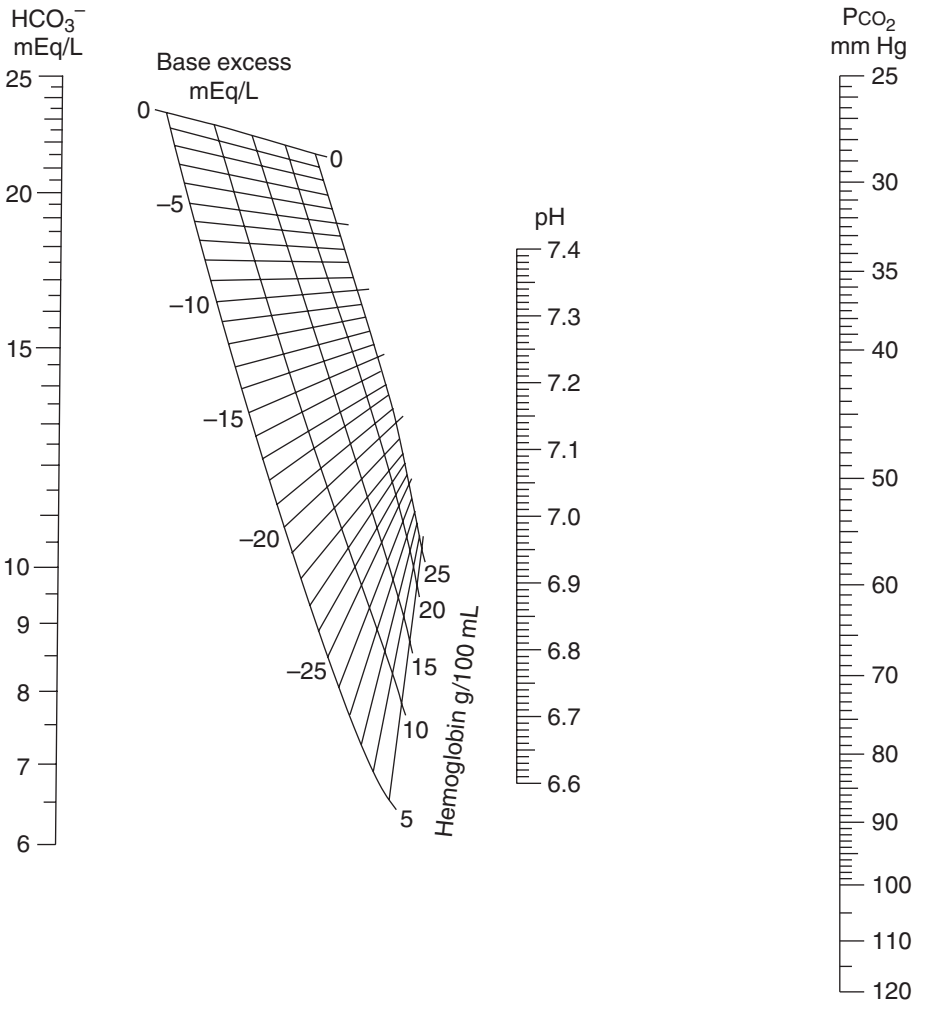

FIGURE 32-4 Nomogram for determining the delta base. (Reproduced with permission from Siggaard-Anderson O: Blood acid–base alignment nomogram. Scand J Clin Lab Invest. 1963;15:211–7.)

base excess occurs when HCO_3^- values are above normal. Importantly, a mixed respiratory–metabolic acidemia with a large base deficit and a low HCO_3^-, for example 12 mmol/L, is more often associated with a depressed neonate than is a mixed acidemia with a minimal base deficit and a more nearly normal HCO_3^- level.

Clinical Significance of Acidemia

Fetal oxygenation and pH generally decline during the course of normal labor. Normal umbilical cord blood pH and blood gas values at delivery in term newborns are summarized in Table 32-4. Similar values have been reported for preterm neonates (Ramin, 1989; Skiold, 2017). The lower limits of normal pH in the newborn range from 7.05 to 7.16 for newborns 28 to 42 weeks' gestation at birth, with some variation based on gestational age (Skiold, 2017). Thus, these values should be considered to define neonatal acidemia. Even so, most fetuses will tolerate intrapartum acidemia with a pH as low as 7.00 without incurring neurological impairment (American College of Obstetricians and Gynecologists, 2014; Lee, 2020). That said, in a study of newborns with

a pH <7.0 from Parkland Hospital, the incidences of neonatal deaths—8 percent, intensive care admissions—39 percent, intubations—14 percent, and seizures—13 percent, were notable (Goldaber, 1991). In a study of more than 51,000 term newborns, the incidence of neonatal encephalopathy in those with a birth pH <7.0 was 3 percent (Yeh, 2012). Even those who had normal 5-minute Apgar scores but who had an arterial cord pH values <7.0 experienced a higher risk of morbidity. This included respiratory distress, neonatal intensive care unit admission, and sepsis (Sabol, 2016). Faster acidemia resolution after birth is associated with better outcome (Casey, 2001a).

Respiratory Acidemia

Acute interruption in placental gas exchange is accompanied by subsequent CO_2 retention and respiratory acidemia. The most common antecedent factor is transient umbilical cord compression. Generally, respiratory acidemia is not harmful to the fetus (Low, 1994).

The degree to which pH is affected by P_{CO_2}—the respiratory component of the acidosis—can be calculated. First, the upper normal neonatal P_{CO_2} value of about 50 mm Hg is subtracted from the cord blood gas P_{CO_2} value. Each additional 10 mm Hg P_{CO_2} increment will lower the pH by 0.08 units (Eisenberg, 1987). Thus, in a mixed respiratory–metabolic acidemia, the benign respiratory component can be calculated. As an example, acute cord prolapse during labor prompts cesarean delivery of a neonate 20 minutes later. The umbilical artery blood gas pH was 6.95 and the P_{CO_2} was 90 mm Hg. The degree to which the cord compression and subsequent impairment of CO_2 exchange affected the pH is calculated using the relationship given earlier and shown below.

$$90 \text{ mm Hg} - 50 \text{ mm Hg} = 40 \text{ mm Hg excess } CO_2$$

$$\text{To correct pH: } (40 \div 10) \times 0.08 = 0.32;\ 6.95 + 0.32 = 7.27$$

Thus, the pH before cord prolapse was approximately 7.27, well within normal limits. Thus, the low pH resulted from respiratory acidosis.

Metabolic Acidemia

The fetus begins to develop metabolic acidemia when oxygen deprivation is sufficiently long and severe to require anaerobic metabolism for cellular energy needs. Low and associates (1997) defined fetal acidosis as a base deficit ≥12 mmol/L, and severe fetal acidosis as a base deficit ≥16 mmol/L. In the Parkland study of more than 150,000 newborns cited earlier, metabolic acidemia was defined using umbilical cord blood gas thresholds that were two standard deviations below the mean (Casey, 2001b). Thus, metabolic acidemia was an umbilical artery blood pH <7.00 accompanied by a P_{CO_2} ≤76.3 mm Hg, with higher values indicating a respiratory component; HCO_3^- concentration ≤17.7 mmol/L; and base deficit ≥10.3 mEq/L. From the standpoint of *possible* neurological injury, the American College of Obstetricians and Gynecologists (2014) defines metabolic acidosis as umbilical arterial pH <7.0 and a base deficit ≥12 mmol/L.

Metabolic acidemia is associated with a high rate of multiorgan dysfunction. In rare cases, such hypoxia-induced metabolic acidemia may be so severe that it causes subsequent hypoxic ischemic encephalopathy (Chap. 33, p. 601). Severe metabolic acidosis is poorly predictive of subsequent neurological impairment in the term neonate (Cahill, 2017). In fact, a fetus without such acidemia cannot by definition have suffered recent hypoxic-induced injury. In preterm infants, newborn acid–base status is more closely linked to intraventricular hemorrhage, periventricular leukomalacia, and poorer long-term neurological outcomes (Baalbaki, 2021; Morgan, 2017).

Associations between metabolic acidemia, low Apgar scores, and neonatal death have been described in term and preterm newborns (Morgan, 2015). Regarding term neonates, the risk of neonatal death was more than 3200-fold greater in term neonates with metabolic acidemia and 5-minute scores ≤3 compared with those with a 5-minute Apgar score ≥7 (Casey, 2001b).

Recommendations for Cord Blood Gas Determinations

In some centers, cord gas analysis is performed in all neonates at birth (Morgan, 2015; Sabol, 2016). Cost-effectiveness analysis for universal cord blood gas measurement suggests benefit and potential cost savings (White, 2016). It seems reasonable to obtain cord blood gas determinations for intrapartum cases of cesarean delivery for fetal compromise, abnormal fetal heart rate tracing, fever, and low 5-minute Apgar score. Multifetal gestation and severely growth-restricted fetuses are others.

Although umbilical cord acid–base blood determinations are poorly predictive of either immediate or long-term adverse neurological outcome, they provide the most objective evidence of the fetal metabolic status at birth.

PREVENTIVE CARE

Eye Infection Prophylaxis

Ophthalmia neonatorum is mucopurulent conjunctivitis of newborns. Gonococcal and chlamydial infections are among the most common causes (American Academy of Pediatrics, 2021b).

Neisseria gonorrhoeae infection acquired at birth was a common cause of childhood blindness in the past. Gonococcal prophylaxis is now mandatory for all neonates in most states (American Academy of Pediatrics, 2017a). For *prophylaxis* soon after delivery, 0.5-percent erythromycin ophthalmic ointment is recommended (U.S. Preventive Services Task Force, 2019).

For a neonate born to a mother with untreated gonorrhea, *treatment* of presumptive neonatal gonococcal conjunctivitis is a single ceftriaxone dose, 25 to 50 mg/kg, intravenously or intramuscularly, not to exceed 125 mg intramuscularly (American Academy of Pediatrics, 2021b). Before treatment, neonatal testing for both gonococcal and chlamydia infections should be obtained.

With *chlamydial conjunctivitis*, adequate neonatal prophylaxis is challenging. Ideally, prenatal screening and treatment for *Chlamydia trachomatis* obviates conjunctival infection (Hammerschlag, 2011) (Chap. 68, p. 1212). In neonates delivered vaginally of mothers with an active chlamydial infection, 30 to 50 percent will develop conjunctivitis (Zikic, 2018).

Prophylactic topical eye treatments do not reliably reduce the incidence of chlamydial conjunctivitis.

Conjunctivitis in a newborn up to age 3 months should prompt consideration for chlamydial infection (Moore, 2015). Treatment for neonatal chlamydial conjunctivitis is oral erythromycin base or ethylsuccinate, 50 mg/kg/d given daily and divided into four doses for 14 days. Another is oral azithromycin, 20 mg/kg given as a single daily dose for 3 days. A second course may be required since the efficacy of erythromycin therapy approximates only 80 percent. Posttreatment follow-up of these infants is recommended (American Academy of Pediatrics, 2021b).

Hepatitis B Immunization

Routine immunization with thimerosal-free vaccine against hepatitis B within the first 24 hours of life is standard practice for all medically stable newborns with birthweights >2000 g (American Academy of Pediatrics, 2017b). If the mother is seropositive for hepatitis B surface antigen, the neonate is also passively immunized with hepatitis B immune globulin. For high-risk or even all seropositive women during pregnancy, some advocate treatment with antiviral nucleoside or nucleotide analogues to minimize fetal transmission (Dunkelberg, 2014) (Chap. 58, p. 1038).

Vitamin K

Supplemental vitamin K injection will prevent vitamin K deficiency bleeding of the newborn (Chap. 33, p. 606). A single intramuscular dose of vitamin K, 0.5 to 1 mg, is given within 1 hour of birth (American Academy of Pediatrics, 2017a).

COVID-19

The novel SARS-CoV-2 virus is very contagious, spreads person to person, and can cause severe morbidity or mortality. Thus, birth attendants at the delivery of a mother with COVID-19 should implement airborne and contact isolation precautions to protect themselves during potentially aerosolizing resuscitation procedures (Edelson, 2020).

National data suggest that approximately 2 percent of newborns of women who test positive for SARS-CoV-2 near delivery have also tested positive in the first 24 to 96 hours of life (American Academy of Pediatrics, 2021a). Newborn death directly attributable to perinatal infection with SARS-CoV-2 is rare in the United States. However, evidence suggests that symptomatic maternal infection at delivery is associated with increased risks of preterm birth and perinatal morbidity (Chap. 67, p. 1188).

Infected mothers should wear a mask while holding their newborn. A mother who is acutely ill with COVID-19 may be unable to care for her neonate and may need temporary separation until she improves. Mothers who are infected but who are not acutely ill can room-in with their well newborn but should maintain a reasonable distance from their babies when possible. Breastfeeding while wearing a mask and maintaining good hand hygiene is suitable (American College of Obstetricians and Gynecologists, 2020b). The newborn should be tested at least once for SARS-CoV-2 prior to discharge (American Academy of Pediatrics, 2021a).

Newborn Screening

Mass-screening tests are available for 35 newborn conditions, and these are recommended by the Advisory Committee on Heritable Disorders in Newborns and Children (2018). Shown in Table 32-5, many are mandated by various state laws. Most states require that all tests in the core panel be performed. Supplemental conditions—*secondary conditions*—are listed on the Advisory Committee's website. Some states require some of these in addition to their mandated core panel. Each practitioner should be familiar with their individual state requirements, which are available at: babysfirsttest.org/newborn-screening/states.

TABLE 32-5. Newborn Screening Core Panel

Organic Acid Metabolism	Fatty Acid Metabolism	Amino Acid Metabolism	Others
Isovaleric acidemia	Medium-chain acyl-CoA dehydrogenase deficiency	Phenylketonuria	Biotinidase deficiency
Propionic acidemia	Very long-chain acyl-CoA dehydrogenase deficiency	Maple syrup urine disease	Galactosemia
Glutaric acidemia type I	Long-chain 3-OH acyl-CoA dehydrogenase deficiency	Homocystinuria	Hearing loss
β-Ketothiolase deficiency	Trifunctional protein deficiency	Citrullinemia, type I	Cystic fibrosis
3-Hydroxy-3-methylglutaric aciduria	Carnitine uptake defect	Argininosuccinic	Critical congenital heart disease
Holocarboxylase synthase deficiency	**Endocrine Disorders**	Tyrosinemia, type I	Severe combined immunodeficiency
3-Methylcrotonyl-CoA carboxylase deficiency	Congenital hypothyroidism	**Hemoglobin Disorders**	Glycogen storage disease, type II
Methylmalonic acidemia (methylmalonyl-CoA mutase)	Congenital adrenal hyperplasia	SS disease	Mucopolysaccharidosis, type 1
Methylmalonic acidemia (cobalamin disorder)		S-β-thalassemia	X-linked adrenoleukodystrophy
		SC disease	Spinal muscular atrophy

From Advisory Committee on Heritable Disorders in Newborns and Children, 2018; Watson, 2006.

ROUTINE NEWBORN CARE

Gestational Age Estimation

Newborn gestational age can be estimated very soon after delivery. The relationship between gestational age and birthweight can identify neonates at risk for complications. For example, neonates who are either small or large for gestational age are at greater risk for hypoglycemia and polycythemia, and measurements of blood glucose and hematocrit are indicated.

Care of Skin and Umbilical Cord

All excess vernix, blood, and meconium is gently wiped off after delivery while keeping the newborn warm. Any remaining vernix is readily absorbed and disappears within 24 hours. The first bath is postponed until the neonate's temperature is stable.

Aseptic precautions are observed in the immediate care of the cord. The American Academy of Pediatrics (2017a) has concluded that keeping the cord dry is sufficient care. The umbilical cord begins to lose water from its Wharton jelly shortly after birth. Within 24 hours, the cord stump loses its characteristic bluish-white, moist appearance and soon becomes dry and black. Within several days to weeks, the stump sloughs and leaves a small, granulating wound, which after healing forms the umbilicus. Separation usually takes place within the first 2 weeks. The umbilical cord dries more quickly and separates more readily when exposed to air (López-Medina, 2020). Thus, a dressing is not recommended.

In resource-poor countries, local antimicrobial prophylaxis is reasonable (Salam, 2014). The World Health Organization (2014) recommends cleansing with chlorhexidine in situations in which hygienic conditions are poor or infection rates are high.

Despite precautions, a serious umbilical infection—*omphalitis*—sometimes develops. The most likely offending organisms are *Staphylococcus aureus*, group A and B streptococcus, and gram-negative rods such as *Escherichia coli* (Stewart, 2016). Typical signs of cellulitis and stump discharge usually aid diagnosis. Mild erythema and some bleeding at the stump site with cord detachment is common, but some cases present with no outward signs.

Feeding and Weight Loss

Exclusive breastfeeding is preferred for the newborn's first 6 months. In 2020, 84 percent of U.S. newborns were initially breastfed, 58 percent were still nursing at 6 months, and 35 percent at 1 year (Centers for Disease Control and Prevention, 2020). In many hospitals, breastfeeding begins in the delivery room. Most term newborns thrive best when fed 8 to 12 times daily for approximately 15 minutes each episode. Preterm or growth-restricted newborns require feedings at shorter intervals. Breastfeeding is discussed further in Chapter 36 (p. 639).

Because most neonates actually receive little nutriment for the first 3 or 4 days of life, they progressively lose weight until the flow of maternal milk is established or other feeding is instituted. Preterm neonates lose relatively more weight and regain their birthweight more slowly. Conversely, growth-restricted but otherwise healthy newborns regain their initial weight more quickly than those born preterm. With proper nourishment, birthweight of term newborns usually is regained by 10 days.

Stools and Urine

For the first 2 or 3 days after birth, the colon contains soft, brown-green meconium. This consists of desquamated epithelial cells from the intestinal tract, mucus, epidermal cells, and lanugo (fetal hair) that have been swallowed along with amnionic fluid. The characteristic color results from bile pigments. During fetal life and for a few hours after birth, the intestinal contents are sterile, but bacteria quickly colonize the bowel contents.

Meconium stooling is seen in 90 percent of newborns within the first 24 hours and in most of the rest within 36 hours. Usually, newborns first void shortly after birth but may not until the second day. Meconium and urine passage indicates patency of the gastrointestinal and urinary tracts, respectively. Failure of the newborn to stool or urinate after these times suggests a congenital defect, such as Hirschsprung disease, imperforate anus, or posterior urethral valve. After the third or fourth day, as a result of milk ingestion, meconium is replaced by light-yellow, softer, homogeneous feces.

Neonatal Hyperbilirubinemia

Between the second and fifth day of life approximately one third of all neonates develop physiological jaundice of the newborn. It has special significance considering most hospitals have policies for early discharge. Guidelines regarding standard phototherapy equipment and monitoring, as well as treatment recommendations per gestational age, hour of life, and risk factors are used (American Academy of Pediatrics, 2017a). Hyperbilirubinemia is discussed further in Chapter 33 (p. 606).

Male Circumcision

Indications

Neonatal circumcision of male newborns has been a controversial topic in the United States for at least 35 years. Even so, scientific evidence supports several medical benefits that include prevention of phimosis, paraphimosis, and balanoposthitis. Circumcision also lowers the incidence of penile cancer and of cervical cancer among their sexual partners. The Centers for Disease Control and Prevention (2011) estimates that the newborn male circumcision rate has declined over the past decades in the United States, and rates vary widely by region. From a national database, the overall circumcision rate decreased from 57 percent in 2003 to 52 percent in 2016 (Jacobson, 2021).

The American Academy of Pediatrics Task Force on Circumcision (2012) concluded that health benefits of newborn male circumcision outweigh the risks. Specific benefits include prevention of urinary tract infections, penile cancer, and transmission of some sexually transmitted infections, including HIV (American Academy of Pediatrics, 2017a). Thus, access to the procedure is justified for families who choose it. The Task Force stopped short of recommending circumcision for *all* newborns.

Surgical Technique

Circumcision is performed only in a healthy neonate. Other contraindications include any genital abnormalities such as hypospadias and a family history of a bleeding disorder, unless excluded in the newborn.

The Task Force (2012) recommends procedural analgesia. Various pain relief techniques include lidocaine-prilocaine topical cream, local analgesia infiltration, dorsal penile nerve block, or ring block. The dorsal penile nerve block or the ring block is superior to topical analgesia. The use of a pacifier dipped in sucrose is a useful adjunct to these methods (Rossi 2021).

After appropriate penile cleansing, the ring block places a wheal of 1-percent lidocaine at the base of the penis and then advances the needle in a 180-degree arc around the base of the penis. The needle is advanced first to one side and then to the other to achieve a circumferential ring of analgesia. The maximum dose of lidocaine is 1.0 mL. *No vasoactive compounds such as epinephrine should ever be added to a local analgesic agent for circumcision.*

The most commonly used instruments are shown in Figure 32-5 and are Gomco and Mogen clamps and the Plastibell device. Compared with the Gomco procedure, Kaufman and colleagues (2002) reported that the Mogen technique required less time to perform and was associated with less apparent discomfort for the newborn. Regardless of the method used, the goal is to remove enough shaft skin and inner preputial epithelium so that the glans is exposed sufficiently to prevent phimosis. Suitable technique ensures that: (1) the amount of external skin to be removed must be accurately estimated, (2) the preputial orifice must be dilated to visualize the glans and ensure that it is normal, (3) the inner preputial epithelium must be freed from the glans epithelium, and (4) the circumcision device must be left in place long enough to produce hemostasis before excising the prepuce (Omole, 2020).

The risks for bleeding, infection, and hematoma formation are low. Unusual complications include distal glans amputation, acquisition of HIV infection or other sexually transmitted infection, meatal stenosis, penile denudation, penile destruction with electrosurgical coagulation, subsequent epidermal inclusion cyst and urethrocutaneous fistula, and ischemia following the inappropriate use of lidocaine with epinephrine (El Bcheraoui, 2014; Pippi-Salle, 2013; Omole, 2020).

FIGURE 32-5 Three different tools used for circumcision. **A.** Mogen clamp. The arms of the clamp open to a 3-mm maximum width. **B.** Gomco clamp, assembled. **C.** Plastibell device.

Rooming In and Hospital Discharge

Hospital *rooming in* places newborns in their mothers' rooms instead of central nurseries. This practice attempts to make all phases of childbearing as natural as possible. It aims to foster early mother-child relationships and establish effective breast feeding practices. By 24 hours, the mother is generally fully ambulatory. Thereafter, she can usually provide routine care for herself and her newborn.

Traditionally, the newborn is discharged with its mother, and in most cases, maternal stay has determined that of the neonate. From 1970 to the mid-1990s, average maternal postpartum length of stay declined steadily, and many mothers were discharged before 48 hours. The World Health Organization (2014) cites a minimal stay of only 24 hours. Although it is clear that most newborns can be safely discharged within 48 hours, this is not uniformly true. When Belgium recently reduced postpartum stays by 1 day, rates of neonatal readmission for jaundice and dehydration increased (Plusquin, 2020). Using Washington state data, Malkin and coworkers (2000) found that the 28-day mortality rate was increased fourfold in newborns discharged within 30 hours of birth, and the 1-year mortality rate grew twofold. Safe discharge for late-preterm newborns has special concerns (Whyte, 2012).

Because of the increased scrutiny regarding short hospital stays, federal legislation—*The Newborns' and Mothers' Health Protection Act of 1996*—was enacted to prohibit insurers from restricting hospital stays for mothers and newborns to less than 2 days for vaginal delivery or 4 days for cesarean delivery. In an analysis of more than 662,000 births in California, Datar and Sood (2006) found that readmission rates declined by 9, 12, and 20 percent, respectively, at 1, 2, and 3 years after the legislation was implemented.

CHAPTER 33

Complications of the Term Newborn

Term newborns are susceptible to various illnesses and injuries. In many instances, clinical manifestations of these disorders are extensions of pathological effects already incurred by the fetus. A common example is the newborn who is depressed and acidotic because of intrapartum septicemia. Susceptibility varies depending upon gestational age, and those more common in term newborns are considered here. Those more frequent in preterm neonates are discussed in Chapter 34. Specific disorders that are the direct consequence of maternal diseases are discussed in pertinent chapters.

RESPIRATORY DISTRESS

At the time of delivery, the newborn must convert rapidly to air breathing as described in Chapter 32 (p. 586). With inspiration, alveoli expand, lung fluid is cleared, and surfactant prevents alveolar collapse. Interference with these functions can create respiratory insufficiency. The neonate demonstrates hypoxemia and compensatory tachypnea, nasal flaring, chest wall retractions, and grunting. In preterm neonates, this is often caused by lung immaturity and insufficient surfactant—*respiratory distress syndrome (RDS)*, which is discussed in Chapter 34 (p. 615).

As fetuses approach term, surfactant deficiency as a cause of respiratory distress diminishes. The leading causes in term newborns are transient tachypnea of the newborn (TTN), meconium aspiration syndrome, pneumonia, and pneumothorax. Less common etiologies are RDS, persistent pulmonary hypertension, acid/base disturbances, central nervous system (CNS) insults, and congenital chest, respiratory tract, CNS, or cardiac anomalies (Alhassen, 2021).

Following birth, successful neonatal transition to air breathing may be delayed. With longer delays, evaluations to identify the cause of respiratory distress are warranted. The initial neonatal evaluation includes chest radiographs. Complete blood count or C-reactive protein levels and blood cultures are obtained to identify infection. Arterial blood gas assessments can define respiratory status and direct oxygenation care.

In general, treatment of respiratory distress is supportive with oxygen therapy provided as needed. Depending on the etiology and severity, continuous positive airway pressure (CPAP) or mechanical ventilation may be needed. Nutritional intake may be oral, gavage, or intravenous depending on the degree of neonatal tachypnea. High respiratory rates can limit effective breastfeeding and raise aspiration risk.

Transient Tachypnea of the Newborn

TTN is benign, self-limited, and stems from slow clearance of fetal lung fluid after birth. Neonates of any gestational age can be affected. However, delivery before 39 weeks' gestation raises risk, and rates vary inversely with gestational age. Other risk factors are cesarean delivery without labor, male gender, perinatal asphyxia, and large- or small-for-gestational-age birthweight. Maternal gestational diabetes or asthma are others.

TTN is a diagnosis of exclusion. Thus, the evaluation outlined in the last section excludes pathological sources.

Treatment is supportive with oxygen therapy as needed. Most TTN cases resolve within 48 hours.

Respiratory Distress Syndrome

This condition stems from surfactant deficiency and has a relatively low incidence at term (Berthelot-Ricou, 2012). Risks include male gender, white race, and maternal diabetes (Anadkat, 2012; Li, 2019). Less frequently, rare mutations in genes that code for surfactant protein synthesis may contribute. Four are *surfactant protein B*, *surfactant protein C*, *adenosine triphosphate (ATP)-binding cassette subfamily A member 3 (ABCA3)*, and *thyroid transcription factor 1* genes (Liszewski, 2017). Regardless of etiology, when surfactant secretion is diminished, the pulmonary pathophysiology, clinical course, and management are similar to that for preterm infants. Treatment includes CPAP or mechanical ventilation and potentially surfactant replacement either through an endotracheal tube or by less invasive surfactant techniques (Chap. 34, p. 616). Bacterial pneumonia, especially related to group B *Streptococcus* in a newborn is often clinically and radiographically indistinguishable from RDS. Thus, empirical antibiotics are often added to respiratory management. The prognosis in term newborns with RDS largely depends on the cause, severity, and response to treatment.

Antenatal maternal corticosteroid treatment is employed for threatened preterm birth and described in Chapter 45 (p. 802). In late-preterm fetuses 34 to 37 weeks' gestation, this therapy also enhances surfactant synthesis (Gyamfi-Bannerman, 2016). At Parkland Hospital, corticosteroids are not given in the late-preterm period for this indication. Neonatal hypoglycemia is a concern with such treatment, and long-term effects are unknown. However, data indicate that hypoglycemia, if promptly treated, creates no adverse sequelae (McKinlay, 2015).

Meconium Aspiration Syndrome

The physiology of meconium passage and amnionic fluid contamination is considered in Chapter 24 (p. 458). In some instances, inhalation of meconium-stained fluid at or near delivery causes acute airway obstruction, chemical pneumonitis, surfactant dysfunction or inactivation, and pulmonary hypertension (Vain, 2017). If severe, hypoxemia may lead to neonatal death or long-term neurological sequelae in survivors.

Meconium-stained fluid in labor is common. Fortunately, severe aspiration leading to overt respiratory failure is much less frequent. In one study, the incidence of severe disease was 4 cases per 1000 newborn hospital discharges, and rates rise progressively from 37 to 43 weeks' gestation (Thornton, 2019). Mortality rates depend on severity.

Fetal morbidity is more often associated with thicker meconium content. Presumably, in most cases, amnionic fluid is ample to dilute the meconium to permit prompt clearance by normal fetal physiological mechanisms. Meconium aspiration syndrome still occasionally develops with light staining. Many newborns are affected after a normal labor and uncomplicated delivery. However, some associated obstetrical factors include postterm pregnancy and fetal-growth restriction. These fetuses are at highest risk because diminished amnionic fluid and labor with cord compression or uteroplacental insufficiency are often comorbid. These can enhance the likelihood of meconium passage that is thick and undiluted (Leveno, 1984).

Prevention

Previously, aspiration was thought to be stimulated by fetal hypoxic episodes, and fetal heart rate tracing abnormalities were used to identify fetuses at greatest risk during labor. Unfortunately, this was found to be an unreliable predictor (Dooley, 1985). As another potential prevention, oropharyngeal suctioning at the perineum was standard care for a time. However, this was abandoned when evidence failed to support a reduction in meconium aspiration syndrome incidence or severity (American College of Obstetricians and Gynecologists, 2021b; Vain, 2004). From other studies, endotracheal intubation and suctioning for both vigorous and nonvigorous meconium-stained neonates provides no benefit and is no longer recommended as a routine (Trevisanuto, 2020; Wiswell, 2000; Wyckoff, 2020). Because neonates born through meconium may need effective positive pressure ventilation for stabilization, it is still critical that pediatric providers attend such deliveries (Aziz, 2020).

Intrapartum amnioinfusion has been used successfully in laboring women with diminished amnionic fluid volume to help resolve frequent variable fetal heart rate decelerations (Chap. 24, p. 459). Earlier, it was also studied as a preventive measure in labors complicated by meconium staining. This practice fails to lower rates of meconium aspiration syndrome in settings with standard peripartum surveillance (Hofmeyr, 2014). A trial was conducted with almost 2000 women at 36 weeks' gestation or later and in whom labor was complicated by thick meconium (Fraser, 2005). The perinatal death rate with and without amnioinfusion was 0.05 percent in both groups. Rates of moderate or severe meconium aspiration also were not significantly different in those with (4.4 percent) and without (3.1 percent) amnioinfusion. Last, cesarean delivery rates were similar—32 versus 29 percent, respectively.

Treatment

Ventilatory support including CPAP, intubation, and mechanical ventilation is carried out as needed (Pandita, 2018). Because some aspects of meconium aspiration syndrome are caused by surfactant deficiency, replacement therapy is beneficial (Natarajan, 2016a). In a review of randomized trials, authors found that surfactant replacement may reduce the need for extracorporeal membrane oxygenation (ECMO) but did not lower the mortality rate (El Shahed, 2014). Inhaled corticosteroids may partially ameliorate the severity of meconium aspiration syndrome, but neither inhaled or systemic corticosteroids consistently improve critical outcomes (Garg, 2016; Yeung, 2021). Newborns with meconium aspiration syndrome and pulmonary hypertension are often treated with inhaled nitric oxide, which reduces rates of death and need for ECMO (Vain, 2017). ECMO therapy is reserved for neonates who remain poorly oxygenated despite maximal ventilatory assistance (Hirakawa, 2017). The proportion that requires ECMO treatment varies. From the California Perinatal Quality Care Collaborative, 0.35 percent of more than 5100 cases of meconium aspiration syndrome required

ECMO treatment. The associated mortality rate was 5.3 percent (Kalra, 2020).

NEONATAL ENCEPHALOPATHY AND CEREBRAL PALSY

Few events evoke more apprehension in parents and obstetricians than the specter of "brain injury," which immediately prompts concerns for disabling cerebral palsy and intellectual disability. Although most brain disorders or injuries are less profound, history has helped to perpetuate the more dismal outlook. In his first edition of this textbook, Williams (1903) limited discussions of brain injury to those sustained from birth trauma. When later editions introduced the concept that *asphyxia neonatorum* was another cause of cerebral palsy, this too was linked to traumatic birth. Even as brain damage caused by traumatic delivery became uncommon during the ensuing decades, the belief—albeit erroneous—was that intrapartum events caused most neurological disability. This was a major reason for the escalating cesarean delivery rate beginning in the 1970s. Unfortunately, because the genesis of cerebral palsy occurs long before labor in most cases, cesarean delivery did little to mitigate cerebral palsy risks. Cerebral palsy rates have remained the same for 50 years despite a sixfold rise in cesarean birth rates (MacLennan, 2015).

These realizations stimulated scientific investigations to determine the etiopathogenesis of fetal brain disorders, including those leading to cerebral palsy. Seminal observations, including those of Nelson and Ellenberg (1984, 1985, 1986a), are discussed subsequently. These investigators are appropriately credited with proving that these neurological disorders are due to complex multifactorial processes caused by a combination of genetic, physiological, environmental, and obstetrical factors. Importantly, these studies showed that few neurological disorders are associated with peripartum events. However, continuing international interest was garnered to codify the potential role of intrapartum events. In 2000, a task force of the American College of Obstetricians and Gynecologists was appointed to study neonatal encephalopathy and cerebral palsy. The multispecialty coalition reviewed data and provided criteria to define various neonatal brain disorders. Their findings were promulgated by the American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2003).

Ten years later, a second task force updated the findings (American College of Obstetricians and Gynecologists, 2014a). The 2014 Task Force findings are more circumspect in contrast to the earlier ones. Specifically, more limitations are cited in identifying cause(s) of peripartum *hypoxic-ischemic encephalopathy (HIE)* compared with other etiologies of neonatal encephalopathy. The 2014 Task Force recommends multidimensional assessment of each affected infant. They add the caveat that no one strategy is infallible, and thus no single strategy will achieve 100-percent certainty in attributing a cause to neonatal encephalopathy.

Neonatal Encephalopathy

The 2014 Task Force defined neonatal encephalopathy as a syndrome of neurological dysfunction identified in the earliest days of life in neonates born at ≥35 weeks' gestation. It is manifested by seizures or subnormal levels of consciousness and is often accompanied by difficulty with initiating and maintaining respiration and by depressed tone and reflexes. The incidence of encephalopathy has been cited to be 1 to 2 cases per 1000 term liveborn neonates, and it is much more frequent in preterm newborns (Ensing, 2015; Laptook, 2016; Novak, 2018; Ravichandran, 2020). The 2014 Task Force concluded that many etiologies may lead to encephalopathy and cerebral palsy, however, it focused on HIE and causes that were thought to be incurred intrapartum. To identify affected infants, a thorough evaluation is necessary and includes maternal history, obstetrical antecedents, intrapartum factors, placental pathology, and newborn course. These are complemented by laboratory and neuroimaging findings.

Three clinically defined levels categorize encephalopathy. *Mild encephalopathy* is characterized by hyperalertness, irritability, jitteriness, and hypertonia and hypotonia. *Moderate encephalopathy* shows lethargy, abnormal tone, and occasional seizures. *Severe encephalopathy* is manifest by coma, multiple seizures, and recurrent apnea.

The 2014 Task Force also concluded that of the several forms of cerebral palsy, only the *spastic quadriplegic* type can result from acute peripartum ischemia. Other forms—*hemiparetic* or *hemiplegic cerebral palsy, spastic diplegia,* and *ataxia*—are unlikely to result from an intrapartum event. Purely dyskinetic or ataxic cerebral palsy, especially when accompanied by a learning disorder, usually has a genetic origin (Nelson, 2015).

Criteria for Hypoxic-Ischemic Encephalopathy

The 2014 Task Force radically revised the 2003 criteria used to define an acute peripartum event that is consistent with HIE and neonatal encephalopathy. These are outlined in Table 33-1 and are considered with the following caveats (American College of Obstetricians and Gynecologists, 2014b).

First, *Apgar scores* that are low at 5 and 10 minutes are associated with greater risk for neurological impairment. Low scores stem from many causes, and most of these infants will not develop cerebral palsy. With a 5-minute Apgar ≥7, it is unlikely that peripartum HIE caused cerebral palsy.

Acid-base study results define a second HIE criterion. Low pH and high base deficit levels raise the likelihood that neonatal encephalopathy was caused by HIE. Decreasing pH levels form a continuum of increasing risk, but most acidemic neonates will be neurologically normal (Lee, 2020b). A cord artery pH ≥7.2 is very unlikely to be associated with HIE.

Magnetic resonance (MR) imaging or *MR spectroscopy (MRS)* is the best modality with which to visualize findings consistent with HIE. The 2014 Task Force concluded that cranial sonography and computed tomography (CT) lack sensitivity in the term newborn. Normal imaging findings after the first 24 hours of life, however, effectively exclude a hypoxic-ischemic cause of encephalopathy. MR imaging between 24 and 96 hours may be more sensitive for the timing of peripartum cerebral injury, and MR imaging at 7 to 21 days following birth is the best technique to delineate the full extent of cerebral injury.

Last, *multisystem involvement* of injury is consistent with HIE. These include renal, gastrointestinal, hepatic, or cardiac

TABLE 33-1. Findings Consistent with an Acute Peripartum or Intrapartum Event Leading to Hypoxic-Ischemic Encephalopathy

Neonatal Findings
Apgar score: <5 at 5 and 10 minutes
Umbilical arterial acidemia: pH <7.0 and/or base deficit ≥12 mmol/L
Neuroimaging evidence of acute brain injury: MR imaging or MRS consistent with HIE
Multisystem involvement consistent with HIE
Type and Timing of Contributing Factors
Sentinel hypoxic or ischemic event occurring immediately before or during delivery
Fetal heart rate monitor patterns consistent with an acute peripartum or intrapartum event

HIE = hypoxic-ischemic encephalopathy; MR = magnetic resonance; MRS = magnetic resonance spectroscopy.

injury; hematological abnormalities; or combinations of these. The severity of neurological injury does not necessarily correlate with injuries to these other systems.

The 2014 Task Force also found that certain contributing factors may be consistent with an acute peripartum event. Of these, *sentinel events* are considered adverse obstetrical events that may lead to catastrophic clinical outcomes. Examples include ruptured uterus, severe placental abruption, cord prolapse, and amnionic fluid embolism. Martinez-Biarge and associates (2012) studied almost 58,000 deliveries and identified 192 cases with one of these sentinel events. Of these 192 fetus/newborns, 6 percent died intrapartum or in the early neonatal period, and 10 percent developed neonatal encephalopathy. Other risk factors for neonatal acidosis include prior or emergent cesarean delivery, maternal age ≥35 years, maternal obesity, thick meconium, chorioamnionitis, and general anesthesia (Johansson, 2018; Johnson, 2014; Nelson, 2014).

Differentiating an *abnormal fetal heart rate (FHR) tracing* on presentation versus one that develops subsequently also was emphasized by the 2014 Task Force. A category 1 or 2 FHR tracing associated with Apgar scores ≥7 at 5 minutes, normal cord gases (±1 SD), or both are not consistent with an acute HIE event (Graham, 2014). An FHR pattern at the time of presentation with persistently minimal or absent variability and lacking accelerations, with duration ≥60 minutes, and even without decelerations is suggestive of an already compromised fetus (Chap. 24, p. 450). The 2014 Task Force further recommended that with these findings present, if fetal well-being cannot be established, the woman should be evaluated for the method and timing of delivery.

Prevention

In term newborns, one of the best-studied interventions for neonatal HIE is postnatally induced hypothermia. Cooling initiated within the first 6 hours of life to a level of 33.5°C for 72 hours reduces death and moderate to severe neurological disability in term newborns (Jacobs, 2013; Natarajan, 2016b). One metaanalysis of more than 1500 neonates concluded that hypothermia improves survival rates and neurodevelopment by 24 months of age (Jacobs, 2013). This neuroprotection extends to childhood (Azzopardi, 2014; Guillet, 2012; Shankaran, 2012). MR imaging studies have demonstrated a slowing of diffusional abnormalities and fewer infarctions with hypothermia (Bednarek, 2012; Natarajan, 2016b). Longer or deeper cooling does not offer additional protection compared with standard cooling (Shankaran, 2017).

Importantly, hospitals should develop plans for timely transfer of encephalopathic newborns to a cooling center for evaluation and possible treatment. A trial of "late" hypothermia, with cooling initiated after 6 hours of life, showed some benefit. However, brain protection was not as robust as with cooling initiated in the first 6 hours (Laptook, 2017).

Since therapeutic hypothermia is not completely protective, adjuvant therapies are being explored. In preclinical HIE models, erythropoietin has both early and late beneficial effects. These include antiapoptosis and antiinflammatory effects and greater neurogenesis, oligodendrogenesis, and angiogenesis (McAdams, 2016). One metaanalysis of small clinical trials evaluating this therapy for neuroprophylaxis reports some reductions in cognitive impairment and cerebral palsy rates (Razak, 2019). A large national trial has completed enrollment and is in the follow-up phase (Juul, 2018). Other adjuvant therapies under investigation are allopurinol, xenon, melatonin, and stem cell therapies (McAdams, 2016).

■ Cerebral Palsy

This term refers to a group of nonprogressive disorders of movement or posture caused by abnormal development or damage to brain centers for motor control. Cerebral palsy is further classified by the type of neurological dysfunction—spastic, dyskinetic, or ataxic—and by the number and distribution of limbs involved—quadriplegia, diplegia, hemiplegia, or monoplegia. Together, the major types are *spastic quadriplegia*—the most common—which has a strong association with mental retardation and seizure disorders; *diplegia,* which is common in preterm or low-birthweight neonates; *hemiplegia; choreoathetoid types;* and *mixed varieties.* Although epilepsy and intellectual disability frequently accompany cerebral palsy, these two disorders seldom are associated with perinatal asphyxia in the absence of cerebral palsy.

Incidence and Epidemiological Correlates

According to the Centers for Disease Control and Prevention (2021), the prevalence of cerebral palsy in the United States

approximates 3 cases in 1000 children. *It is crucial to emphasize that this rate is derived from all children—including those born preterm.* Because of the remarkably greater survival rates of the latter currently, and despite the elevated cesarean delivery rate, the overall rate of cerebral palsy has remained essentially unchanged (Fig. 33-1). For example, neonates born at 23 to 27 weeks' gestation in a Swedish birth cohort had a cerebral palsy incidence of 105 cases per 1000 infants alive at 1 year (Hafström, 2018). Similar findings have been reported for Australian births (Smithers-Sheedy, 2016). In absolute numbers, term newborns constitute half of cerebral palsy cases because preterm births are proportionately far fewer. It is again emphasized that most studies of cerebral palsy rates have not made distinctions between term and preterm neonates.

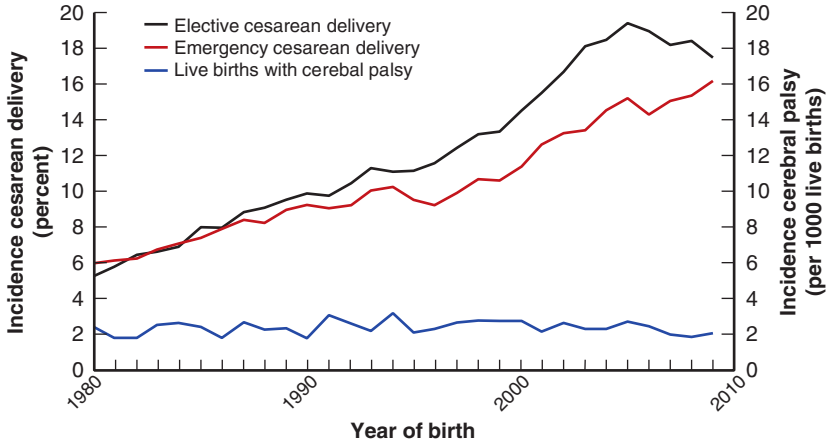

FIGURE 33-1 Elective and emergency cesarean deliveries and live births with cerebral palsy. (Reproduced with permission from Nelson KB, Blair E: Prenatal factors in singletons with cerebral palsy born at or near term, N Engl J Med. 2015 Sep 3;373(10):946–953.)

As noted earlier, Nelson and Ellenberg (1984, 1985, 1986a) made many fundamental observations concerning cerebral palsy. Their initial studies emanated from data from the Collaborative Perinatal Project. This included children from almost 54,000 pregnancies who were followed until age 7. They found that the most frequently associated risk factors for cerebral palsy were: (1) evidence of genetic abnormalities such as maternal mental retardation or fetal congenital malformations; (2) birthweight <2000 g; (3) birth before 32 weeks; and (4) perinatal infection. They also found that obstetrical complications were not strongly predictive, and only a fifth of affected children had markers of perinatal asphyxia. *For the first time, solid evidence supported that the cause of most cases of cerebral palsy was unknown, and importantly, only a small proportion stemmed from neonatal HIE.* Equally importantly, no foreseeable single intervention would likely prevent a large proportion of cases.

Numerous studies have since confirmed many of these findings and have identified an imposing list of other risk factors (Table 33-2). As expected, preterm birth continues to be the single most important risk (Nelson, 2015). Small-for-gestational-age neonates also are at higher risk. In one study, cerebral palsy was due to antepartum factors in more than 90 percent of growth-restricted newborns (Stoknes, 2012).

Many other placental and neonatal risk factors are associated with neurodevelopmental abnormalities (MacLennan, 2015). Some placental factors are discussed further in Chapter 6 (p. 111). One example is the substantively greater risk from chorioamnionitis (Shevell, 2014; Shi, 2017). Of neonatal causes, one is arterial ischemic stroke, which may be associated with inherited fetal thrombophilias (Harteman, 2013; Wanenaar, 2018). Additionally, newborns with isolated congenital heart lesions have an elevated risk for microcephaly, possibly due to chronic fetal hypoxemia (Barbu, 2009). Other miscellaneous etiologies of cerebral palsy include fetal anemia, twin-twin transfusion syndrome, intrauterine transfusions, and fetal alcohol syndrome (DeJong, 2012; Nelson, 2015; O'Leary, 2012; Rossi, 2011; Schou, 2019).

Apart from these causes, intrapartum hypoxemia was linked to only a few cases of cerebral palsy by the National Collaborative Perinatal Project. The contribution of HIE to subsequent neurological disorders was discussed earlier. The 2003 Task Force applied these criteria to more contemporaneous outcomes and determined that only 1.6 cases of cerebral palsy per 10,000 deliveries are attributable solely to intrapartum hypoxia.

TABLE 33-2. Perinatal Risk Factors Reported to Be Increased in Children with Cerebral Palsy

Risk Factors	Risk Ratio	95% CI
Hydramnios	6.9	1.0–49.3
Placental abruption	7.6	2.7–21.1
Interval between pregnancies <3 mo or >3 yr	3.7	1.0–4.4
Spontaneous preterm labor	3.4	1.7–6.7
Preterm delivery at 23–27 weeks	78.9	56.5–110
Breech or face presentation, transverse lie	3.8	1.6–9.1
Severe birth defect	5.6	8.1–30.0
Nonsevere birth defect	6.1	3.1–11.8
Time to cry >5 minutes	9.0	4.3–18.8
Obesity	1.2–2	1.1–2.8
Low placental weight	3.6	1.5–8.4
Placental infarction	2.5	1.2–5.3
Chorioamnionitis		
Clinical	2.4	1.5–3.8
Histological	1.8	1.2–2.9
Others[a]	—	—

[a]Includes respiratory distress syndrome, meconium aspiration, emergent cesarean or operative vaginal delivery, hypoglycemia, gestational hypertension, hypotension, advanced maternal age, genetic factors, twins, thrombotic states, nighttime delivery, seizures, fetal-growth restriction, male gender, and nulliparity.
CI = confidence interval.
From Ahlin, 2013; Blair, 2011; McIntyre, 2013; Moster, 2008; Nelson, 2015; O'Callaghan, 2011; Shatrov, 2010; Takenouchi, 2012; Torfs, 1990; Villamor, 2017; Wu, 2012.

This finding is supported by a study of nearly 1000 infants in which fetal-growth restriction and birth defects recognized by age 6 years were more substantial contributors to cerebral palsy and neonatal death than potentially asphyxial birth events and inflammation (McIntyre, 2013).

Intrapartum Fetal Heart Rate Monitoring

Despite persistent attempts to validate continuous intrapartum electronic FHR monitoring as effective to prevent adverse perinatal outcomes, evidence does not support its ability to predict or reduce cerebral palsy risk (Alfirevic, 2017). Moreover, no specific FHR patterns is predictive of cerebral palsy, and no relationship has been found between the clinician's response to abnormal patterns and neurological outcome. Efforts using computer-assisted analysis of FHR tracings have not enhanced predictions (Alfirevic, 2017; INFANT Collaborative Group, 2017). Indeed, an abnormal heart rate pattern in fetuses that ultimately develop cerebral palsy may reflect a preexisting neurological abnormality (Phelan, 1994). Because of these studies, the American College of Obstetricians and Gynecologists (2019a; 2021a) concludes that electronic FHR monitoring does not reduce the incidence of long-term neurological impairment.

Apgar Scores

In general, 1- and 5-minute Apgar scores are poor predictors of long-term neurological impairment (American College of Obstetricians and Gynecologists, 2021c). However, if the 5-minute Apgar score is ≤3, neonatal death or the risk of neurological sequelae rises substantially (Chen, 2020; Nelson, 1984). In a Swedish study, 5 percent of such children subsequently required special schooling (Stuart, 2011). In a Scottish study, the incidence of these low Apgar scores was 0.3 percent in more than 750,000 children who were born at term and were in national school census records. Low Apgar score was strongly associated in a dose-dependent manner with the need for additional educational support in later life, after adjusting for confounding factors. The strongest association was for the support of physical and motor impairments and was followed by visual, hearing, and cognitive impairments (Tweed, 2016).

Persistence past 5 minutes of these extremely low scores correlates strongly with a higher risk for neurological morbidity and death (Foglia, 2020). This of course is not absolute, and the 2003 Task Force cited a 10-percent risk for cerebral palsy for neonates with 10-minute scores of 0 to 3. For 15-minute scores ≤2, the cited mortality rate was 53 percent, and cerebral palsy rate was 36 percent. For 20-minute scores ≤2, the mortality rate was 60 percent, and cerebral palsy rate was 57 percent. Outcomes from a Norwegian population study of neonates who were born from low-risk pregnancies and who had low 5-minute Apgar scores are shown in Table 33-3 (Moster, 2001).

Umbilical Cord Blood Gas Studies

Objective evidence of metabolic acidosis, that is, cord arterial blood pH <7.0 and base deficit ≥12 mmol/L, is a risk factor for encephalopathy and for cerebral palsy (p. 601). The risk accrues as acidosis worsens. From one review of 51 studies, low pH in arterial umbilical cord blood correlates with greater risk for neonatal encephalopathy and cerebral palsy (Malin, 2010). When used alone, however, these determinations are not accurate in predicting long-term neurological sequelae (Yeh, 2012).

TABLE 33-3. Comparison of Mortality and Morbidity in Norwegian Infants Weighing >2500 g According to 5-Minute Apgar Scores

Outcome	Apgar 0–3 (%)	Apgar 7–10 (%)	Relative Risk (95% CI)
Number	292	233, 500	
Mortality rates			
Neonatal	16.5	0.05	386 (270–552)
Infant	19.2	0.3	76 (56–103)
1–8 yr	3	0.2	18 (8–39)
Morbidity rates			
Cerebral palsy	6.8	0.09	81 (48–128)
Mental retardation	1.3	0.1	9 (3–29)
Other neurological	4.2	0.5	9 (5–17)
Non-neurological	3.4	2.0	2 (0.8–5.5)

CI = confidence interval.

Data from several studies corroborate that a pH <7.0 is the threshold for clinically significant acidemia (Gilstrap, 1989; Goldaber, 1991). The likelihood of neonatal death grows as the cord artery pH falls to ≤7.0. Casey and colleagues (2001) reported that when the pH was ≤6.8, the neonatal mortality rate rose 1400-fold. When the cord pH was ≤7.0 *and* the 5-minute Apgar score was 0 to 3, the risk of neonatal death rose 3200-fold.

In a study from Oxford, the rate of adverse neurological outcomes was 0.36 percent with pH <7.1 and was 3 percent with pH <7.0 (Yeh, 2012). A systematic review that includes 12 studies suggests that cord blood lactate levels also help predict neonatal outcomes (Allanson, 2017).

Nucleated Red Blood Cells and Lymphocytes

Both immature red cells and lymphocytes enter the circulation of term newborns in response to hypoxia or hemorrhage. During the past two decades, quantification of these cells has been proposed as a measure of hypoxia, but not all studies support this premise (Boskabadi, 2017; Silva, 2006; Walsh, 2011, 2013).

Neuroimaging Studies in Encephalopathy and Cerebral Palsy

Various neuroimaging techniques have provided important insight into the etiology and evolution of perinatal HIE and later cerebral palsy. Findings vary by fetal age, and the preterm neonatal brain responds differently to an ischemic episode than that of a term newborn. Other factors include insult severity and duration and restoration of cerebrovascular hypoperfusion. *Thus, precise timing of an injury with neuroimaging studies is not a realistic goal.* Moreover, the grade of neonatal encephalopathy, that is, mild, moderate, or severe, does not correlate with MR imaging findings (Walsh, 2017).

Neuroimaging in the Neonatal Period

The 2014 Task Force concluded that for term newborns, imaging studies are helpful in timing an injury, but they provide only a time window that is imprecise. The 2014 Task Force reported that these head imaging techniques provide the following information:

1. Neonatal sonography findings are generally normal on the day of birth. With injury, the thalami and basal ganglia become increasingly echogenic beginning at approximately 24 hours. This progresses over 2 to 3 days and persists for 5 to 7 days.
2. CT images are usually normal the first day in term newborns. With injury, the thalami or basal ganglia show decreased density beginning at approximately 24 hours, and this persists for 5 to 7 days.
3. MR imaging will detect some abnormalities on the first day. Within 24 hours, MR imaging may show restricted water diffusion that peaks at approximately 5 days and disappears within 2 weeks. T1- and T2-weighted images display variable abnormalities, which have an onset from less than 24 hours to several days. In a study of 175 term neonates with acute encephalopathy, MR imaging that showed basal ganglia lesions accurately predicted motor impairment at 2 years of age (Martinez-Biarge, 2012).

Neuroimaging in Older Children with Cerebral Palsy

Imaging studies performed in children diagnosed with cerebral palsy frequently show abnormal findings. Wu and associates (2006) used CT or MR imaging to study 273 children who were born after 36 weeks' gestation and who were later diagnosed with cerebral palsy. Although a third of these imaging studies were normal, focal arterial infarction was seen in 22 percent; brain malformations in 14 percent; and periventricular white-matter injuries in 12 percent. In another study of 351 children with cerebral palsy, of whom approximately half were born near term, MR imaging findings were abnormal in 88 percent (Bax, 2006). One MR imaging study found pathological findings in 84 percent of children with spastic quadriplegia (Robinson, 2008). Remember, the 2014 Task Force concluded that this neurological lesion correlated with neonatal encephalopathy.

Imaging techniques in older children also help define the timing of fetal or perinatal cerebral injury. Due to concerns regarding the radiation exposure of CT scans, MR imaging is more often used. Wiklund and coworkers (1991a,b) studied 83 children between ages 5 and 16 years who were born at term and who developed hemiplegic cerebral palsy. Nearly 75 percent had abnormal CT findings, and these investigators concluded that more than half had CT changes that suggested a *prenatal injury.* Approximately 20 percent were attributed to a *perinatal injury.*

■ Intellectual Disability and Seizure Disorders

These both frequently accompany cerebral palsy. However, when either manifests alone, it is seldom caused by perinatal hypoxia (Nelson, 1984, 1986a, 2015). Severe mental disability has a prevalence of 3 cases per 1000 children, and its most frequent causes are chromosomal, gene mutation, and other congenital malformations. Last, preterm birth also is associated with these (Hientz, 2018).

The major predictors of seizure disorders are fetal malformations—cerebral and noncerebral; family history of seizures; and neonatal seizures (Nelson, 1986b; Pisani, 2015). Neonatal encephalopathy causes a small proportion of seizure disorders. Reports from the Neonatal Research Network and other studies conclude that increasing severity of encephalopathy correlates best with seizures (Glass, 2011; Kwon, 2011).

Autism Spectrum Disorders

According to the Centers for Disease Control and Prevention, the frequency of autism spectrum disorders is 15 cases per 1000 8-year-old children (Christensen, 2016). Although these may be associated with maternal metabolic conditions, none has been linked convincingly to peripartum events (Krakowiak, 2012).

NEONATAL ABSTINENCE SYNDROME

This is a drug-withdrawal syndrome that most commonly follows in-utero exposure to maternal opioids. It also can complicate exposure to alcohol or benzodiazepines. The syndrome shows hypertonia, autonomic instability, irritability, poor sucking reflex, and seizures (Finnegan, 1975). Its incidence has risen six- to sevenfold during the past decade, coincidental with growing opioid use. For example, 4 percent of all neonatal intensive care unit days in 2013 were attributed to care of these affected newborns (Tolia, 2015).

Care includes close observation, and pharmacotherapy is usually given. In addition to morphine and methadone, other treatment may include phenobarbital, benzodiazepines, and clonidine (Tolia, 2015). More recently, buprenorphine compared with morphine was reported to result in shorter lengths of treatment and hospital stays (Kraft, 2017; Lee, 2019). Consensus is lacking regarding the most effective regimen. The American College of Obstetricians and Gynecologists and the American Society of Addiction Medicine (2019c) have taken the lead in screening, intervention, and treatment of opioid use disorders in pregnant women (Chap. 64, p. 1150).

HEMATOLOGICAL DISORDERS

Obstetricians should be familiar with a few neonatal disorders of erythrocytes, platelets, and coagulation. Many of these manifest in the fetus and persist in the newborn.

■ Anemia

After 35 weeks' gestation, the mean cord hemoglobin concentration approximates 17 g/dL, and values below 14 g/dL are considered abnormal. In newborns, delayed umbilical cord clamping raises hemoglobin levels at birth and improves iron stores in the first several months. A review of nearly 9200 late-preterm and term deliveries found delayed cord clamping was associated with a mean neonatal hemoglobin rise of 1.2 g/dL at birth (Gomersall, 2021). However, rates of infant anemia at 6 months were similar in groups with or without delayed cord clamping. Moreover, this practice raises the incidence of hyperbilirubinemia that

requires phototherapy but does not prolong hospital stay. Discussed further in Chapter 27 (p. 500), the American College of Obstetricians and Gynecologists (2020) recommends a 30- to 60-second delay in cord clamping in all healthy newborns.

Significant neonatal anemia may predate or follow delivery. First, neonatal anemia may reflect an extension of antenatal fetal anemia. General etiological groups are immune-medicated red cell destruction, aneuploidy, hematology-related genetic defects, fetomaternal hemorrhage, fetal infection, and placental abnormalities such as chorioangioma or twin anastomotic defects.

Second, at delivery, acute anemia with hypovolemia can follow laceration of the placenta, fetal vessel, or umbilical cord. Intracranial or extracranial injury or trauma to fetal intraabdominal organs also can cause hemorrhage with acute anemia (Malec, 2020).

Polycythemia

Neonatal polycythemia can be associated with chronic or acute fetal hypoxia, twin anemia-polycythemia syndrome, maternal diabetes or hypertension, placental- and fetal-growth restriction, aneuploidy, and delayed cord clamping. When the hematocrit rises above 65, blood viscosity markedly increases. Routine neonatal screening is not recommended in newborns without symptoms (Remon, 2011). Frequent signs are hypotonia, a ruddy complexion (plethora), respiratory distress with cyanosis, jitteriness, or hypoglycemia. Because of the shorter life span of macrocytic fetal erythrocytes, hyperbilirubinemia commonly follows. Associated blood hyperviscosity can lead to end-organ damage and neurodevelopmental harm. Isovolemic partial exchange transfusion (PET) with saline can lower the hematocrit and improve symptoms, however, it is not neuroprotective and has associated complications (Dempsey, 2006). From limited data, PET is often reserved for neonates with acute symptoms or hypoglycemia (Hopewell, 2011).

Hyperbilirubinemia

Excessive serum bilirubin levels can be neurotoxic for newborns. In fetuses, hepatic maturation is incomplete, and some unconjugated bilirubin is cleared by placental transfer to be conjugated and excreted by the mother. After delivery, clearance relies on neonatal hepatic function, and thus varying degrees of neonatal hyperbilirubinemia arise. Even in the mature newborn, serum bilirubin levels usually increase for 3 to 4 days to reach up to 10 mg/dL. After this, concentrations usually fall rapidly. In approximately 15 percent of term newborns, bilirubin levels cause jaundice. Of risks, polycythemia, hemolysis such as from ABO incompatibility or glucose-6-phosphate dehydrogenase deficiency, and extravasation of blood such as from a cephalohematoma all raise bilirubin burden. Decreased bilirubin clearance is seen with prematurity.

With excessive serum bilirubin levels, toxicity has two forms. *Acute bilirubin encephalopathy* develops in the first days of life and may cause hypotonia, poor feeding, lethargy, and abnormal auditory-evoked responses. Immediate recognition and treatment will usually mitigate progressive neurotoxicity.

The chronic form is termed *kernicterus*. With this, profound neuronal degeneration follows bilirubin deposition and staining of the basal ganglia and hippocampus. Survivors have spasticity, muscular incoordination, and varying degrees of mental deficiencies. Continuing hemolysis is a risk factor for kernicterus (El Houchi, 2017; Vandborg, 2012).

Initial prevention emphasizes effective breastfeeding to avoid neonatal dehydration. Surveillance for jaundiced skin is recommended at the same time other newborn vital signs are obtained. Moreover, prior to hospital discharge, universal screening of total serum bilirubin assessment from blood or more commonly by transcutaneous bilirubinometry is done (Maisels, 2009). The latter is a handheld meter that directs light into the skin and measures the intensity of specific returned wavelengths.

Once diagnosed, various forms of phototherapy are used to treat neonatal hyperbilirubinemia. These "bili-lights" emit a spectrum of 460 to 490 nm, which augments bilirubin oxidation to enhance its renal clearance and lower serum levels. Sunlight filtered to remove ultraviolet light can be used in resource-poor countries (Slusher, 2015). Light that penetrates the skin also raises peripheral blood flow, which further enhances photo-oxidation.

For term newborns, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) stress early detection and prompt phototherapy to prevent bilirubin encephalopathy. Despite these measures, bilirubin encephalopathy persists, and this is somewhat related to early hospital discharges (Kuzniewicz, 2014). In the United States, hospitalizations for kernicterus in term newborns were 5 cases per 100,000 in 1988 (Burke, 2009). Since then, this rate has dropped to 0.4 to 2.7 cases per 100,000 births (Watchko, 2013). Legislation to minimize brief postpartum hospital stays may be contributory (Chap. 36, p. 645).

Vitamin K Deficiency Bleeding

Newborns are vitamin K deficient due to insufficient antenatal liver stores, limited synthesis in an initially sterile gut, and low vitamin K content in breast milk. *Vitamin K deficiency bleeding (VKDB)* describes spontaneous internal or external bleeding, and its onset is grouped as early, classic, or late onset. Most cases result from abnormally low levels of the vitamin K–dependent clotting factors. Early onset is within the first 24 hours, and one cause is maternal vitamin K deficiency. Classic hemorrhagic disease is usually apparent between days 2 and 7 of life in neonates not given vitamin K prophylaxis at delivery. Delayed hemorrhage may occur at 2 to 12 weeks in exclusively breastfed infants.

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) recommend routine prophylaxis with a single, intramuscular, 0.5- to 1-mg dose of vitamin K_1 (phytonadione). Oral administration is less effective, and maternal vitamin K administration results in very little transport to the fetus (Sankar, 2016). Evidence does not support initial links with vitamin K and childhood leukemia (Fear, 2003; Roman, 2002).

Hemorrhagic disease of the newborn includes VKDB but also bleeding from other etiologies. These include congenital clotting factor deficiency, disseminated intravascular coagulopathy, birth trauma, and thrombocytopenia.

Thrombocytopenia

Abnormally low platelet concentrations in term newborns are often categorized as *early onset*, within the first 72 hours, and *late onset* thereafter. In the term neonate, causes include immune disorders, infections, inherited platelet defects, or congenital syndromes (American College of Obstetricians and Gynecologists, 2019b; Cremer, 2016). Of immunologic sources, neonatal thrombocytopenia stemming from alloimmunization or from maternal idiopathic thrombocytopenic purpura are described in Chapter 18 (p. 359). Neonatal lupus syndrome can also show thrombocytopenia (Chap. 62, p. 1113). With all these, antiplatelet IgG transferred to the fetus may cause accelerated platelet destruction.

Alternatively, thrombocytopenia can be an extension of fetal infection with B19 parvovirus, cytomegalovirus, toxoplasmosis, and others discussed in Chapters 67 and 68. Neonatal thrombocytopenia has been reported with maternal antiretroviral therapy for human immunodeficiency virus (HIV) infection (Smith, 2016). Term newborns with sepsis can have accelerated platelet consumption (Eissa, 2013). Last, inherited platelet disorders are described in Chapter 59 (p. 1059).

NEWBORN INJURIES

Incidence

Birth injury can complicate any term delivery, and from population studies, its incidence approximates 2 percent of deliveries (Linder, 2012; Sauber-Schatz, 2010). Imprecision in these numbers may stem from lumping of major and minor injuries and trauma definitions. In one population study from Washington State, the rate of neonatal birth trauma declined by 14 percent and from 5.3 events per 1000 live births in 2004 to 4.5 in 2013 (Wen, 2017). Major injury rates were highest with forceps or vacuum delivery and substantially lower for all caesarean delivery categories.

Cranial Injuries

The fetal head has considerable plasticity and can undergo appreciable molding during labor. However, traumatic head injuries can occur and result in bony fracture or in intracranial or extracranial hemorrhage. With intra- and extracranial hemorrhages, anatomical location defines their classification (Table 33-4).

Intracranial Hemorrhage

Most aspects of neonatal intracranial hemorrhage are related to gestational age. Of the categories shown in Table 33-4, the term newborn may suffer subdural and intracerebral hemorrhages most often. Intraventricular, subarachnoid, or cerebellar hemorrhages are more frequent in the preterm neonate. In those born preterm, blood pressure instability, hypoxia, and ischemia are prominent causes and described in Chapter 34 (p. 618). In term neonates, birth trauma is the most frequent etiology. Other uncommon causes or contributors include acquired or congenital fetal coagulopathy, vascular anomaly, tumor, genetic mutation, and infection (Tan, 2018). *Importantly, in some newborns, intracranial hemorrhage may follow an apparently uneventful vaginal delivery, and no cause is found.*

Term newborns with intracranial hemorrhage may initially display seizures, apnea or tachypnea, poor feeding, and temperature instability (Ou-Yang, 2010). Imaging options are

TABLE 33-4. Major Types of Cranial Hemorrhage

Type	Collection Site	Associations in Term Neonates	Clinical Outcomes
INTRACRANIAL			
Epidural	Between periosteum and dura mater	Difficult or prolonged birth Idiopathic	Usually good
Subdural	Between dura and arachnoid mater		
Subarachnoid	Between arachnoid and pia mater		
Intraventricular	Ventricles (lateral, 3rd, or 4th)	Birth trauma, hypoxia, or coagulation dysfunction	Variable; worse with high IVH grade and thalamic source
Intracerebral	Cerebral parenchyma	Coagulation dysfunction, vascular anomalies, intrapartum factors	Variable; affected by size, location, or comorbid hydrocephalus
Intracerebellar	Cerebellar parenchyma	Abnormal FHR, OVD, resuscitation required	Variable; affected by size and comorbid lesions
EXTRACRANIAL			
Cephalohematoma	Subperiosteal	OVD, especially VAD Dystocia	Good; risk of anemia or hyperbilirubinemia
Subgaleal	Between galea aponeurotica and periosteum	OVD, especially VAD Dystocia	Variable; worse with associated acidosis, hypovolemia, and comorbid lesions

OVD = operative vaginal delivery; VAD = vacuum-assisted delivery.

sonography or CT, but MR imaging is often preferred. With most lesions, treatment is supportive and nonsurgical. However, acute hydrocephalus, rising intracranial pressure, or mass effects are infrequent complications that can prompt surgery (Tan, 2018).

Names of intracranial lesions reflect anatomy. First, the meninges forms from the dura, arachnoid, and pia mater, and the dura mater is the external layer. *Subdural hemorrhage* collects between the dura and arachnoid mater. Prolonged and difficult delivery can produce cranial molding, dural stretch, and tearing of bridging veins in the subdural space (Towner, 1999; Hong, 2018). Asymptomatic subdural hemorrhage can also accompany uneventful vaginal or cesarean delivery (Rooks, 2008). In asymptomatic newborns, prognosis is good (Zamora, 2021). Poorer outcome may attend those with comorbid conditions or lesions (Hong, 2018).

Less commonly, *subarachnoid hemorrhage* collects between the arachnoid and pia mater. Rarely, *epidural hemorrhage* collects outside the dura mater and beneath the periosteum. In both these hemorrhage types, risks, mechanisms, and recovery are similar to subdural hemorrhage (Hong, 2018; Shah, 2016).

Intraventricular hemorrhage is less common in term than preterm newborns. Described in Chapter 34 (p. 618), the vascular germinal matrix is a vulnerable site for preterm neonates but has mainly regressed by term. Instead, the choroid plexus, thalamus, or residual germinal matrix are bleeding sources at term. Etiology can include birth trauma, hypoxia, or coagulation dysfunction. Additional rare causes are listed in this section's first paragraph. However, in small case series, one to two thirds had no identified antecedent (Roland, 1990; Wu, 2003). Prognosis varies, and worse outcomes are associated with advanced hemorrhage grade or thalamic hemorrhage (Kaur, 2020).

Intracerebral hemorrhage or *neonatal hemorrhagic stroke* is uncommon at term. Risk factors are coagulation defects, vascular anomalies, and intrapartum factors that include FHR abnormalities and low Apgar scores. Trauma is less often implicated (Cole, 2017).

Intracerebellar hemorrhage is infrequent in the term newborn. In one series, associated factors were FHR abnormalities, operative vaginal delivery, emergent cesarean delivery, and delivery-room resuscitation (Limperopoulos, 2009). Prognosis with both intracerebral and intracerebellar hemorrhages is affected by lesion size, presence of additional hemorrhage sites, and associated hydrocephalus or elevated intracranial pressure.

Extracranial Hemorrhage

These blood collections accumulate outside the calvarium (see Table 33-4). From its most superficial surface inward, the scalp consists of skin, subcutaneous tissue, galea aponeurotica, subgaleal space, and calvarium periosteum (Fig. 33-2). The galea aponeurotica is dense fibrous tissue, whereas the subgaleal space contains loose, fibroareolar tissue. Traversing across the subgaleal space are *emissary veins*, which connect the dural sinuses inside the skull with superficial scalp veins.

Caput succedaneum is soft-tissue edema of the scalp. It forms from repetitive contractions that press the head against an unyielding cervix. The caput is maximal at birth, rapidly grows smaller, and usually disappears within hours or days.

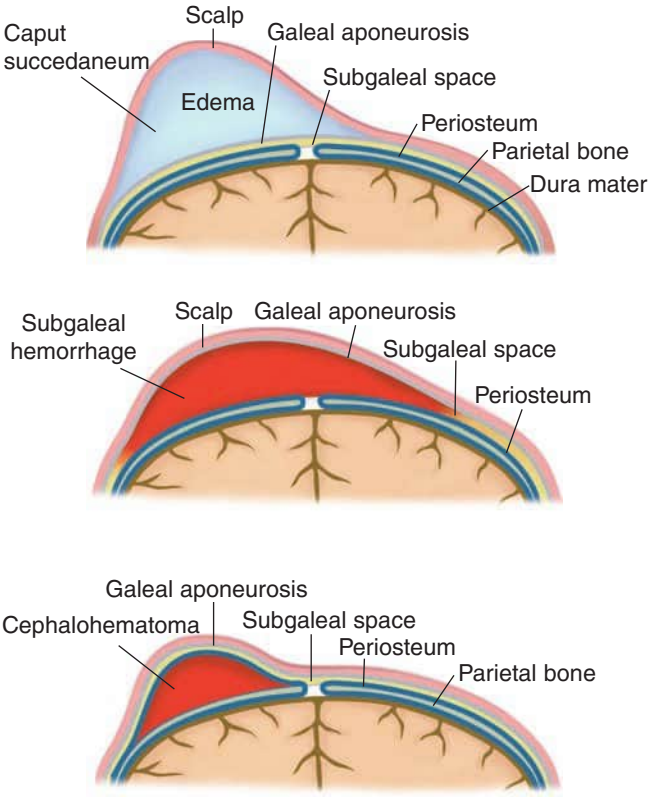

FIGURE 33-2 Schematic of extracranial lesions in the neonate that include caput succedaneum, subgaleal hemorrhage, and cephalohematoma.

Cephalohematoma is a cranial subperiosteal hematoma. It has an incidence of 1 percent and makes up a large percentage of birth injuries (Werner, 2011; Kekki, 2020). It usually develops in the setting of dystocia or operative vaginal delivery. Vacuum-assisted births have a greater association than births by forceps or cesarean delivery (Alexander, 2006; Werner, 2011). Cephalohematoma develops from shearing forces during labor and delivery, which lacerate the emissary or diploic veins. Fortunately, the densely adhered periosteum impedes rapid enlargement and limits final hematoma size. Hemorrhage can be over one or both parietal bones, but collections do not cross suture lines. A cephalohematoma may not be apparent until hours after delivery, when bleeding is sufficient to raise the periosteum. After it is identified, it often grows larger and persists for weeks or even months, and bleeding may cause anemia or hyperbilirubinemia. Outcomes are good in the absence of additional injuries. Rare hematoma complications are infection or calcification (Kandemirli, 2020; Zimmermann, 2016).

Subgaleal hemorrhage is rare and results from emissary vein laceration and bleeding between the galea aponeurotica and the skull periosteum. Both the galea aponeurotica and subgaleal space span across the occipital, parietal, and frontal bones. Because of its loose areolar tissue and large surface area, significant blood volumes can collect in this potential space and may extend from the neck to the orbits and laterally to the temporal fascia above the ears (Modanlou, 2016). Resulting hypovolemia

can lead to shock and significant morbidity, and cited mortality rates approximate 15 percent (El Dib, 2019; Lee, 2018; Swanson, 2011). Other findings are seizures, enlarging head circumference, and respiratory distress. The subgaleal hemorrhage rate is 0.05 percent with spontaneous birth but is ten times greater with vacuum-assisted delivery (Colditz, 2015). The most frequent associate is operative vaginal delivery, especially with vacuum devices, but cases can follow spontaneous vaginal or cesarean delivery (Christensen, 2011).

In general, diagnosis of extracranial lesions begins with head ultrasound (Bansal, 2018). This may be sufficient for cephalohematomas. CT or MR imaging may benefit those with subgaleal hemorrhage to exclude comorbid cranial injuries.

Skull Fractures

These are rare but are especially worrisome because of their association with intracranial hemorrhage. The incidence of birth-related skull fractures approximates 1 case per 100,000 births (Högberg, 2020). Operative vaginal delivery is an associated factor (Dupuis, 2005). However, cases can also attend spontaneous or cesarean delivery (Fig. 33-3) (Dolivet, 2018; Merhar, 2016). In these, fracture may result from tight skull compression against the bony pelvis, by hand pressure used by the surgeon to lift the head at cesarean delivery, or from transvaginally applied upward hand pressure by an assistant. Fractures are diagnosed with radiographs or CT. Depending on type, a fracture may be managed expectantly or require surgery. Prognosis is mainly influenced by comorbid intra- or extracranial injuries.

Spinal Cord Injury

Overstretch of the spinal cord and its associated hemorrhage and edema are rare. The cervical spine is most often injured, and excessive traction, rotation, or hyperextension during shoulder dystocia manipulations, breech vaginal delivery, and operative vaginal delivery are implicated (Lee, 2020a; Menticoglou, 1995). Upper cervical spinal cord injury is often fatal, and survivors can be quadriplegic (Lee, 2020a). Immediate treatment has included ventilator support coupled with corticosteroids or therapeutic hypothermia.

FIGURE 33-3 Depressed skull fracture evident immediately after cesarean delivery. Labor had progressed, and the head was deep in the pelvis. Dislodgment of the head from the birth canal was performed by an assistant using manual pressure upward through the vagina. (Reproduced with permission from Dr. Kimberly M. Spoonts.)

Peripheral Nerve Injuries

Brachial Plexopathy

Injury can involve a single nerve or can affect a nerve root, plexus, or trunk. Trauma to the brachial plexus is infrequent. In one database study, the rate was 1 case per 1000 term births in the United States. The incidence was 1.3 per 1000 vaginal deliveries and 0.2 per 1000 cesarean deliveries (Chen, 2021). Shoulder dystocia, labor dystocia, and breech delivery are risks (Johnson, 2020).

With plexopathy, the injury damages the nerve roots that supply the brachial plexus—$C_{5–8}$ and T_1. With hemorrhage and edema, axonal function may be temporarily impaired, but the recovery chances are good. However, with avulsion, the prognosis for complete recovery is poor. Damage to the $C_{5–6}$ nerve roots can cause *Erb palsy*. Injuries with breech delivery are normally of this type, whereas the more extensive and persistent lesions can follow difficult cephalic deliveries. The latter are more often forceps or vacuum-assisted vaginal deliveries (Wilson, 2016). The $C_{5–6}$ roots join to form the upper trunk of the plexus, and injury leads to paralysis of the deltoid, infraspinatus, and flexor muscles of the forearm. The affected arm is held straight and internally rotated, the elbow is extended, and the wrist and fingers flexed. Finger function usually is retained.

Damage to the C_8-T_1 roots supplying the lower plexus results in *Klumpke palsy,* in which the hand is flaccid. With total involvement of all brachial plexus nerve roots, flaccidity of the arm and hand results. Rarely, with severe injury, phrenic nerve damage can cause ipsilateral diaphragm paralysis, or injury to sympathetic nerve fibers can cause *Horner syndrome*, which manifests as ptosis, miosis, and anhidrosis (Rizeq, 2020). Clavicle or humeral fracture can be comorbid, and clinical concern may prompt chest radiography. MR imaging may be obtained with concern for nerve avulsion (Govindan, 2019).

Because of the importance of brachial plexopathy, the American College of Obstetricians and Gynecologists (2014b) convened a task force to review extant studies. This Task Force concluded that shoulder dystocia cannot be accurately predicted, but in most cases, axonal death does not occur and the prognosis is good. Lindqvist and associates (2012) reported complete recovery in 86 percent of children with $C_{5–6}$ trauma, which was the most common injury, and in 38 percent of those with $C_{5–7}$ damage. However, those with global $C_{5–8}$–T_1 injuries always had permanent disability.

Early physical therapy is initiated to prevent contractures or joint deformity. Maintaining passive joint motion, promoting extremity use, strengthening affected muscles, and providing compensatory techniques are goals (Smith, 2018). Severe injuries may require surgical exploration and nerve reconstruction, usually at 3 to 6 months (Vuillermin, 2016; Wilson, 2016).

FIGURE 33-4 Left facial nerve injury. Classically, the eye fails to close tightly, the labionasal fold is lost, and the mouth pulls to the unaffected side during crying. This was almost completely resolved two days after delivery.

Facial Paralysis

The facial nerve can be injured as it emerges from the stylomastoid foramen, and this may cause facial paralysis (Fig. 33-4). From one series, the incidence was 0.3 cases per 1000 term births (Al Tawil, 2010). Of these vaginal births, forceps were used in one fourth, and three fourths followed spontaneous birth. Pressure from the forceps blade or the bony pelvis, respectively, are suggested injury mechanisms. It can follow cesarean delivery (Alexander, 2006). Spontaneous recovery within a few days is the rule, however, permanent paralysis has been described (Al Tawil, 2010).

Fractures

Most long-bone fractures follow difficult deliveries, however, this is not always the case. At minimum, palpation of the clavicles and long bones is indicated for all newborns after a difficult delivery. Overlying crepitation or irregularity will prompt radiography.

Clavicular fractures are common, unpredictable, and unavoidable complications of normal birth (Ahn, 2015; Roberts, 1995). Their incidence approximates 5 cases in 1000 live births (Kekki, 2020; Linder, 2012). Rates are tenfold higher with vaginal birth than with cesarean delivery (Ahn, 2015). With vaginal birth, shoulder dystocia is an association (Högberg, 2020). With cesarean delivery, greater birth weight is a factor (Choi, 2017).

Humeral fractures and *femoral fractures* are rare. For the humerus, associated settings are breech delivery or posterior arm delivery during shoulder dystocia release (Rietberg, 2003; von Heideken, 2020). Those of the femur are usually associated with breech presentation. Because most breech-presenting fetuses now undergo cesarean delivery, most of these fractures are associated with this mode (Kancherla, 2012). As potential prevention for both fracture types, careful splinting of the bone along its long axis and avoiding perpendicular forces during extraction are encouraged.

Last, *rib fractures* are rare at term. In one series, none was associated with cardiopulmonary resuscitation (Högberg, 2020). Instead, compression forces to the chest during difficult birth or shoulder dystocia are implicated (van Rijn, 2009).

Soft Tissue Injury

Conceivably, any fetal organ or part could be injured with either vaginal or cesarean delivery. Intraabdominal hemorrhage is rare and most often stems from the liver, spleen, or adrenal glands, which are disproportionally large in the newborn. Risks are difficult delivery, especially those presenting breech; cardiac resuscitation; macrosomia; or pathologic enlargement of the involved organ (Schullinger, 1993). Retroperitoneal bleeding with these may manifest as bruising of the flanks, umbilicus, groin, upper thigh, or scrotum (Akin 2011; Heyman, 2011; Raveenthiran, 2008). Pale skin, distended abdomen, and falling hematocrit reflect associated hypovolemia. Treatment involves hemodynamic resuscitation and control of bleeding.

Congenital Deformity Injuries

In *congenital torticollis*, one sternocleidomastoid muscle fails to elongate sufficiently. The head gradually turns toward the side of the injury. Its etiology is unclear. Some cases are associated with breech presentation, operative vaginal birth, or difficult delivery. However, many follow uncomplicated birth, and intrauterine positioning, genetics, and ischemia are some suggested theories (Hardgrib, 2017; Sargent, 2019). Early physical therapy is recommended (Kaplan, 2018).

With *congenital deformations*, a normally developed fetal structure becomes deformed usually by restrictive intrauterine mechanical forces. Common factors are chronic oligohydramnios, multifetal gestation, or abnormally shaped or small uterine cavity. Some mechanical deformations include *talipes equinovarus* (clubfoot) and *oligohydramnios sequence* (Hall, 2014; Society for Maternal-Fetal Medicine, 2019). The latter may lead to pulmonary hypoplasia and deformations of the head, face, skin, and limbs. This sequence and talipes can also be associated with genetic abnormalities or malformations and are discussed in Chapters 14 and 15 (p. 260 and 303).

Last, *congenital hip dislocation* is strongly associated with an in-utero breech presentation (Yang, 2019). Physical examination screening for all newborns is recommended. Treatment may include observation or bracing (Shaw, 2016).

CHAPTER 34

The Preterm Newborn

At the time of this textbook's first edition in 1903, preterm delivery was often followed by neonatal death. However, subsequent scientific innovation has advanced the threshold of viability to 22 to 24 weeks' gestation (Watkins, 2020). Moreover, the overall survival rate for preterm neonates <29 weeks' gestation approaches 80 percent (Travers 2018). Still, the preterm newborn is susceptible to many serious medical complications both early and later in life (Table 34-1).

The complications of prematurity can be serious, and this is reflected in overall neonatal mortality rates. In 2018, two thirds of all infant deaths in the United States were in the 10 percent born before 37 weeks (Ely, 2020; Hamilton, 2021). Fortunately, rates of preterm birth have declined from approximately 12 percent in 2007 to 10 percent in 2020. The rate of early preterm births (<34 weeks' gestation) declined from 2.77 to 2.69 percent, which is the lowest level reported since 2007 (Hamilton, 2021).

RESPIRATORY DISTRESS SYNDROME

The seminal complication of the preterm newborn is *respiratory distress syndrome (RDS)*. This results from immature lungs that are unable to sustain necessary oxygenation due to surfactant deficiency. The resulting hypoxia can be associated with pulmonary hypertension and neurologic damage such as cerebral palsy. In addition, hyperoxia, a side effect of RDS treatment, contributes to other preterm morbidities including bronchopulmonary dysplasia, necrotizing enterocolitis, periventricular leukomalacia, and retinopathy of prematurity.

Etiopathogenesis

To provide blood gas exchange immediately following delivery, the lungs must rapidly fill with air while being cleared of fluid. Concurrently, pulmonary arterial blood flow must rise. Although some of the fluid is expelled as the chest is compressed during vaginal delivery, most is absorbed through the pulmonary lymphatics via complex mechanisms described in Chapter 32 (p. 586). Sufficient surfactant, synthesized by type II pneumocytes, is essential to stabilize the air-expanded alveoli. This lipoprotein lowers surface tension and thereby prevents lung collapse during expiration (Chap. 7, p. 131). If surfactant is inadequate, hyaline membranes form in the distal bronchioles and alveoli, and RDS develops. Although

TABLE 34-1. Complications of Prematurity

Respiratory distress syndrome (RDS)

Intraventricular hemorrhage (IVH)
Periventricular leukomalacia (PVL)
Cerebral palsy (CP)
Neurodevelopmental Impairment (NDI)

RDS is generally a disease of preterm neonates, it can develop in term newborns, especially with sepsis, pneumonia, or meconium aspiration. In these cases, surfactant can be inactivated by inflammation and/or the presence of meconium (Chap. 33, p. 600).

With inadequate surfactant, alveoli are unstable and collapse with the low pressures of end expiration. Pneumocyte nutrition is compromised by hypoxia and systemic hypotension. Partial persistence of the fetal circulation may lead to pulmonary hypertension and a relative right-to-left shunt. Eventually, alveolar cells undergo ischemic necrosis. When oxygen therapy is initiated, the pulmonary vascular bed dilates, and the shunt reverses. Protein-filled fluid leaks into the alveolar ducts, and the cells lining the ducts slough. Hyaline membranes composed of fibrin-rich protein and cellular debris line the dilated alveoli and terminal bronchioles. The epithelium underlying the membrane becomes necrotic. At autopsy, with histological staining of lung tissue with hematoxylin-eosin, these membranes appear amorphous and eosinophilic, like hyaline cartilage. Because of this, respiratory distress syndrome is also termed *hyaline membrane disease*.

Clinical Course

In typical RDS, tachypnea develops, the chest wall retracts, and expiration is accompanied by nostril flaring and by grunting—in an attempt to provide a positive end-expiratory pressure to prevent lung collapse. Shunting of blood through nonventilated lung contributes to hypoxemia and to metabolic and respiratory acidosis. Poor peripheral circulation and systemic hypotension may be evident. The typical chest radiograph shows a diffuse reticulogranular infiltrate and an air-filled tracheobronchial tree—*air bronchograms* (Fig. 34-1).

Respiratory insufficiency can also be caused by sepsis, pneumonia, meconium aspiration, pneumothorax, persistent fetal circulation, heart failure, and congenital malformations involving thoracic structures, such as diaphragmatic hernia (Chap. 33, p. 599). Common mutations in surfactant protein production and the phospholipid transporter (ABCA3) are rare causes of RDS (Singh, 2021).

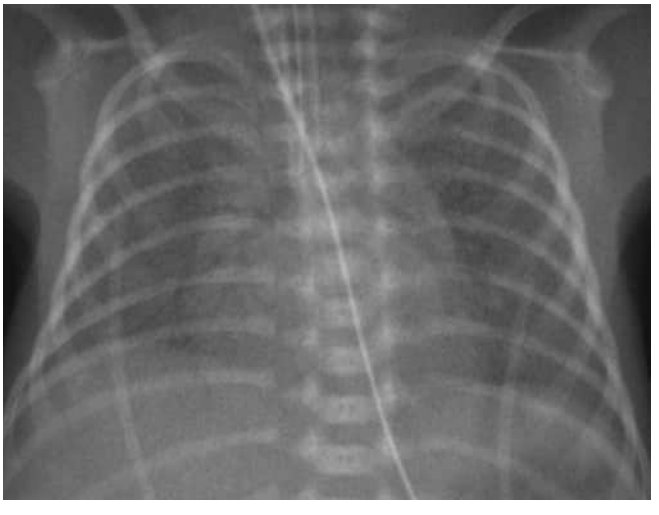

FIGURE 34-1 Chest radiograph of a preterm newborn with moderate respiratory distress syndrome. Note the diffuse granularity throughout the lungs and mild, central, air bronchograms. The lungs are only eight ribs expanded despite mechanical ventilation.

Treatment

An important factor influencing survival is neonatal intensive care. Although hypoxemia prompts application of supplemental oxygen, excess oxygen can damage the pulmonary epithelium, retina, and other immature tissues. Despite this, advances in mechanical ventilation technology have improved neonatal survival rates. For example, *continuous positive airway pressure (CPAP)* prevents the collapse of unstable alveoli. This allows high concentrations of inspired oxygen to be reduced, thereby minimizing its toxicity. To help limit the need for tracheal intubation and intermittent positive-pressure ventilation, CPAP has been studied in well-designed trials (Morley, 2008; SUPPORT Study Group, 2010b). An initial CPAP strategy coupled with subsequent selective surfactant use is a beneficial alternative to immediate intubation and surfactant for neonates of extremely early gestational age (Wyckoff, 2020). Less-invasive surfactant administration techniques allow surfactant delivery while maintaining the preterm newborn on CPAP. Such methods reduce the need for intubation and mechanical ventilation in the first 72 hours and decrease rates of death or bronchopulmonary dysplasia (Abdel-Latif, 2021).

Mechanical ventilation has undoubtedly improved survival rates, but it is an important factor in the genesis of chronic lung disease of prematurity—*bronchopulmonary dysplasia (BPD)*. Namely, mechanical ventilation places a newborn at risk for barotrauma and volutrauma. Moreover, hyperoxia can create reactive oxygen species that trigger inflammation. Infection also can be contributory. In affected newborns, alveolar and pulmonary vascular development is disrupted, leading to hypoxia, hypercarbia, and chronic oxygen dependence. It can also affect adult lung function (Thébaud, 2019). BPD remains the most frequent complication of extreme preterm birth (Stoll, 2015).

High-frequency oscillatory ventilation is an alternative to conventional mechanical ventilation for preterm newborns. However, benefits and risks vary considerably between studies (Cools, 2015). Similarly, thus far, the evidence for *high-frequency jet ventilation* is not superior to conventional ventilation for this population (Rojas-Reyes, 2015).

In the past, ventilator-dependent preterm neonates were often treated with *glucocorticoids* to prevent and treat BPD. This differs from antenatal use, described in the next sections. The American Academy of Pediatrics now recommends against routine neonatal corticosteroid use because of limited benefits and greater rates of impaired motor and cognitive function and school performance in exposed newborns (Watterberg, 2010). The risk of adverse neurodevelopment is highest if dexamethasone is given to preterm newborns at low risk of BPD. Attempts have been made to identify the highest-risk neonates for whom the benefits would exceed the risks (Cuna, 2018). Different types of corticosteroids, with various timing and administration routes, have been studied. Current trials are focused on corticosteroids, mixed with surfactant, delivered intratracheally directly to the lung. This approach may avoid some systemic adverse effects of corticosteroids (Cheong, 2019).

In other efforts to prevent BPD, early animal studies demonstrated significant improvements in lung function with weeks of *inhaled nitric oxide* (McCurnin, 2005). Despite initial enthusiasm, clinical trials failed to demonstrate a consistent benefit (Greenough, 2020). A National Institutes of Health (NIH) consensus statement concluded that the available data do not support its use to prevent or treat BPD (Cole, 2011).

Caffeine has been used widely to treat apnea of prematurity, but it also has bronchodilatory effects. One large randomized trial of caffeine versus placebo showed lower BPD rates, improved neurodevelopmental outcomes during early childhood, and good evidence of safety up to 11 years (Schmidt, 2006, 2012, 2017). This therapy is now widely used for newborns weighing ≤1250 g.

The antioxidant *vitamin A* is necessary for normal lung growth and the integrity of respiratory tract epithelial cells. Preterm newborns have low vitamin A levels at birth, and this is associated with a greater risk of developing BPD. Randomized trials support the use of vitamin A to modestly reduce BPD rates for very-low-birthweight neonates weighing <1500 g (Darlow, 2016). Unfortunately, production shortages have limited the use of vitamin A prophylaxis in the past decade.

Surfactant Prophylaxis and Rescue Therapy

Surfactant replacement was established decades ago as an effective and safe therapy for RDS. Surfactant improves mortality rates, reduces the need for ventilation, and improves short-term outcomes for low-birth-weight neonates (Hentschel, 2020). It is standard therapy for newborn RDS (American Academy of Pediatrics, 2017).

Exogenous surfactant products are most commonly delivered via endotracheal tube to help treat RDS. They contain biological or animal surfactants such as bovine—*Survanta*, calf—*Infasurf*, or porcine—*Curosurf*. One Cochrane review found that animal-derived surfactants led to better outcomes than synthetic ones, which do not contain important surfactant proteins (Ardell, 2015). Currently, no synthetic surfactants are available, yet newer ones are in testing (Hentschel, 2020).

For rescue surfactant therapy, less invasive methods of delivery to spontaneously breathing preterm neonates have been developed. These include surfactant application into the pharynx, surfactant nebulization, and application via laryngeal mask (Hentschel, 2020). Administration of surfactant via a thin catheter while maintaining the newborn on CPAP is associated with reduced risk of death or BPD, lower intubation rate in the first 72 hours, reduced incidence of major complications, and a reduced in-hospital mortality rate compared with administration via an endotracheal tube (Abdel-Latif, 2021).

Surfactant has been used for *prophylaxis* of preterm, at-risk newborns. Given together, antenatal corticosteroids and postnatal surfactant result in an even greater reduction in the overall death rate. However, randomized trials indicate that in populations with high use of antenatal corticosteroids and routine use of CPAP in the delivery room, prophylactic surfactant is no longer beneficial and is associated with greater risk of death or BPD (Rojas-Reyes, 2012; Sardesai, 2017).

Prevention

Antenatal Corticosteroids

More than two decades ago, the NIH (2000) concluded that a single course of antenatal corticosteroid therapy reduces RDS and intraventricular hemorrhage rates in preterm neonates born between 24 and 34 weeks' gestation (p. 619). The American College of Obstetricians and Gynecologists (2020a) considers all women at risk for preterm birth in this gestational-age range to be potential candidates for therapy. It also may be *considered* for pregnant women starting at 23 weeks' gestation who are at risk of preterm delivery within 7 days. For the periviable fetus, other management guidelines are listed in Table 45-4 (p. 786). Administration of corticosteroids for pregnant women during the periviable period who are at risk of preterm delivery within 7 days should be linked to a family's decision regarding resuscitation and should be considered in that context. Thus, as survival at even earlier gestations improves, the threshold for administration may decrease as well.

Administration of antenatal corticosteroids to women at risk for late-preterm delivery (34 to 36 weeks' gestation) reduces the rate of neonatal respiratory complications (Gyamfi-Bannerman, 2016). *Consideration* of a single course of betamethasone for women at risk for late-preterm delivery is supported by the American College of Obstetricians and Gynecologists (2020a). Based on data presented in Chapter 45 (p. 802), at Parkland Hospital, this is not currently our practice.

Amniocentesis to Assess Fetal Lung Maturity

Amniocentesis to assess fetal lung maturity was used previously to predict the neonatal risk for RDS. However, this use of amniocentesis to guide delivery decisions in any clinical situation of pregnancy is not currently supported or recommended (American College of Obstetricians and Gynecologists, 2021a,b).

NECROTIZING ENTEROCOLITIS

This newborn bowel disorder has clinical findings that include abdominal distention, emesis, ileus, bilious gastric aspirates, and bloody stools. Often, radiological images show *pneumatosis intestinalis*, which is bowel wall gas derived from invading bacteria (Fig. 34-2). Other classic imaging findings include hepatobiliary gas and pneumoperitoneum. Bowel perforation necessitates prompt resection.

Necrotizing enterocolitis (NEC) is seen primarily in low-birthweight newborns but occasionally in mature neonates. Hypothesized causes include perinatal hypotension, hypoxia, sepsis, umbilical catheterization, exchange transfusions, blood transfusions, and the feeding of cow milk and hypertonic solutions (Neu, 2011). The pathophysiology is thought to be multifactorial, and genetic disposition, intestinal immaturity, imbalance in microvascular tone, abnormal microbial colonization in the intestine, exposure to enteral feeds, and highly immunoreactive intestinal mucosa play potential roles (Bazacliu, 2019; Neu, 2011).

Medical treatment includes abdominal decompression, bowel rest, broad-spectrum antibiotics, and parenteral nutrition. Surgery

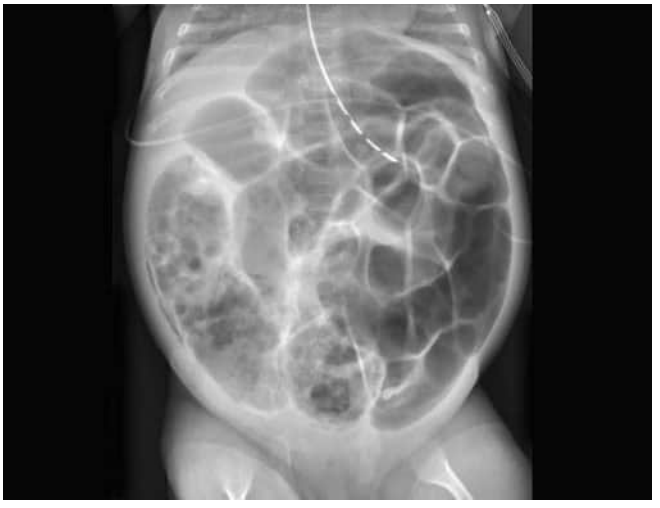

FIGURE 34-2 Abdominal radiograph of a preterm newborn with necrotizing enterocolitis. Note the distended air-filled loops of large and small bowel. Significant pneumatosis intestinalis, which is intramural bowel gas, is visualized within the right lower quadrant and within the pelvis. Not seen here, an associated finding is air in the portal veins of the liver.

is reserved for neonates with intestinal perforation or deteriorating clinical or biochemical status. Possible surgical procedures include drain placement, exploratory laparotomy with resection of diseased bowel, or enterostomy with creation of a stoma (Neu, 2011).

RETINOPATHY OF PREMATURITY

By 1950, this condition, formerly known as *retrolental fibroplasia,* became the largest single cause of blindness in this country. After the discovery that the disease resulted from hyperoxemia, its frequency declined but began to rise again with the increasing survival rates of extremely preterm newborns.

Normally, the fetal retina vascularizes centrifugally from the optic nerve starting at approximately the fourth month, and this continues until shortly after birth. During vascularization, excessive oxygen induces severe retinal vasoconstriction, which leads to endothelial damage and vessel obliteration. This is followed by subsequent aberrant neovascularization, in which the new vessels penetrate the retina and extend into the vitreous. Here, they are prone to leak proteins or to burst and bleed. Adhesions can form to detach the retina. Vascular endothelial growth factor (VEGF) contributes to normal angiogenesis and is upregulated during retinopathy of prematurity (ROP) development (Hellström, 2019). This understanding has opened new avenues of treatment with anti-VEGF therapies.

The precise levels of hyperoxemia that can be sustained without causing ROP are unknown. After birth, there is a "relative" hyperoxia compared with in-utero oxygen content, even in newborns not exposed to higher inspired oxygen concentrations. To better understand the oxygen saturation threshold necessary to minimize ROP without raising rates of other adverse outcomes, the Neonatal Research Network performed a randomized trial of oxygenation in 1316 neonates born between 24 and 27 weeks' gestation (SUPPORT Study Group, 2010a). The two target ranges of oxygen saturation were 85 to 89 percent in one arm and 91 to 95 percent in the other arm. These targets were both commonly employed in neonatal intensive care units. Death before discharge occurred significantly more frequently in the lower-oxygen saturation group—20 versus 16 percent. However, severe ROP among survivors developed significantly less often in the lower-oxygen saturation group—8.6 versus 17.9 percent.

BRAIN DISORDERS

Central nervous system injury usually creates different neuroanatomical sequelae in preterm newborns compared with those at term (Chap. 33, p. 607). In preterm neonates, cerebral lesions detected by neuroimaging include intraventricular hemorrhage, cerebellar hemorrhage, periventricular hemorrhagic infarction, cystic periventricular leukomalacia, and diffuse white matter injury. All of these are strongly associated with adverse neurodevelopmental outcomes (Kwon, 2014).

Cranial sonography remains the preferred approach for detecting frequently occurring brain abnormalities and acute events in the preterm neonate. It is readily available and reliable for detecting common abnormalities and monitoring brain growth. Because cystic injuries may take 2 to 5 weeks to evolve, serial scans are obtained during this time. In those whose findings are transient and resolve in the neonatal period, prognosis is improved compared with infants whose lesions remain and evolve. At the same time, however, between 4 and 10 percent of prematurely born children may develop cerebral palsy (CP) in the absence of lesions. Put another way, 90 to 96 percent of preterm newborns with CP have cerebral lesions that are detectable using cranial sonography.

Intracranial Hemorrhage

There are five major categories of intracranial hemorrhage in the neonate (Table 33-4, p. 607) (Volpe, 2016). *Primary subarachnoid hemorrhage* is more common in those born preterm and is frequently benign. *Cerebellar hemorrhage* is also more frequent in preterm neonates and is increasingly recognized as a cause of serious sequelae. *Intraventricular hemorrhage (IVH)* is almost exclusively seen in preterm newborns, is relatively common, and can have serious effects (Hintz, 2015, 2018). *Subdural hemorrhages* are more frequent in term newborns and can be serious (Chap. 33, p. 608). *Miscellaneous intraparenchymal hemorrhage* is also more frequent in those born at term and is of variable concern.

Intraventricular Hemorrhage

The germinal matrix is a highly cellular and vascular region of the developing brain located beneath the lateral ventricles. In preterm neonates, the germinal matrix capillary network is fragile for several reasons. First, the subependymal germinal matrix provides poor support for the vessels coursing through it. Second, venous anatomy in this region causes stasis and congestion, which makes vessels susceptible to bursting if intravascular pressure rises. Third, vascular autoregulation is impaired in the preterm neonate (Verhagen, 2014; Volpe, 2016).

If fragile capillaries in the germinal matrix rupture, blood escapes into the ventricular system—*intraventricular hemorrhage (IVH)*. This may dilate the ventricle, which then can obstruct venous drainage of the surrounding tissue. As a result, venous infarction and hemorrhage, termed *periventricular hemorrhagic infarction*, may follow.

Risk of severe IVH is inversely related to gestational age (Stoll, 2015). IVH is a serious complication of preterm neonates born before 32 weeks and is particularly frequent in those born before 27 weeks. The germinal matrix involutes between 34 and 36 weeks' gestation. Thus, IVH is infrequent after that period of brain development (Guillot, 2020). Most hemorrhages develop within 72 hours of birth (Hand, 2020). Because IVH usually is recognized within 3 days of delivery, its genesis is sometimes erroneously attributed to birth events. It is important to realize that *prelabor* IVH also can occur (Dunbar, 2021).

The pathogenesis of IVH is multifactorial and includes hypoxic-ischemic events, carbon dioxide elevations, anatomical factors, blood pressure instability, coagulopathy, genetic factors, and many others (Gilard, 2020; Leijser, 2019). Moreover, preterm birth is frequently associated with infection, which further predisposes to endothelial activation, platelet adherence, and thrombi (Villamor-Martinez, 2018). Respiratory distress and mechanical ventilation are commonly associated factors (Leijser, 2019).

Almost half of hemorrhages are clinically silent. Most small germinal matrix hemorrhages and those confined to the cerebral ventricles resolve without impairment. But, nearly half do show some sign of neurological impairment (Leijser, 2019). Survivors of extensive periventricular/intraventricular hemorrhage can have major neurodevelopmental handicaps (Mukerji, 2015). Large lesions can result in hydrocephalus or in degenerated cystic areas termed *periventricular leukomalacia (PVL)*, discussed later. Importantly, the extent of PVL correlates with CP risk (Dorner, 2018).

Incidence and Severity

IVH incidences vary according to gestational age at birth. Severe IVH rates have declined (Handley, 2018; Yeo, 2020). From the Neonatal Research Network, the incidence from 1993 to 2012 for neonates <29 weeks' gestation dropped from 19 to 13 percent (Stoll, 2015). In 2012, the incidence ranged from 11 percent in those born at 23 weeks to only 5 percent for those born at 28 weeks.

The severity of IVH can be assessed by neuroimaging studies. Papile and coworkers (1978) devised the most widely used grading scheme to quantify the lesion extent and estimate prognosis. Since the initial report, the Papile classification has been modified (Hand, 2020):

- *Grade I*—hemorrhage is limited to the germinal matrix
- *Grade II*—IVH occupies 10 to 50 percent of the ventricular area
- *Grade III*—hemorrhage with >50 percent of the ventricular area involved
- *Parenchymal hemorrhage (previously called Grade IV)*—most likely attributable to hemorrhagic venous infarction rather than extension of IVH into the parenchyma.

Antenatal Corticosteroids

If given at least 48 hours before delivery, corticosteroids prevent or reduce the incidence of severe IVH (Battarbee, 2020). A Consensus Development Conference of the NIH (1994) concluded that such therapy reduced rates of mortality, RDS, and IVH in preterm neonates born between 24 and 32 weeks' gestation. A second consensus statement by the NIH (2000) recommended that repeated courses of corticosteroids not be given (Chap. 45, p. 803).

Subsequently, the Maternal–Fetal Medicine Units Network reported that repeated corticosteroid courses were associated with some improved preterm neonatal outcomes, but also with reduced birthweight and increased risk for fetal-growth restriction (Wapner, 2006). Surveillance of this cohort through age 2 to 3 years found that children exposed to repeated versus single-dose corticosteroid courses did not differ significantly in physical or neurocognitive measures (Wapner, 2007). It was worrisome, however, that infants exposed to multiple courses had a nonsignificant 5.7-fold relative risk of CP.

At the same time, the 2-year follow-up of the Australian Collaborative Trial was reported by Crowther and coworkers (2007). In more than 1100 newborns, the incidence of CP was almost identical—4.2 versus 4.8 percent—in those given repeated versus single-course corticosteroids, respectively. More recently, it was reported that for those born before 28 weeks' gestation, if 10 days or more had passed since betamethasone administration, the incidence of severe IVH was higher (Liebowitz, 2016). This is not a consistent finding in all studies (Battarbee, 2020).

The most recent recommendations from the American College of Obstetricians and Gynecologists (2020a) are for a single course of corticosteroids for pregnant women between $24^{0/7}$ weeks and $33^{6/7}$ weeks' gestation who are at risk for preterm delivery. They further note that those given their initial course more than 14 days prior and who have imminent risk of preterm delivery may receive a second "rescue" course.

Other Preventive Methods

Although antenatal *magnesium sulfate* for those at risk for preterm delivery does not reduce the incidence of IVH, it does offer protection from neurodevelopmental impairment (Shepherd, 2018). The American College of Obstetricians and Gynecologists (2020b) recommends its use for this indication, as discussed further in Chapter 45 (p. 803). Antenatal *vitamin K* and *phenobarbital* and postnatal phenobarbital have not consistently reduced the incidence of IVH in studies (Crowther, 2010a,b; Smit, 2013). Although *vitamin E* reduced IVH rates, the associated risk for sepsis was increased (Brion, 2003). Metaanalyses of the many randomized trials of postnatal *indomethacin* and other prostaglandin inhibitors show inconsistent results regarding reductions in IVH rates (Fowlie, 2010; Mitra, 2018). None has shown improvements in neurodevelopmental impairment.

The benefits of cesarean delivery compared with vaginal birth to lower IVH rates remains controversial. One metaanalysis reported that cesarean delivery for very-low-birthweight neonates had no effect on rates of severe IVH but did reduce

overall IVH rates (Barzilay, 2016). The benefits of cesarean delivery to lower IVH rates in breech and growth-restricted fetuses are unclear from current observational data (Baalbaki, 2018). Prospective trials are needed.

Delayed umbilical cord clamping compared to immediate cord clamping has been reported to reduce the risk for any grade of IVH in preterm newborns but has not reduced rates of severe IVH (Rabe, 2019; Seidler, 2021). In preterm neonates, deferred cord clamping may also raise hemoglobin and hematocrit levels and improve survival rates (Seidler, 2021). Cord milking is associated with higher rates of severe IVH in neonates <28 weeks' gestation and should be avoided (Katheria, 2019; Wyckoff, 2020).

Periventricular Leukomalacia

This histological description refers to cystic areas deep in brain white matter that develop after hemorrhagic or ischemic infarction. Tissue ischemia leads to regional necrosis. Because brain tissue does not regenerate and the preterm neonate has minimal gliosis, these irreversibly damaged areas appear as echolucent cysts in neuroimaging studies. Generally, they require at least 2 weeks to form but may develop as late as 4 months after the initial insult. Thus, their presence at birth may help to determine the timing of an inciting event.

CEREBRAL PALSY

This group of conditions is characterized by chronic movement or posture abnormalities that are cerebral in origin, arise early in life, and are nonprogressive (Nelson, 2003). Epilepsy and mental retardation frequently accompany CP. Its cause differs in preterm and term neonates, and the latter is described in Chapter 33 (p. 602).

CP is commonly classified by the type of neurological dysfunction—spastic, dyskinetic, or ataxic—and by the number and distribution of limbs involved—quadriplegia, diplegia, hemiplegia, or monoplegia.

- *Spastic quadriplegia* has a strong association with developmental retardation and epilepsy. Spastic quadriplegia is the most severe form of spastic CP and affects all four limbs, the trunk, and the face.
- *Spastic diplegia* is common in preterm or low-birthweight neonates. In this CP type, muscle stiffness is mainly in the legs, and the arms are less or not involved. Affected persons might have difficulty walking because tight extremity muscles cause their legs to pull together, turn inward, and cross at the knees.
- *Spastic hemiplegia* affects only one side of a person's body, and the arm is affected usually more than the leg.
- *Dyskinetic CP* includes *athetoid, choreoathetoid, and dystonic cerebral* forms. Poor control of hand, arm, feet, and leg movements make sitting and walking difficult. Movements may be slow and writhing or rapid and jerky.
- *Ataxic CP* manifests as problems with balance and coordination.
- *Mixed CP* manifests with symptoms of more than one CP type. The most common type is spastic–dyskinetic CP (National Institute of Neurological Disorders and Stroke, 2020).

Incidence

According to the Centers for Disease Control and Prevention (2020a), the prevalence of CP in the United States approximates 3 cases in 1000 children. Hafström and coworkers (2018) reported the 6-year follow-up of all babies born at gestational ages <28 weeks in Sweden from 2004 to 2007. The CP rate overall was 10.5 percent, and no linear association was found between gestational age at birth and CP rates in this cohort.

Risks

Intraventricular Hemorrhage

Various clinical and pathological data link CP with associated severe IVH (grade III or IV) and resulting PVL. Low-grade IVH is generally considered benign, but it is associated with higher rates of CP in school-aged children born extremely preterm (Hollebrandse, 2021). Higher IVH grades are associated with even greater rates.

Ischemia

Preterm newborns are susceptible to brain ischemia and PVL. This is in part due to immature cerebral vasculature and an immature cerebrovascular autoregulation system that is pressure passive. In response to systemic hypotension, preterm infants cannot increase cerebral perfusion to border-zone regions of the brain supplied by the immature penetrating cerebral vasculature (Novak, 2018). This triggers a cascade of events caused by hypoxia–ischemia that results in pyramidal tract damage, which can cause spastic diplegia.

Perinatal Infection/Inflammation

PVL is associated with infection and inflammation. In one study of 753 neonates born between 24 and 32 weeks' gestation, 9 percent developed PVL (Zupan, 1996). Those born before 28 weeks, those who had inflammatory events during the last days to weeks before delivery, and those who had both were at highest risk. In another study, PVL was strongly associated with prolonged membrane rupture, chorioamnionitis, and neonatal hypotension (Perlman, 1996). Bailis and coworkers (2008) reported that chronic—and not acute—placental inflammation was associated with PVL. In another study of 3094 singletons born before 33 weeks' gestation, 15 percent had evidence of clinical chorioamnionitis (Soraisham, 2009). Compared with noninfected infants, cases complicated by infection had significantly higher rates of IVH—22 versus 12 percent.

Fetal infection may be a key element in the pathway between preterm birth and CP (Burd, 2012; Leviton, 2010, Novack, 2018). As discussed in Chapter 45 (p. 789), chorioamnionitis is a major cause of spontaneous preterm delivery. In the pathway proposed in Figure 34-3, antenatal reproductive tract infection evokes the production of cytokines such as tumor necrosis factor (TNF) and interleukins 1, 6, and 8. These in turn stimulate prostaglandin production and preterm labor. Preterm fetal intracranial blood vessels are susceptible to rupture and damage, and the cytokines that stimulate preterm labor also have direct toxic effects on oligodendrocytes and myelin. Vessel rupture, tissue hypoxia, and cytokine-mediated

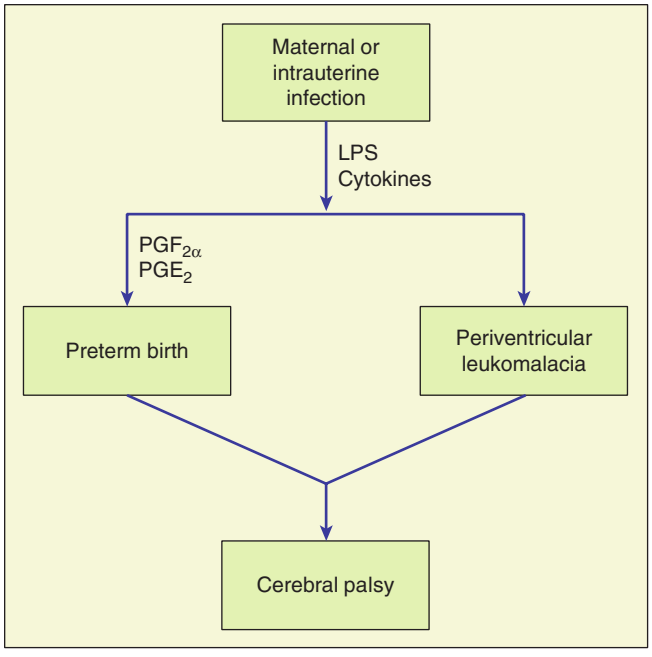

FIGURE 34-3 Schematic representation of the hypothesized pathway between maternal or intrauterine infection and preterm birth or periventricular leukomalacia. Both potentially lead to cerebral palsy. LPS = lipopolysaccharide; PG = prostaglandin.

damage result in massive neuronal cell death. Glutamate is released, which stimulates membrane receptors to allow excess calcium to enter the neurons. High intracellular calcium levels are toxic to white matter, and glutamate may be directly toxic to oligodendrocytes (Khwaja, 2008). Inflammation induced by the activation of microglia and macrophages with the production and release of proinflammatory cytokines, chemokines, proteases, complement factors, excitotoxic amino acids, reactive oxygen species, and nitric oxide further exacerbates secondary brain injury (Novack, 2018).

Many studies show that infection and cytokines can directly damage the immature brain (Chau, 2014; Yoon, 1997a). TNF and interleukin 6 were more frequently found in the brains of infants who died with PVL (Yoon, 1997b). Cytokines are strongly linked to white matter lesions even when organisms cannot be demonstrated (Yoon, 2000).

■ Prevention—Neuroprotection

The benefits of antenatal magnesium sulfate and corticosteroids are well described (Gentle, 2020). Another potential neuroprotective therapy is *erythropoiesis-stimulating agents (ESAs)* such as erythropoietin and darbepoetin. In addition to stimulating erythropoiesis, ESAs protect the developing brain in animal models (Wassink, 2017). One recent metaanalysis found decreased rates of IVH and PVL in preterm neonates treated with ESAs soon after birth. The effects on neurodevelopmental impairment are unclear (Ohlsson, 2020). In one large trial, early high-dose erythropoietin compared with placebo did not lower the risk of severe neurodevelopmental impairment or death at age 2 years (Juul, 2020). A large trial of the longer-acting darbepoetin has completed enrollment and is in the follow-up phase (clinicaltrials.gov/ct2/show/NCT01471015). Last, discussed in Chapter 33 (p. 602) for neonates >36 weeks, induced hypothermia for neuroprotection is not recommended for preterm newborns. This stems from their different pattern of gray and white matter injury and their greater susceptibility to cold stress. The exact gestational age for which therapeutic cooling for hypoxic-ischemic encephalopathy (HIE) would provide more benefit than harm is unknown. A trial of cooling for neonates born at $33^{0/7}$ to $35^{6/7}$ weeks' gestation with moderate/severe HIE has completed enrollment and is in the follow-up phase.

CHAPTER 35

Stillbirth

Perinatal mortality combines fetal and neonatal deaths and is one measure of healthcare quality before, during, and after delivery. Fetal mortality data from the National Vital Statistics system are usually presented for fetal deaths after the 20-week threshold. Using this threshold, the numbers of fetal deaths in the United States in 2013 slightly surpassed numbers of neonatal deaths when considering fetal deaths beyond 20 weeks (Fig. 35-1) (MacDorman, 2015a).

DEFINITIONS

As discussed in Chapter 1 (p. 3), the current definition of fetal death adopted in the United States by the National Center for Health Statistics is based on one recommended by the World Health Organization (MacDorman, 2015a). It states that "*Fetal death means death prior to complete expulsion or extraction from the mother of a product of human conception irrespective of the duration of pregnancy and which is not an induced termination of pregnancy. The death is indicated by the fact that after such expulsion or extraction, the fetus does not breathe or show any other evidence of life such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles. Heartbeats are to be distinguished from transient cardiac contractions; respirations are to be distinguished from fleeting respiratory efforts or gasps.*"

Reporting requirements for fetal deaths in the United States are determined by each state, and thus criteria differ. Most states mandate reporting of deaths of fetuses that are 20 weeks' gestation or older or have a minimum birthweight of 350 g, which roughly equates to that at 20 weeks—or a combination of both. However, evidence shows that not all required fetal deaths are reported, especially at earlier gestational ages (MacDorman, 2015a).

Similarly, comparisons of rates among countries are limited by incomplete fetal death data. Internationally, less than 5 percent of neonatal deaths have formalized documentation (Lawn, 2016). Further, comparative analyses using birthweight versus gestational age among countries yield discordant results. In the

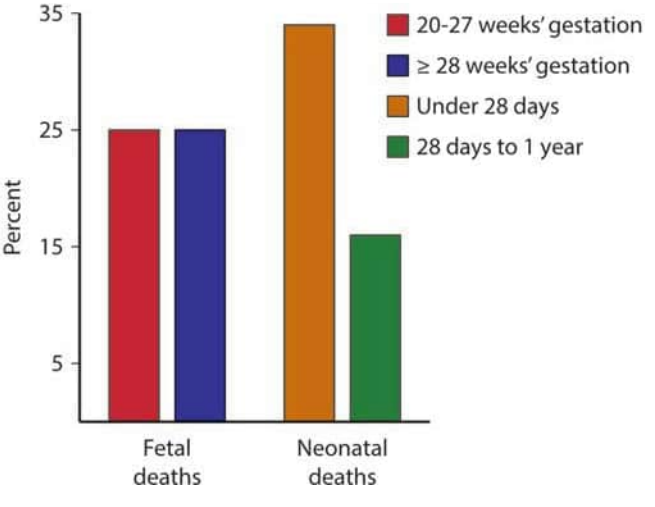

FIGURE 35-1 Distribution of fetal and neonatal deaths in the United States, 2013. (Data from MacDorman, 2015a.)

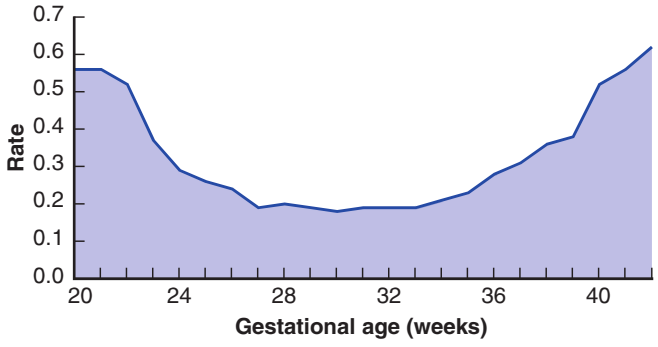

FIGURE 35-2 National Vital Statistics Report: fetal mortality rate per 1000 births by weeks' gestation. (Data from MacDorman, 2015a.)

United States, if stillbirth were defined by a birthweight ≥500 g, the stillbirth rate would be reduced by 40 percent compared with a 20-week-age defined cohort (Blencowe, 2016).

Three fetal mortality epochs are generally recognized. *Early* describes deaths before 20 completed weeks' gestation; *intermediate* for those between 20 and 27 weeks; and *late* for those ≥28 weeks. The fetal mortality rate in each epoch has changed little since 2006. As shown in Figure 35-2, fetal death rates are highest at the earliest and latest gestational ages, which suggests etiological differences.

ETIOLOGIES

To ascertain stillbirth causes in racially and geographically diverse populations in the United States, the *Eunice Kennedy Shriver* National Institute of Child Health and Human Development (NICHD) organized the Stillbirth Collaborative Research Network Writing Group (2011b). The group examined reasons for death at 20 weeks' gestation or later between 2006 and 2008 in 59 tertiary care and community hospitals in five states. Standardized evaluations included autopsy, placental histology, and testing of maternal or fetal blood/tissues, including fetal karyotyping. Evaluations were performed in 500 women with 512 stillbirths. Of these losses, 83 percent were before labor. Causes were divided into eight categories (Table 35-1). These categories were then classified as probable, possible, or unknown causes. As an example, diabetes was considered a *probable cause* if the fetus had diabetic embryopathy with lethal anomalies or if the mother had diabetic ketoacidosis. It was a *possible cause* if the mother had poor glycemic control and the fetus had abnormal growth. A probable or possible source was identified in 76 percent of cases. This proportion is similar to that from Australia using a comparable national audit tool (Lehner, 2019).

This Network study is unprecedented in the United States for several reasons. It was a population-based cohort of stillbirths, in which all underwent systematic and thorough evaluation. Each assigned cause of fetal death is reasonably straightforward and comprehensible except for "placental abnormalities." This category contains uteroplacental insufficiency and a few other less clearly defined placental entities. This aside, the leading reasons for fetal death were obstetrical and primarily included abruption, multifetal gestation complications, and spontaneous labor or ruptured membranes before viability. Structural anomaly was another (Son, 2021a). This study also illustrated that systematic evaluation may identify a likely cause in approximately three fourths of stillbirths. This high rate emphasizes the importance of standardized evaluation. However, a Cochrane database study concluded that evidence specifically from randomized trials to support specific tests for stillbirth evaluation was lacking (Wojcieszek, 2018b).

RISK FACTORS

Many factors are associated with an increased stillbirth risk (Table 35-2). Major associations include sociodemographic factors such as non-Hispanic black women, who have higher incidences of hypertension, diabetes, placental abruption, and preterm premature rupture of membranes (Healy, 2006). Other common associations are maternal age at either end of the spectrum, obesity, preeclampsia, diabetes, substance use, and late-term pregnancy (American College of Obstetricians and Gynecologists, 2020; Page, 2018). Multifetal pregnancies, especially monochorionic gestations, are high risk (Korlesky, 2019). Women with prior adverse pregnancy outcomes—such as stillbirth, preterm birth, or growth restriction—also carry an increased risk (Reddy, 2010; Varner, 2014). Pregnancies complicated by current fetal-growth restriction are particularly vulnerable because of their associations with hypertension, diabetes,

TABLE 35-1. Causes of 512 Stillbirths in the Stillbirth Collaborative Research Network Study

Cause	Percent	Examples
Obstetrical complications	29	Placental abruption, multifetal gestation, ruptured membranes at 20–24 weeks
Placental abnormalities	24	Uteroplacental insufficiency, maternal vascular disorders
Fetal malformations	14	Major structural abnormalities and/or genetic abnormalities
Infection	13	Involving the fetus or placenta
Umbilical cord abnormalities	10	Prolapse, stricture, thrombosis
Hypertensive disorders	9	Preeclampsia, chronic hypertension
Medical complications	8	Diabetes, antiphospholipid antibody syndrome
Undetermined	24	Not applicable

Percentages are rounded and total more than 100 percent because some stillbirths had more than one cause.
Overall, a probable or possible cause was identified in 76 percent of stillbirths.

TABLE 35-2. Maternal Risk Factors and Estimated Stillbirth Rate

Condition	Estimated Rate (per 1000 births)
All pregnancies	6.4
Low-risk pregnancies	4.0–5.5
Hypertensive disorders	
Chronic hypertension	6–25
Preeclampsia	
Nonsevere	9–51
Severe	12–29
Diabetes: insulin requiring	6–35
SLE	40–150
Renal disease	15–200
Thyroid disease	12–20
Cholestasis of pregnancy	12–30
Smoking >10 cigarettes	10–15
Obesity	
BMI 25–29.9 kg/m^2	12–15
BMI >30	13–18
Education (<12 yr vs ≥12 yr)	10–13
Fetal-growth restriction	10–47
Prior fetal-growth restriction	12–30
Late-term pregnancy	14–40
Oligohydramnios	14
Antiphospholipid syndrome	NS
Prior stillbirth	9–20
Multifetal gestation	
Twins	12
Triplets	34
Maternal age	
35–39 yr	11–14
≥49 yr	11–21
Black women (versus white)	12–14

BMI = body mass index; NS = not stated; SLE = systemic lupus erythematosus.

fetal infection, autoimmune disorders, and chronic renal disease (Brackett, 2020; Silver, 2018). Recently, the SARS-CoV-2 pandemic has posed both direct and indirect risks for adverse perinatal outcomes. Data are mixed as to whether rates of stillbirth have been higher during the pandemic (Khalil, 2020; Srivastava, 2021; Simon, 2021; Son, 2021b). Some suggest greater risks in low-source countries (Leisher, 2021). Although with recognized limitations, these findings merit further investigation regarding perinatal care during this pandemic (Hu, 2021; Rasmussen, 2020). In 245 gravidas with SARS-CoV-2 infection at Parkland Hospital, the stillbirth rate was not increased compared with that in gravidas with negative test results during the same period.

To help lower stillbirth rates, two major studies assessed whether risk factors could be identified either before or shortly after pregnancy confirmation. In the first, Reddy and colleagues (2010) analyzed data from the NICHD Consortium on Safe Labor. Briefly, the pregnancy outcomes of 206,969 women delivered between 2002 and 2008 at 19 hospitals in the United States were analyzed. When stillbirths were apportioned according to gestational age, most occurred primarily at term. These investigators concluded that their results did not support routine antenatal surveillance for any demographic risk factors.

The second analysis of risk factors was included in the Stillbirth Collaborative Research Network study described earlier (2011a). The validity of stillbirth prediction was assessed based on risks identified in early pregnancy. They found that pregnancy factors known at the start of pregnancy accounted for only a small proportion of stillbirth risk. Indeed, except for prior stillbirth or pregnancy loss from causes such as preterm birth or fetal-growth restriction, other risks had limited predictive value. Prior stillbirth as a risk for recurrence has been emphasized by others (Lamont, 2015; Sharma, 2006). Specifically, the stillbirth risk was fivefold higher in women with a prior stillbirth. From another report, prior preterm birth, fetal-growth restriction, preeclampsia, and placental abruption were strongly associated with subsequent stillbirth (Rasmussen, 2009).

EVALUATION OF THE STILLBORN FETUS

Clinical Examination

Determining the cause of fetal death aids maternal coping, helps assuage perceived guilt, permits more accurate counseling regarding recurrence risk, and may prompt intervention to prevent a recurrent outcome. Identification of inherited syndromes also assists other family members. Important tests include autopsy, chromosomal analysis, and pathological examination of the placenta, cord, and chorioamnionic membranes (Pinar, 2014). Page and coworkers (2017) found placental pathology and fetal autopsy to be the most useful.

Clinically, the fetal weight, head circumference, and length and the placental weight are measured (Fig. 35-3). Photographs are taken of the extremities and palms. Frontal plus profile views of the whole fetus and face also are obtained. A full radiograph of the fetus—a *fetogram*—may be performed (American College of Obstetricians and Gynecologists, 2020). Postnatal magnetic resonance (MR) imaging, radiographs, or sonography may be especially important if parents decline a full autopsy (McPherson, 2017; Shruthi, 2018). Findings are documented in the medical record, and relevant ante- and intrapartum events are delineated.

The reported incidence of fetal anomalies varies. For example, Faye-Petersen and colleagues (1999) reported that if autopsy and chromosomal studies are performed, up to 35 percent of stillborn fetuses were discovered to have major structural anomalies. Approximately 20 percent had dysmorphic features or skeletal anomalies, and 8 percent had chromosomal abnormalities (Pauli, 1994; Saller, 1995). As shown in Table 35-1, however, the incidence of structural anomalies in the Stillbirth Collaborative Research Network (2011b) was only 14 percent.

Laboratory Evaluation

In the absence of anatomical dysmorphology, up to 5 percent of stillborn fetuses will have a chromosomal abnormality (Korteweg, 2008). Previously, karyotyping all stillborn fetuses

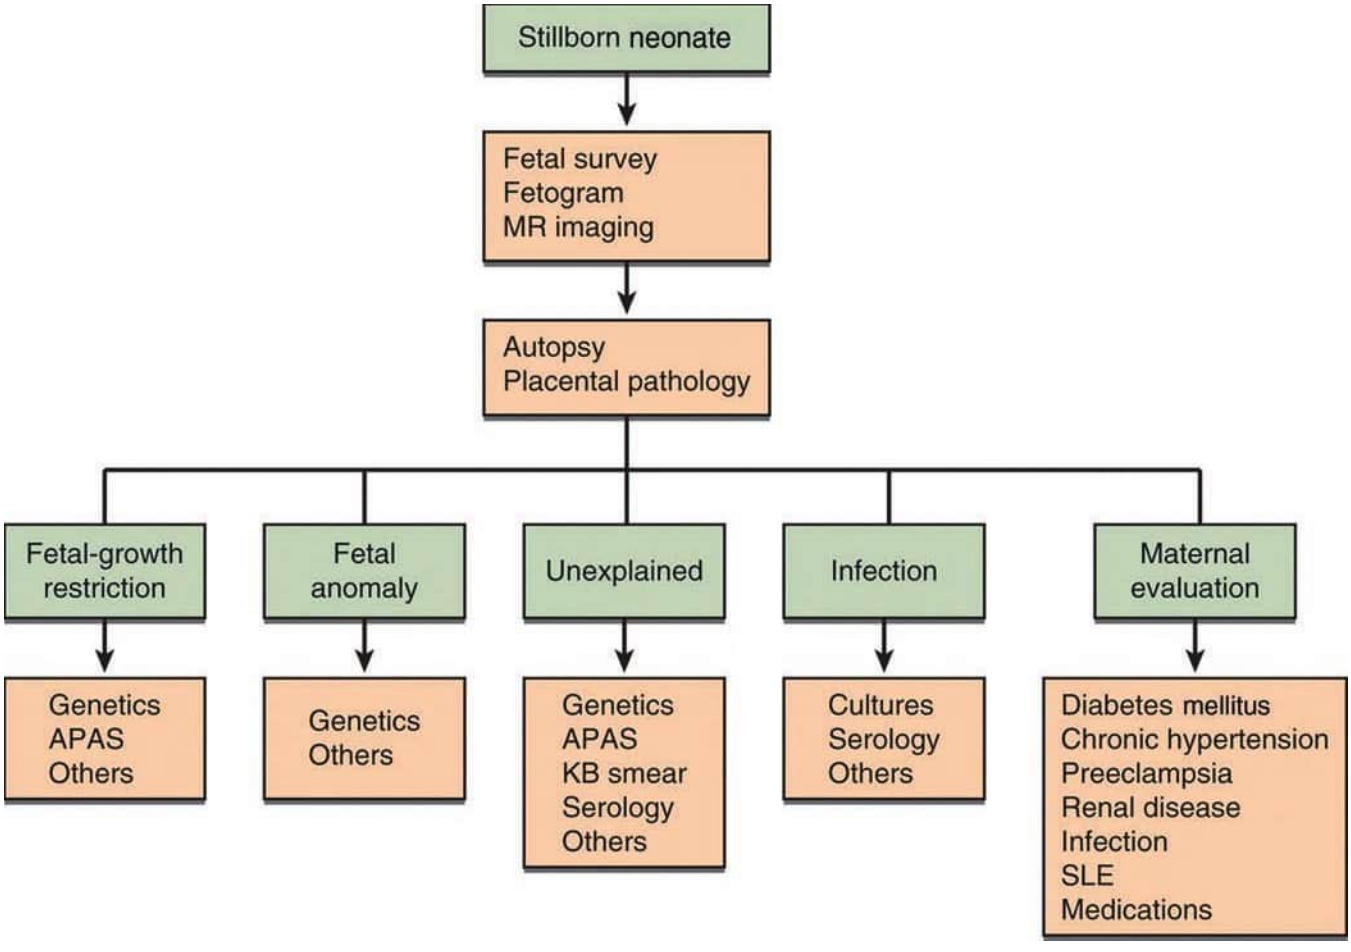

FIGURE 35-3 Flow chart for stillbirth evaluation. APAS = antiphospholipid antibody syndrome; KB = Kleihauer-Betke; MR = magnetic resonance; SLE = systemic lupus erythematosus. (From American College of Obstetricians and Gynecologists, 2020; Page, 2017, 2018.)

was standard practice, but whole-genome sequencing—such as with *chromosomal microarray analysis (CMA)*—is now recommended for stillborns (American College of Obstetricians and Gynecologists, 2020; Holmes, 2018; Martinez-Portilla, 2019). Described further in Chapter 16 (p. 325), this technique does not require dividing cells. This is especially helpful because culturing of macerated fetal tissue is frequently unsuccessful (Reddy, 2012).

Looking to the future, Stanley and associates (2020) evaluated exome sequencing in 246 unexplained stillbirths to search for disease-causing variants in the coding region of the genome. These investigators found that 8.5 percent of stillbirths with a normal chromosomal microarray and without probable maternal or obstetrical causes were probably attributable to mendelian disorders. These findings suggest that a portion of stillbirth cases is caused by pathological variants in genes known to underlie disorders in infants and adults. In addition, a similar number of cases are caused by loss-of-function variants in genes that are critical to in-utero survival but not currently known to be associated with stillbirth. Thus, the full phenotypic spectrum of many known mendelian disorders is not fully understood without the inclusion of cases resulting in stillbirth (Wojcik, 2020).

To take fetal samples, a provider must obtain appropriate parental consent. Any type of fetal or placental tissue or amnionic fluid can be submitted for genetic testing using CMA (American College of Obstetricians and Gynecologists, 2018). Contamination with maternal tissue or blood is ideally avoided. Specimens are collected by sterile technique and kept at room temperature. If fetal blood cannot be withdrawn from the umbilical cord or heart, at least one of the following can be sent for testing: (1) placental block measuring 1 × 1 cm taken below the cord insertion site in a specimen not fixed in formalin; (2) 1.5-cm-long umbilical cord segment; or (3) internal fetal tissue sample from the costochondral junction, fascia lata, or patella. Tissue is washed with sterile saline and suspended in Ringer solution, or sterile cytogenetic medium. Formalin or alcohol kills viable cells.

If conventional karyotyping is the only test available and the death is recent, amnionic fluid can be obtained by amniocentesis. This is particularly valuable if delivery is not expected imminently. As such, these cells provide a greater likelihood of cell growth and eventual results compared with tissue harvested after delivery.

Maternal blood is obtained for Kleihauer-Betke staining; for antiphospholipid antibody and lupus anticoagulant testing if indicated; and for serum glucose measurement to exclude overt diabetes (Silver, 2013). Testing for syphilis is reasonable if no prior screen has been performed, if the patient has exposure risk factors, or if patient, fetus, or placenta show suggestive findings, described in Chapter 68 (p. 1208) (Page, 2017).

Although some have recommended routine evaluation of heritable thrombophilias, no evidence supports the clinical

efficiency of screening in an unselected population. Silver and colleagues (2016) found that most maternal and fetal thrombophilias were not associated with stillbirth and recommended against routine testing. This is echoed by the American College of Obstetricians and Gynecologists and the Society for Maternal-Fetal Medicine (2020).

Placental Examination

Gross and microscopical examination of the placenta, membranes, and cord by a perinatal pathologist is ideal. Numerous maternal and fetal disorders can be identified. Cord knotting and placental microvascular abnormalities are examples and discussed in Chapter 6 (p. 107). Implicated infections are described in Chapters 67 and 68.

Autopsy

Parents are encouraged to allow a full autopsy, which is more likely to yield valuable data. Pinar and coworkers (2012) provide the autopsy protocol used by the Stillbirth Collaborative Research Network. An analysis of 400 consecutive fetal deaths in Wales showed that autopsy altered the presumed cause of death in 13 percent and provided new data in another 26 percent (Cartlidge, 1995). Other investigators have found that autopsy results changed the recurrence risk estimates and parental counseling in 25 to 50 percent of cases (Faye-Petersen, 1999; Silver, 2007). Miller and associates (2016) reported that placental examination with autopsy altered future medical management in 45 percent of cases. Limited autopsy protocols can also yield valuable information. Of components, external examination combined with photography, radiography, MR imaging, bacterial cultures, and selective use of chromosomal and histopathological studies often aids determination.

According to one survey, most hospitals do not audit stillbirths (Goldenberg, 2013). In other centers, including ours, maternal records and autopsy findings are reviewed monthly by a stillbirth committee composed of obstetricians, maternal-fetal medicine specialists, neonatologists, geneticists, and perinatal pathologists. If possible, the cause of death is assigned from available evidence. Most importantly, parents are then contacted and offered counseling regarding the cause of death, the potential recurrence risk, and possible strategies to avoid recurrence (Page, 2020).

PERINATAL CARE

Fetal death is psychologically traumatic for a woman and her family. Further stressors include an interval of more than 24 hours between the diagnosis of fetal death and labor induction; not seeing her neonate for as long as she desires; having no tokens of remembrance; and poor communication with caregivers (Heazell, 2016; Siassakos, 2018). Seeing and holding a stillborn neonate assists parental psychological well-being (Kingdon, 2015). Unfortunately, few obstetrical providers receive formal training in perinatal bereavement care (Nuzum, 2014). At Parkland Hospital, care is coordinated through a dedicated nursing team affiliated with labor and delivery. Intervention includes time with the neonate, keepsake items, photographs, chaplaincy consultation, and bereavement support information. These principles dovetail with the recent global consensus recommendations for bereavement care (Shakespeare, 2020). A woman experiencing a stillbirth or early miscarriage is at increased risk for depression and posttraumatic stress disorder and should be closely monitored (Nelson, 2013) (Chap. 64, p. 1145).

Distinct from stillbirth, fetuses with life-limiting conditions and short survival also merit special consideration. Conceptually, *perinatal palliative care* provides obstetrical and neonatal care to maximize the comfort and quality of life for these newborns (American College of Obstetricians and Gynecologists, 2019). Components of this care include review of the diagnosis, creation of a birth plan, bereavement counseling, and consultation with neonatal services. This care is typically provided by a team that is able to offer medical, psychological, and spiritual support. During planning, parents' values, goals, and fears are a focus.

PRIOR STILLBIRTH

The woman with a prior stillbirth has a substantial risk for a recurrence (see Table 35-2). Preterm or growth-restricted stillborn fetuses magnify this risk (Malacova, 2018). In one cohort of 43 women with a recurrent stillbirth, most fetuses died before 28 weeks' gestation (Fig. 35-4) (Whitham, 2020).

An outlined approach for women with a prior stillbirth is shown in Table 35-3. Importantly, these recommendations are based primarily on limited or inconsistent scientific evidence or on expert opinions. Few studies address management of affected women (Wojcieszek, 2018a).

Very few risk factors for stillbirth are modifiable (Whitham, 2020). Intuitively some such as hypertension or diabetes warrant disease-specific prevention strategies. Women with a prior fetal death due to placental insufficiency also are at increased risk for subsequent adverse perinatal outcomes (Monari, 2016). According to Reddy (2007), almost half of fetal deaths are associated with growth restriction, and thus sonographic anatomical assessment beginning at midpregnancy is recommended. This is followed by serial growth studies beginning at 28 weeks. Detection of growth restriction may lead to

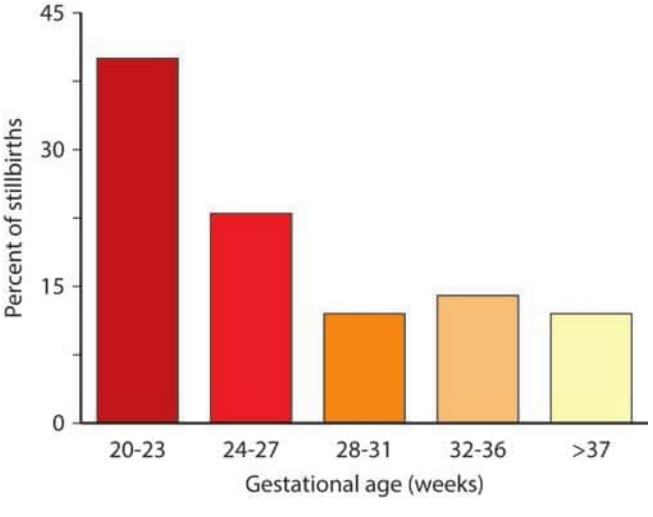

FIGURE 35-4 Stillbirth Collaborative Research Network: gestational age distribution of recurrent stillbirths.

TABLE 35-3. Management of Subsequent Pregnancy after Stillbirth

Preconceptional or Initial Prenatal Visit
Detailed medical and obstetrical history
Review evaluation of prior stillbirth
Determination of recurrence risk
Discuss recurrence of comorbid obstetrical complications
Smoking cessation
Preconceptional weight loss in obese women
Genetic counseling if familial genetic condition exists
Diabetes screen
Screen for antiphospholipid antibodies
Reassurance

First Trimester
Dating sonography
First-trimester screen: PAPP-A, hCG, cfDNA, NT
Reassurance

Second Trimester
Sonographic anatomy survey at 18–20 weeks' gestation
Maternal serum screening (quadruple) *or* single-marker AFP if first-trimester screening elected
Possible uterine artery Doppler studies at 22–24 weeks
Reassurance

Third Trimester
Sonographic screening for fetal-growth restriction, starting at 28 weeks
Kick counts starting at 28 weeks
Antepartum fetal surveillance starting at 32 weeks *or* 1–2 weeks earlier than prior stillbirth
Reassurance

Delivery
Labor induction at 39 weeks
Delivery before 39 weeks for obstetrical indications

AFP = alpha-fetoprotein; cfDNA = cell-free DNA; hCG = human chorionic gonadotropin; NT = nuchal translucency; PAPP–A = pregnancy-associated plasma protein-A.

iatrogenic prematurity and its associated long-term childhood consequences but to fewer intrauterine deaths (Andreasen, 2021).

Weeks and associates (1995) evaluated fetal biophysical testing in 300 women whose only indication was prior stillbirth. There was one subsequent stillbirth, and only three fetuses had abnormal testing results before 32 weeks. Notably, the gestational age of the prior stillborn fetus did not relate to the incidence or timing of abnormal test results or fetal jeopardy in the subsequent pregnancy. These investigators concluded that antepartum surveillance should begin at 32 weeks' gestation or later in the otherwise healthy woman with a history of stillbirth. The American College of Obstetricians and Gynecologists and the Society for Maternal-Fetal Medicine (2020) support this, with the caveat that it increases the iatrogenic preterm delivery rate. Although fetal movement counting strategies are routinely employed and described in Chapter 20 (p. 384), few data guide its use in clinical practice for those with a prior stillbirth (Mangesi, 2015). Unless other indications intervene, delivery at 39 weeks' gestation is recommended. This timing minimizes fetal mortality rates, although the degree of risk reduction may be greater for older women (Page, 2013). Labor induction is suitable, and cesarean delivery is reserved for those with a contraindication to induction.

CHANGES IN STILLBIRTH RATES

As noted, following declines through 2011, the United States fetal mortality rate has changed little (Middleton, 2018). Interpretation of these rates in the context of changing healthcare strategies has spawned debate. One example is the trend against nonmedically indicated deliveries before 39 weeks' gestation and its subsequent effect on term stillbirth rates (Middleton, 2018). This practice's value for neonatal outcome is described in Chapter 26 (p. 486). To analyze whether implementation of this 39-week rule has altered the term stillbirth rate, data from 45 states and the District of Columbia were examined (Nicholson, 2016). The proportion of births before 39 weeks progressively declined from 2007 and 2013, but the term stillbirth rate increased. This suggests that the 39-week rule may cause unintended harm. One review of studies with 15 million pregnancies showed that the prospective risk of stillbirth rose from 0.11 per 1000 births at 37 weeks to 3.18 per 1000 births at 42 weeks (Muglu, 2019).

MacDorman and associates (2015b) also evaluated trends in stillbirth rates by gestational ages in the United States between 2006 and 2012. They used a "traditional stillbirth rate," which was calculated using a denominator composed of the live-birth number *plus* the stillbirth number at a given gestational age. They found increased rates at 24 to 27, 34 to 36, and 38 weeks' gestation. Alternatively, no differences were found in "prospective stillbirth rates." These rates were calculated using a denominator composed of the number of women who are pregnant at a given gestational age for weeks 21 through 42. The discrepancies in stillbirth rates appear to primarily derive from the decline in the birth numbers in the preterm and early-term gestational ages.

In sum, implementation of the 39-week rule has reduced the number of elective births before 39 weeks' gestation, although an unintended consequence may be an increase in term stillbirths—especially among women with medical complications. The importance of induction before 39 weeks in pregnant women with complications to prevent stillbirth is underscored by Little and colleagues (2015). These authors performed a retrospective multistate analysis of early-term deliveries—$37^{0/7}$ to $38^{6/7}$ weeks—from 2005 to 2011. They noted a decline in the number of early-term deliveries during this time but not a significant change in the term stillbirth rates. There was, however, a 25-percent rise in the rate of term, singleton stillbirths among women with diabetes, and this was attributed to clinicians misapplying early-term delivery policies to high-risk women. Undoubtedly, continued surveillance of stillbirth rates is warranted for both high- and low-risk pregnancies at the state and national level.

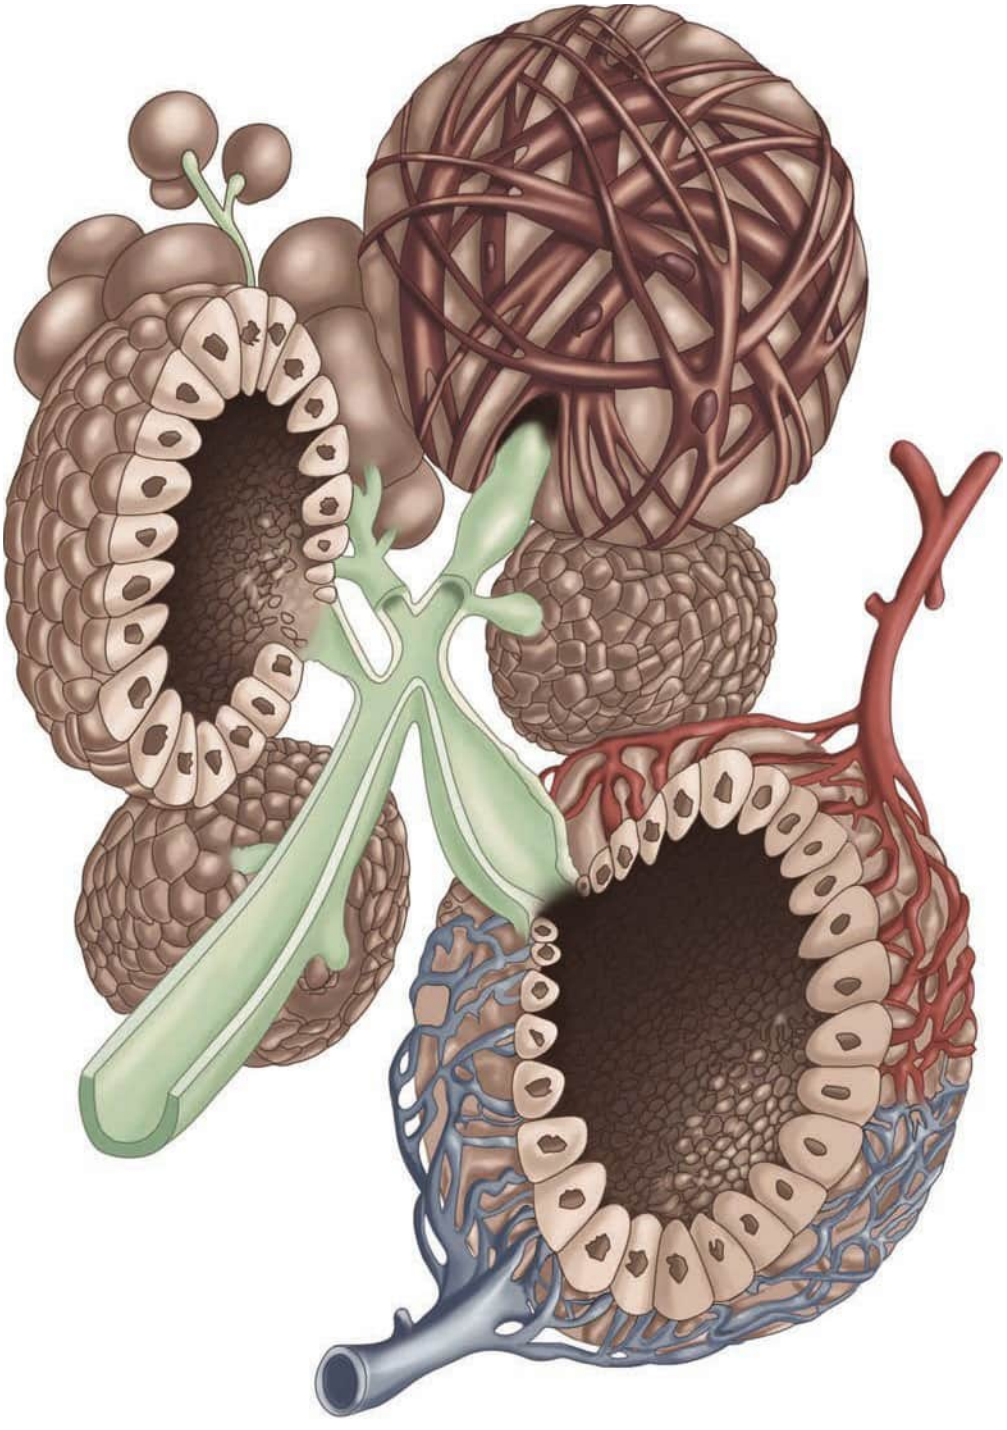
SECTION 10

THE PUERPERIUM



CHAPTER 36

The Puerperium

The word *puerperium* is derived from Latin—*puer*, child + *parus*, bringing forth. It defines the time following delivery during which pregnancy-induced maternal anatomical and physiological changes return to the nonpregnant state. Its duration is inexact but is considered to last between 4 and 6 weeks. Although much less complex compared with pregnancy, the puerperium has appreciable changes, and maternal morbidity is surprisingly common. For example, in a survey of 1246 British mothers, 3 percent required hospital readmission within 8 weeks (Thompson, 2002). Moreover, almost three fourths of women continue to have health problems for up to 18 months (Glazener, 1995). Of self-reported concerns, pain, breastfeeding, and psychosocial topics are prominent. Table 36-1 lists data on these from the Pregnancy Risk Assessment Surveillance System—PRAMS—of the Centers for Disease Control and Prevention (CDC).

THE FOURTH TRIMESTER

Because the weeks following childbirth are a critical period for the woman and her infant, the American College of Obstetricians and Gynecologists (2018a) promulgated the concept of a "fourth trimester." This concept reinforces the importance of the 12 weeks following birth, and components of this model are outlined in Table 36-2. Thus, the comprehensive postpartum visit includes a full assessment of physical, social, and psychological well-being.

An initial visit is recommended at 3 weeks postdelivery and a final summary visit at 12 weeks. Between this time, visits can be added as needed. For example, women with chronic hypertension, overt diabetes, cardiovascular disease, and depression may require additional multidisciplinary care during this period. For all puerpera, a discussion of positive lifestyle changes can be initiated. This time also affords the opportunity to update immunizations (American College of Obstetricians and Gynecologists, 2019). At the end of the 12-week fourth

trimester, follow-up then transitions into well-woman care, ongoing primary or specialty care, and when necessary, preconceptional counseling (Chap. 9, p. 165).

REPRODUCTIVE TRACT INVOLUTION

Birth Canal

Return of the tissues in the birth canal to the nonpregnant state begins soon after delivery. The vagina and its outlet gradually diminish in size but rarely regain their nulliparous dimensions. Rugae begin to reappear by the third week but are less prominent than before. The hymen is represented by several small tags of tissue, which scar to form the myrtiform caruncles. The vaginal epithelium reflects the hypoestrogenic state, and it does not begin to proliferate until 4 to 6 weeks. This timing is usually coincidental with resumed ovarian estrogen production. Lacerations or stretching of the perineum during delivery can lead to vaginal outlet relaxation. Some damage to the pelvic floor may be inevitable, and parturition predisposes to pelvic organ prolapse (Chap. 30, p. 548).

Uterus

The massively augmented uterine blood flow necessary to maintain pregnancy derives from significant hypertrophy and remodeling of pelvic vessels. After delivery, their caliber gradually diminishes to approximately that of the prepregnant state. Within the puerperal uterus, larger blood vessels become obliterated by hyaline changes. They are gradually resorbed and replaced by smaller ones. Minor vestiges of the larger vessels, however, may persist for years.

During labor and vaginal delivery, the margin of the dilated cervix, which corresponds to the external os, may be lacerated. The cervical opening contracts slowly, and for a few days immediately after labor, it readily admits two fingers. By the end of the first week, this opening narrows, the cervix thickens, and the endocervical canal reforms. The external os does not completely resume its pregravid appearance. It remains somewhat wider, and typically, ectocervical depressions at the site of lacerations become permanent. These changes are characteristic of a parous cervix (Fig. 36-1). Cervical epithelium also undergoes

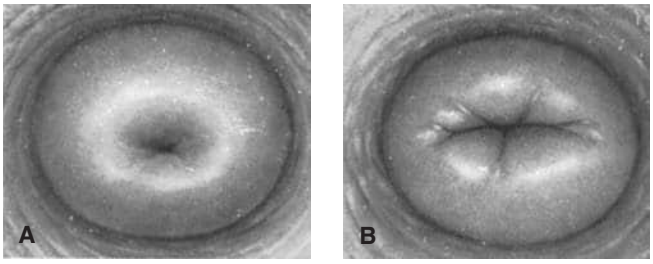

FIGURE 36-1 Common appearance of nulliparous **(A)** and parous **(B)** cervices.

considerable remodeling. This actually may be salutary because almost half of women have regression of high-grade dysplasia following delivery (Ahdoot, 1998; Kaneshiro, 2005).

After delivery, the fundus of the contracted uterus lies slightly below the umbilicus. It consists mostly of myometrium covered by serosa and internally lined by decidua. The markedly attenuated lower uterine segment contracts and retracts, but not as forcefully as the uterine corpus. During the next few weeks, the lower segment is converted from a clearly distinct substructure large enough to accommodate the fetal head to a barely discernible uterine isthmus located between the corpus and internal cervical os. Immediately postpartum, the anterior and posterior walls, which lie in close apposition, are each 4 to 5 cm thick (Buhimschi, 2003). At this time, the uterus weighs approximately 1000 g.

Myometrial involution is a truly remarkable feat of destruction or deconstruction that begins as soon as 2 days after delivery (Williams, 1931). The total number of myocytes does not decline appreciably—rather, their size decreases markedly. Weights from removed uteri approximate 500 g by 1 week postpartum, 300 g by 2 weeks, and at 4 weeks, involution is complete and the uterus weighs approximately 100 g (Williams, 1931). After each successive delivery, the uterus is usually slightly larger than before the most recent pregnancy.

Sonographic Findings

Uterine involution and declining uterine volume is best measured by sonography (Fig. 36-2) (Wataganara, 2015). With

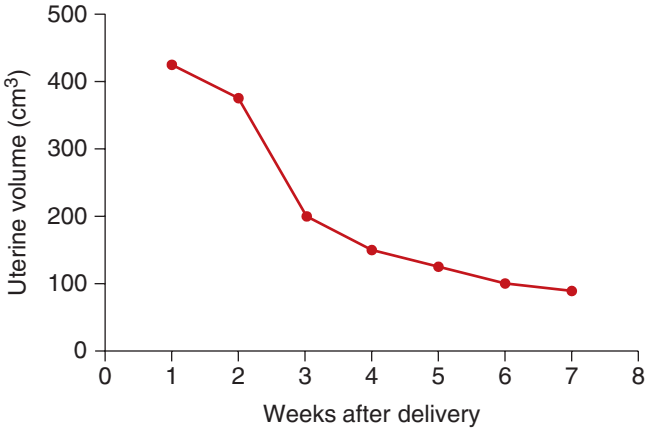

FIGURE 36-2 Pattern of uterine involution through 7 weeks postpartum as estimated by sonography.

this, estimates again show uterine size declines of more than half, from 450 to 200 g, in the first 2 weeks. Sonographically, the uterus and endometrium return to the pregravid size by 8 weeks postpartum. Complete involution in the multiparous uterus is longer than for the nulliparous organ (Paliulyte, 2017). In the event of a cesarean delivery, the residual myometrial thickness over the uterine incision is thicker if a two-layer closure was used (Roberge, 2016).

In a study of 42 normal puerperas, fluid in the endometrial cavity was noted in 78 percent of women at 2 weeks, 52 percent at 3 weeks, 30 percent at 4 weeks, and 10 percent at 5 weeks (Tekay, 1993). Belachew and coworkers (2012) used three-dimensional sonography and visualized intracavitary tissue matter in a third on day 1, 95 percent on day 7, 87 percent on day 14, and 28 percent on day 28. By day 56, the small cavity was empty.

Doppler ultrasound of the uterine artery shows continuously increasing vascular resistance throughout the first 7 weeks postpartum (Sohn, 1988; Wataganara, 2015). Uterine artery flow impedance does not differ between women undergoing vaginal versus cesarean delivery (Baron, 2016).

Decidual and Endometrial Regeneration

Because separation of the placenta and membranes involves the spongy layer, the decidua basalis is not sloughed. The in situ decidua varies markedly in thickness, it has an irregular jagged border, and it is infiltrated with blood, especially at the placental site. Within 2 or 3 days after delivery, the remaining decidua becomes differentiated into two layers. The superficial layer becomes necrotic and is sloughed in the lochia. The basal layer adjacent to the myometrium remains intact and is the source of new endometrium. Decidual vessels are near normal by delivery and endovascular trophoblasts are diminished. These vessels and the spiral arteries also undergo involution (Zhang, 2018).

Endometrial regeneration is rapid, except at the placental site. Within a week or so, the free surface becomes covered by epithelium. Sharman (1953) identified a fully restored endometrium in all biopsy specimens obtained from the 16th day onward. Histological endometritis is part of the normal reparative process. Also, microscopic inflammatory changes characteristic of noninfectious acute salpingitis are seen in almost half of women between 5 and 15 days (Andrews, 1951).

Clinical Aspects

Afterpains. Several clinical findings coincide with uterine involution. In primiparas, the uterus tends to remain tonically contracted following delivery. In multiparas, however, it often contracts vigorously at intervals and gives rise to *afterpains*, which are similar to but milder than labor contractions. These are more pronounced as parity increases and worsen when the newborn suckles, likely because of oxytocin release (Holdcroft, 2003). Usually, afterpains decrease in intensity and become mild by the third day. We have encountered unusually severe and persistent afterpains in women with postpartum uterine infections (Chap. 37, p. 651).

Lochia. Early in the puerperium, sloughing of decidual tissue results in a vaginal discharge of variable quantity. The discharge is termed *lochia* and contains erythrocytes, shredded decidua, epithelial cells, and bacteria. For the first few days after delivery, there is blood sufficient to color it red—*lochia rubra.* After 3 or 4 days, lochia becomes progressively pale in color—*lochia serosa.* After approximately the 10th day, because of an admixture of leukocytes and reduced fluid content, lochia assumes a white or yellow-white color—*lochia alba.* The average duration of lochial discharge ranges from 24 to 36 days (Fletcher, 2012). Because of this expected leukocyte component, saline preparations of lochia for microscopic evaluation in cases of suspected puerperal metritis are typically uninformative.

PLACENTAL SITE INVOLUTION

Complete extrusion of the placental site takes up to 6 weeks (Williams, 1931). Immediately after delivery, the placental site is approximately palm-sized. Within hours of delivery, it normally contains many thrombosed vessels that ultimately undergo organization. By the end of the second week, it measures 3 to 4 cm in diameter.

Placental site involution is an exfoliation process, which is prompted in great part by undermining of the implantation site by new endometrial proliferation (Williams, 1931). Thus, involution is not simply absorption in situ. Exfoliation consists of both extension and "downgrowth" of endometrium from the margins of the placental site, as well as "upward" development of endometrial tissue from the glands and stroma left deep in the decidua basalis after placental separation. Anderson and Davis (1968) concluded that placental site exfoliation results from sloughing of infarcted and necrotic superficial tissues followed by a remodeling process.

Subinvolution

In some cases, uterine involution is hindered because of incompletely remodeled spiral arteries, retained placental fragments, or infection. Such *subinvolution* is accompanied by varied intervals of prolonged lochia and by irregular or excessive uterine bleeding. During bimanual examination, the uterus is larger and softer than would be expected.

Inadequate conversion of spiral arteries into remodeled uteroplacental arteries can cause subinvolution (Kavalar, 2012). These noninvoluted vessels are filled with thromboses and lack an endothelial lining. Perivascular trophoblasts are also identified in the vessel walls, which suggests an aberrant interaction between uterine and trophoblast cells.

With bleeding, pelvic sonography may help differentiate subinvolution from retained placenta. Characteristic findings of retained products include a thickened endometrium or endometrial mass (Fig. 36-3). Vascularity within this area increases the likelihood of retained products (Sellmyer, 2013). Comparatively, subinvolution is characterized by an enlarged uterus with tubular hypoechoic areas in the myometrium. These tubular structures reflect neovascularization and dilated uterine vessels.

For treatment, uterotonics are recommended by many but their efficacy is questionable (Hoyveda, 2001; American College of Obstetricians and Gynecologists, 2017d). At Parkland hospital, conservative management is undertaken with methylergonovine

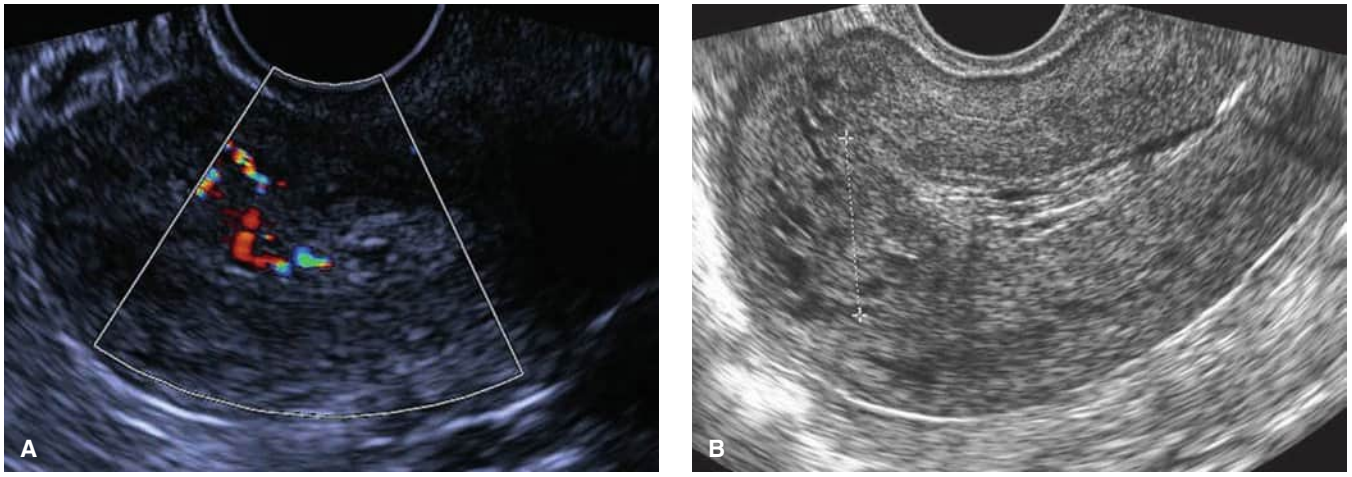

FIGURE 36-3 Sonographic appearance of puerperal uterine complications. **A.** Retained products of conception. Tissue vascularity is highlighted here by color Doppler. **B.** Retained clot marked by calipers shows mixed echogenicity in a woman with subinvolutional hemorrhage. Anechoic cystic areas within the fundal myometrium reflect dilated vessels.

(Methergine) 0.2 mg orally every 3 to 4 hours for 24 to 48 hours. For initially brisk bleeding, an intramuscular dose of methylergonovine may be coupled with an infusion of synthetic oxytocin (Pitocin) (20 units in 1 L crystalloid).

For cases with suspected comorbid infection, antimicrobial therapy usually leads to a good response. Wager and associates (1980) reported that a third of late cases of postpartum metritis are caused by *Chlamydia trachomatis.* Empirical therapy with azithromycin or doxycycline usually prompts resolution regardless of bacterial etiology. At our institution, common oral options taken twice daily for 7 to 10 days include azithromycin, 500 mg; amoxicillin-clavulanate (Augmentin), 875 mg; or doxycycline, 100 mg.

Late Postpartum Hemorrhage

The American College of Obstetricians and Gynecologists (2017d) defines *secondary postpartum hemorrhage* as bleeding 24 hours to 12 weeks after delivery. Clinically worrisome uterine hemorrhage develops within 1 to 2 weeks in perhaps 1 percent of women. Such bleeding most often stems from abnormal involution of the placental site. It occasionally is caused by retention of a placental fragment or by a uterine artery pseudoaneurysm. Rarely, retained products may undergo necrosis with fibrin deposition and neovascularization, thus forming a *placental polypoid mass.* Severe hemorrhage occurs in only 6 percent of these cases due to rupture of blood vessels (Marques, 2011). Sonographically, a discrete hypervascular endometrial mass that may extend into the myometrium is visualized (Fig. 36-4). As discussed in Chapter 59 (p. 1062), delayed postpartum hemorrhage may also be caused by von Willebrand disease or other inherited coagulopathies (Lipe, 2011).

In our experiences, few women with delayed hemorrhage are found to have retained placental fragments. Thus, we and others do not routinely perform curettage (Lee, 1981). Another concern is that curettage may worsen bleeding by avulsing part of the implantation site. Thus, in a stable patient, if sonographic examination shows an empty cavity, then oxytocin, methylergonovine, or a prostaglandin analogue is given. Suitable dosing is found in Table 13-3 (p. 240). Antimicrobials are added if uterine infection is suspected. If large clots are seen in the uterine cavity with sonography, then *gentle* suction curettage is considered. Otherwise, curettage is carried out only if appreciable bleeding persists or recurs after medical management.

URINARY TRACT

Normal pregnancy-induced glomerular hyperfiltration persists during the puerperium but returns to prepregnancy baseline by 2 weeks (Hladunewich, 2004). Parturition induces a transient rise in excretion of glomerular podocytes (Furuta, 2017). Dilated ureters and renal pelves return to their prepregnant state by 2 to 8 weeks postpartum. Because of this dilated collecting system, coupled with residual urine and bacteriuria in a traumatized bladder, symptomatic urinary tract infection remains a concern in the puerperium.

FIGURE 36-4 Sonogram of a polypoid placental mass with color Doppler applied. The mass is demarcated by the dashed white lines. Hypervascularity is seen extending from the mass into the myometrium.

Funnell and colleagues (1954) used cystoscopy immediately postpartum and described varying degrees of submucosal hemorrhage and edema. Bladder trauma is associated most closely with labor length and thus to some degree accompanies normal vaginal delivery. Postpartum, the bladder has a greater capacity and a relative insensitivity to intravesical pressure. Consequently, overdistention, incomplete emptying, and excessive residual urine are frequent (Buchanan, 2014; Mulder, 2014). Acute urinary retention is more common with epidural or narcotic analgesia (Kandadai, 2014). The management of urinary retention is discussed later (p. 643).

Stress urinary incontinence during the puerperium may occur in 5 percent of women (Wang, 2017). Much attention has been given to the potential for subsequent development of urinary incontinence and other pelvic floor disorders in the years following delivery (Colla, 2018). A more detailed discussion is found in Chapter 30 (p. 548).

PERITONEUM AND ABDOMINAL WALL

The broad and round ligaments require considerable time to recover from stretching and loosening during pregnancy. The abdominal wall remains soft and flaccid as a result of ruptured elastic fibers in the skin and prolonged distention by the gravid uterus. If the abdomen is unusually lax or pendulous, an ordinary girdle is often satisfactory. An abdominal binder is another temporary measure. Several weeks are required for these structures to return to normal, and exercise aids recovery. These may be started anytime following vaginal delivery. After cesarean delivery, a 6-week interval to allow anterior abdominal wall fascia to heal and abdominal soreness to diminish is reasonable. Silvery abdominal striae commonly develop as *striae gravidarum* (Chap. 4, p. 55). Except for these, the abdominal wall usually resumes its prepregnancy appearance. When muscles remain atonic, however, the abdominal wall also remains lax.

Marked separation of the rectus abdominis muscles—*diastasis recti*—may result. This separation develops from a gradual thinning and widening of the linea alba and is coupled with a general laxity of the ventral abdominal wall muscles. Importantly, musculofascial continuity and lack of a true hernia sac differentiates this from a ventral hernia (Mommers, 2017).

BLOOD AND BLOOD VOLUME

Hematological and Coagulation Changes

Marked leukocytosis and thrombocytosis may occur during and after labor. The white blood cell count seldom exceeds 25,000/μL, and the rise is predominantly due to granulocytes (Arbib, 2016; Sanci, 2017). A relative lymphopenia and an absolute eosinopenia is typical. Normally, during the first few postpartum days, hemoglobin concentration and hematocrit decrease moderately. If they fall much below prelabor levels, a considerable amount of blood has been lost.

By the end of pregnancy, laboratory values that assess coagulation are altered (Kenny, 2015). These changes are discussed in Chapter 4 (p. 61) and listed in the Appendix (p. 1228). Many extend variably in the puerperium. For example, a markedly higher plasma fibrinogen level is maintained at least through the first week. This contributes to hypercoagulability (Chap. 55, p. 975). As one result, the pregnancy-associated risks for deep-vein thrombosis and pulmonary embolism persist in the 12 weeks following childbirth (Kamel, 2014).

Pregnancy-Induced Hypervolemia

When the amount of blood attained by normal pregnancy hypervolemia is lost as postpartum hemorrhage, the woman almost immediately regains her nonpregnant blood volume (Chap. 42, p. 732). If less has been lost at delivery, blood volume generally nearly returns to its nonpregnant level by 1 week after delivery. Cardiac output usually remains elevated for 24 to 48 hours postpartum and declines to nonpregnant values by 10 days (Robson, 1987). Heart rate changes follow this pattern, and blood pressure similarly returns to nonpregnant values (Fig. 36-5). Correspondingly, systemic vascular resistance remains in the lower range characteristic of pregnancy for 2 days postpartum and then begins to steadily rise to normal nonpregnant values (Hibbard, 2015). Despite this, Morris and coworkers (2015) found that reduced arterial stiffness persists following pregnancy. They suggest a significant favorable effect of pregnancy on maternal cardiovascular remodeling. This may represent a mechanism by which preeclampsia risk is reduced in subsequent pregnancies.

Postpartum Diuresis

Normal pregnancy is associated with appreciable extracellular sodium and water retention, and postpartum diuresis is a physiological reversal of this process. Chesley and associates (1959) demonstrated an approximate 2 liter decline in sodium space during the first week postpartum. This corresponds with loss of residual pregnancy hypervolemia. In preeclampsia, pathological retention of fluid antepartum and then its normal diuresis postpartum may be prodigious (Chap. 41, p. 724).

Postpartum diuresis results in a relatively rapid weight loss of 2 to 3 kg, which is additive to the 5 to 6 kg incurred by delivery and normal blood loss. Weight loss from pregnancy itself likely peaks by the end of the second week postpartum.

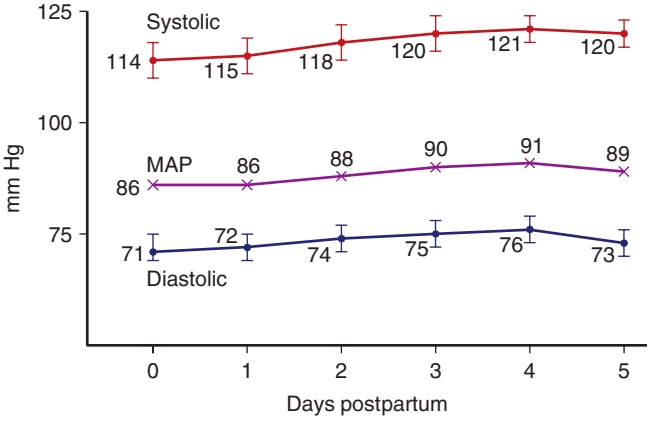

FIGURE 36-5 During the early puerperium, blood pressure normally rises toward nonpregnant values. MAP = mean arterial pressure.

Any residual weight compared with prepregnancy values probably represents fat stores that will persist.

LACTATION AND BREASTFEEDING

Breast Anatomy and Secretory Products

Each mature mammary gland or breast is composed of 15 to 25 lobes. They are arranged radially and are separated from one another by varying amounts of fat. Each lobe consists of several lobules, which in turn are composed of numerous alveoli. Each alveolus is provided with a small duct that joins others to form a single larger duct for each lobe (Fig. 36-6). These *lactiferous ducts* open separately on the nipple, where they may be distinguished as small but distinct orifices. The alveolar secretory epithelium synthesizes the various milk constituents.

After delivery, the breasts begin to secrete *colostrum*, which is a deep-yellow liquid. It usually can be expressed from the nipples by the second postpartum day. Compared with mature milk, colostrum is rich in immunological components and contains more minerals and amino acids (Y de Vries, 2018). It also has more protein, much of which is globulin, but less sugar and fat. Secretion persists for 5 to 14 days, with gradual conversion to mature milk by 4 to 6 weeks. The colostrum content of immunoglobulin A (IgA) offers the newborn protection against enteric pathogens. Other host resistance factors found in colostrum and milk include complement, macrophages, lymphocytes, lactoferrin, lactoperoxidase, and lysozymes.

TABLE 36-3. Average Composition of Human Breast Milk

Fat	g/100 mL
Total	4.2
Fatty acids	Trace
PUFA	0.6

Protein	g/100 mL
Total	1.1
Casein	0.3
α-Lactalbumin	0.3
Lactoferrin	0.2
Carbohydrate	g/100 mL
Lactose	7
Oligosaccharides	0.5

PUFA = Polyunsaturated fatty acids.

A lactating mother produces upwards of 600 mL of milk daily, and maternal gestational weight gain has little impact on its quantity or quality. Mature milk is a complex and dynamic biological fluid that includes fat, proteins, carbohydrates, bioactive factors, minerals, vitamins, hormones, and many cellular products (Table 36-3). The contents and concentrations of human milk change even during a single feed and are influenced by maternal diet and by newborn age, health, and needs. Milk is isotonic with plasma, and lactose accounts for half of the osmotic pressure. Essential amino acids are derived from blood, and nonessential amino acids are derived in part from blood or synthesized in the mammary gland. Most milk proteins are unique and include alpha-lactalbumin, beta-lactoglobulin, and casein. Fatty acids are synthesized in the alveoli from glucose and are secreted by an apocrine-like process. Variable amounts of most vitamins are found in human milk. Vitamin K is virtually absent, and thus, an intramuscular dose is given to the newborn (Chap. 33, p. 606). Vitamin D content is low, and newborn supplementation is recommended by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017).

Whey is milk serum and contains large amounts of interleukin-6 and other chemokines (Polat, 2016). Human milk has a whey-to-casein ratio of 60:40, which is considered ideal for absorption. *Prolactin* appears to be actively secreted into breast milk. *Epidermal growth factor* has been identified, and because it is not destroyed by gastric proteolytic enzymes, it may be absorbed to promote growth and maturation of newborn intestinal mucosa. Other critical components in human milk include melatonin and oligosaccharides.

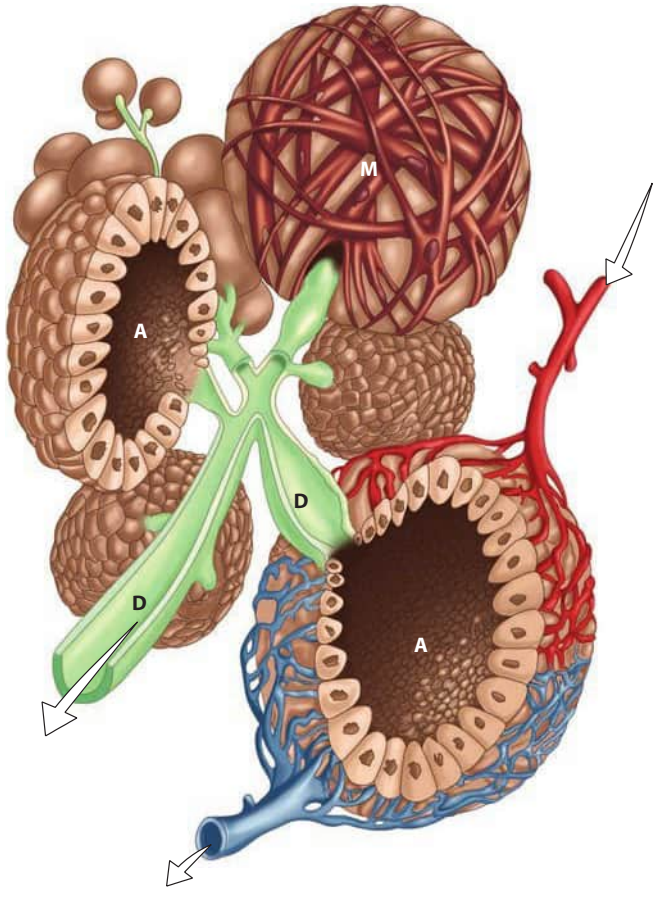

FIGURE 36-6 Schematic of the alveolar and ductal system during lactation. Note the myoepithelial fibers (*M*) that surround the outside of the uppermost alveolus. The secretions from the glandular elements are extruded into the lumen of the alveoli (*A*) and ejected by the myoepithelial cells into the ductal system (*D*), which empties through the nipple. Arterial blood supply to the alveolus is identified by the upper right arrow and venous drainage by the arrow beneath.

Lactation Endocrinology

The precise humoral and neural mechanisms involved in lactation are complex. Progesterone, estrogen, and placental lactogen, as well as prolactin, cortisol, and insulin, appear to act in concert to stimulate the growth and development of the milk-secreting apparatus (Stuebe, 2014). With delivery, the maternal serum levels of progesterone and estrogen decline abruptly and profoundly. This drop removes the inhibitory influence of progesterone on alpha-lactalbumin production and stimulates lactose synthase to raise milk lactose levels. Progesterone withdrawal also allows prolactin to act unopposed in its stimulation of alpha-lactalbumin production. Activation of calcium-sensing receptors in mammary epithelial cells downregulates parathyroid hormone–related protein (PTHrP) and increases calcium transport into milk (Vanhouten, 2013). Serotonin also is produced in mammary epithelial cells and has a role in maintaining milk production (Collier, 2012).

The intensity and duration of subsequent lactation are controlled, in large part, by the repetitive stimulus of suckling and emptying of milk from the breast. Prolactin is essential for lactation, and women with extensive pituitary necrosis—*Sheehan syndrome*—do not lactate (Chap. 61, p. 1104). Although plasma prolactin levels fall after delivery to levels lower than during pregnancy, each act of suckling triggers a rise in levels. Presumably a stimulus from the breast curtails the release of dopamine—also known as *prolactin-inhibiting factor*—from the hypothalamus. In turn, this transiently induces increased prolactin secretion.

The posterior pituitary secretes oxytocin in pulsatile fashion. This stimulates milk expression from a lactating breast by causing contraction of myoepithelial cells in the alveoli and small milk ducts (see Fig. 36-6). Milk ejection, or *letting down*, is a reflex initiated especially by suckling, which stimulates the posterior pituitary to liberate oxytocin. The reflex may even be provoked by an infant cry and can be inhibited by maternal fright or stress (Stuebe, 2014).

Immunological Consequences of Breastfeeding

Human milk contains several protective immunological substances, including secretory IgA and growth factors. The antibodies in human milk are specifically directed against maternal environmental antigens such as *Escherichia coli* (Macpherson, 2017). According to the CDC, breastfeeding decreases the incidence of ear, respiratory, and gastrointestinal infections; necrotizing enterocolitis; and sudden infant death syndrome (SIDS) (Perrine, 2015). Breastfeeding is especially important for immunity in preterm infants (Lewis, 2017).

Much attention has been directed to the role of maternal breast milk lymphocytes in neonatal immunological processes. Milk contains both T and B lymphocytes, but the T lymphocytes appear to differ from those found in blood. Specifically, milk T lymphocytes are almost exclusively composed of cells that exhibit specific membrane antigens. These memory T cells appear to be an avenue for the neonate to benefit from the maternal immunological experience.

Lactation

The ideal time to begin breastfeeding is within an hour of birth. Human milk is ideal food for newborns in that it provides age-specific nutrients, immunological factors, and antibacterial substances. Milk also contains factors that act as biological signals for promoting cellular growth and differentiation. A list of the advantages of breastfeeding is shown in Table 36-4. Lactation has long-term benefits for both the mother and the infant. For example, women who breastfeed have a lower risk of breast and reproductive cancer. Children who were breastfed have higher adult intelligence scores independent of a wide range of possible confounding factors (Jong, 2012; Kramer, 2008). In the short term, lactation is associated with less postpartum weight retention (Baker, 2008). In addition, rates of SIDS are significantly lower among breast-fed infants. Bartek and colleagues (2013) estimate that a 90-percent breastfeeding rate for 12 months would save more than $3 billion annually in excess infant and maternal morbidity costs. For all these reasons, the American Academy of Pediatrics and American College of Obstetricians and Gynecologists (2017) support the World Health Organization (2011) recommendations of exclusive breastfeeding for up to 6 months.

Currently, 55 percent of women breastfeed at 6 months compared with a Healthy People 2020 goal of 61 percent. (American College of Obstetricians and Gynecologists 2018b). The Baby-Friendly Hospital Initiative is an international program to raise rates of exclusive breastfeeding and to extend its duration. It is based on the World Health Organization (2018) *Ten Steps to Successful Breastfeeding* (Table 36-5). Worldwide, almost 20,000 hospitals are deemed "baby-friendly," however, only 15 to 20 percent of hospitals in the United States are so designated (Baby-Friendly USA, 2018; Perrine, 2015). In a large population-based study done in the United States, fewer than two thirds of term neonates were exclusively breastfed at the time of discharge (McDonald, 2012). By 3 months, according to the CDC, less than half of these infants are exclusively breastfed (Olaiya, 2016).

Various individual resources are available online for lactating mothers from the American Academy of Pediatrics (www.aap.org) and La Leche League International (www.llli.org).

Breast Care

The nipples require little attention other than cleanliness and attention to skin fissures. Fissured nipples render lactation

TABLE 36-5. Ten Steps to Successful Breastfeeding

1. Have a written breastfeeding policy that is regularly communicated to all health-care staff
2. Train all staff in skills necessary to implement this policy
3. Inform all pregnant women about the benefits and management of breastfeeding
4. Help mothers initiate breastfeeding within an hour of birth
5. Show mothers how to breastfeed and how to sustain lactation, even if they should be separated from their infants
6. Feed newborns nothing but breast milk, unless medically indicated, and prioritize donor breast milk when supplementation is needed
7. Practice rooming-in, which allows mothers and newborns to remain together 24 hours a day
8. Encourage breastfeeding on demand
9. Give no artificial pacifiers to breastfeeding newborns
10. Help start breastfeeding support groups and refer mothers to them

Adapted from the World Health Organization, 2018.

painful, and they may have a deleterious influence on milk production. These cracks also provide a portal of entry for pyogenic bacteria. Because dried milk is likely to accumulate and irritate the nipples, washing the areola with water and mild soap is helpful before and after nursing. When the nipples are irritated or fissured, some recommend topical lanolin and a nipple shield for 24 hours or longer (Dennis, 2014). If fissuring is severe, the newborn should not be permitted to nurse on the affected side. Instead, the breast is emptied regularly with a pump until the lesions are healed.

Poor latching of the neonate to the breast can create such fissures. For example, the newborn may take into its mouth only the nipple, which is then is forced against the hard palate during suckling. Ideally, the nipple and areola are both taken in to evenly distribute suckling forces. Moreover, the force of the hard palate against the lactiferous sinuses aids their efficient emptying, while the nipple is thereby positioned closer to the soft palate.

Breastfeeding Contraindications

Lactation is contraindicated in women who take street drugs or do not control their alcohol use; have an infant with galactosemia; have human immunodeficiency virus (HIV) infection; have active, untreated tuberculosis; take certain medications; or are undergoing breast cancer treatment (American Academy of Pediatrics, 2017). Breastfeeding has been recognized for some time as a mode of HIV transmission and is proscribed in developed countries in which adequate nutrition is otherwise available (Chap. 68, p. 1222). Other viral infections do not contraindicate lactation. For example, with maternal cytomegalovirus infection, both virus and antibodies are present in breast milk. And, although hepatitis B virus is excreted in milk, breastfeeding is not contraindicated if hepatitis B immune globulin is given to the newborns of affected mothers. Maternal hepatitis C infection is not a contraindication because breastfeeding has not been shown to transmit infection. Women with active herpes simplex virus may suckle their infants if there are no breast lesions and if particular care is directed to hand washing before nursing. From the CDC (2021a), those with COVID-19 should wear a mask and practice hand-hygiene.

Drugs Secreted in Milk

Most drugs given to the mother are secreted in breast milk, although the amount ingested by the infant typically is small. Factors influencing drug excretion include plasma concentration, degree of protein binding, plasma and milk pH, degree of ionization, lipid solubility, and molecular weight (Rowe, 2013). The ratio of drug concentration in breast milk to that in maternal plasma is the *milk-to-plasma drug-concentration ratio.* Ideally, to minimize infant exposure, medication selection favors drugs with a shorter half-life, poorer oral absorption, and lower lipid solubility. If multiple daily drug doses are required, each is taken by the mother *after* the closest feed. Single daily-dosed drugs may be taken just before the longest infant sleep interval—usually at bedtime.

Only a few drugs are absolutely contraindicated while breastfeeding (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2017). Cytotoxic drugs may interfere with cellular metabolism and potentially cause immune suppression or neutropenia, affect growth, and at least theoretically, increase the childhood cancer risk. Examples include cyclophosphamide, cyclosporine, doxorubicin, methotrexate, and mycophenolate (Briggs, 2017). If a medication presents a concern, its importance should be ascertained. A provider can also seek a safer alternative or determine if neonatal exposure can be minimized if the medication dose is taken immediately after each breastfeeding session. Last, recreational drugs such as marijuana and alcohol should be avoided (American College of Obstetricians and Gynecologists, 2017c; Metz, 2018). Data on individual drugs are available through the National Institutes of Health website, LactMed, which can be found at www.ncbi.nlm.nih.gov/books/NBK501922/.

Radioactive isotopes of copper, gallium, indium, iodine, sodium, and technetium rapidly appear in breast milk. Consultation with a nuclear medicine specialist is recommended before performing a diagnostic study with these isotopes (Chap. 49, p. 875). Ideally, a radionuclide with the shortest excretion time in breast milk is selected. The mother should pump her breasts before the study and store enough milk in a freezer to feed the infant. After the study, she should pump her breasts to maintain milk production but discard all milk produced during

the time that radioactivity is present. This ranges from 15 hours to 2 weeks, depending on the isotope used. Importantly, radioactive iodine concentrates and persists in the thyroid. Its special considerations are discussed in Chapter 66 (p. 1174). For magnetic resonance (MR) imaging, breastfeeding should not be interrupted after gadolinium administration (American College of Obstetricians and Gynecologists, 2017a).

Breast Engorgement

This is common in women who do not breastfeed. It is typified by milk leakage and breast pain, which peak 3 to 5 days after delivery. Up to half of affected women require analgesia for breast pain relief, and as many as 10 percent report severe pain for up to 14 days.

Evidence is insufficient to firmly support any specific treatment (Mangesi, 2016). That said, breasts can be supported with a well-fitting brassiere, breast binder, or sports bra. Cool packs and oral analgesics for 12 to 24 hours aid discomfort. Pharmacological or hormonal agents in general are not recommended to suppress lactation.

Fever caused by breast engorgement was common before the renaissance of breastfeeding. In one study, 13 percent of puerperas with engorgement had fever ranging from 37.8 to 39°C (Almeida, 1986). Fever seldom persists for longer than 4 to 16 hours. The incidence and severity of engorgement and of the fever associated with it are much lower if women breastfeed. Other causes of fever, especially those due to infection, must be excluded. *Mastitis* is infection of the mammary parenchyma and is relatively common in lactating women (Chap. 37, p. 659).

Other Lactation Issues

With *inverted nipples*, lactiferous ducts open directly into a depression at the center of the areola. With these depressed nipples, nursing is difficult. If the depression is not deep, milk sometimes can be drawn out by a breast pump. If instead the nipple is greatly inverted, daily attempts are made during the last few months of pregnancy to draw or "tease" the nipple out with the fingers.

Extra breasts—*polymastia*, or extra nipples—*polythelia*, may develop along the former embryonic mammary ridge. Also termed the *milk line*, this line extends from the axilla to the groin bilaterally. In some women, rests of accessory breast tissue can be found in the mons pubis or vulva (Wagner, 2013). In the general population, the incidence of accessory breast tissue ranges from 0.22 to 6 percent (Loukas, 2007). These breasts may be so small as to be mistaken for pigmented moles, or if without a nipple, for lymphadenopathy or lipoma. Polymastia has no obstetrical significance, although occasionally enlargement of these accessory breasts during pregnancy or engorgement postpartum may result in patient discomfort and anxiety.

Galactocele is a milk duct that becomes obstructed by inspissated secretions. The amount is ordinarily limited, but an excess may form a fluctuant mass—a galactocele—that can cause pressure symptoms and have the appearance of an abscess. It may resolve spontaneously or require aspiration.

Among individuals, the volume of milk secreted varies markedly. This depends not on general maternal health but on breast glandular development. Rarely, there is complete lack of mammary secretion—*agalactia*. Occasionally, mammary secretion is excessive—*polygalactia*.

Lactation-Associated Osteoporosis

This is a rare disorder of unknown etiology that may be associated with severe back pain or vertebral fractures (Li, 2018; Zhang, 2017). Preliminary studies indicate that bisphosphonates are effective in its management. However, for almost all women, lactation is not associated with later-onset osteoporosis (Crandall, 2017). Pregnancy-associated osteoporosis is discussed in Chapter 61 (p. 1100).

HOSPITAL CARE

For 2 hours after delivery, blood pressure and pulse are taken every 15 minutes, at minimum. Temperature is assessed every 4 hours for the first 8 hours and then at least every 8 hours subsequently (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2017). If regional analgesia or general anesthesia was used for labor or delivery, the mother should be observed in an appropriately equipped and staffed recovery area. Expected anesthesia recovery and complications are described in Chapter 25 (p. 473).

Because the likelihood of significant hemorrhage is greatest immediately postpartum, vaginal bleeding is closely monitored. The uterine fundus is palpated to ensure that it is well contracted. If relaxation is detected, the uterus should be massaged through the abdominal wall until it remains contracted. Uterotonics also are sometimes required. Blood may accumulate within the uterus without external bleeding. This may be detected early by uterine enlargement during fundal palpation in the first postdelivery hours. Postpartum hemorrhage is discussed in Chapter 41.

Early ambulation within a few hours after delivery is encouraged. An attendant should be present for at least the first time, in case the woman becomes syncopal. The many confirmed advantages of early ambulation include fewer bladder complications, less frequent constipation, and reduced rates of puerperal venous thromboembolism. As discussed, deep-vein thrombosis and pulmonary embolism are common in the puerperium. In our audits of puerperal women at Parkland Hospital, the frequency of venous thromboembolism is extremely low. We attribute this to early ambulation. Risk factors and other measures to diminish the frequency of thromboembolism are discussed in Chapter 55 (p. 984).

Diets need not be restricted for women who give birth vaginally. Generally, two hours after uncomplicated vaginal delivery, a woman is allowed to eat. With lactation, the level of calories and protein consumed during pregnancy is increased slightly as recommended by the Food and Nutrition Board of the National Research Council (Chap. 10, p. 184). If the mother does not breastfeed, dietary requirements are the same as for a nonpregnant woman. We recommend oral iron supplementation for at least 3 months after delivery and hematocrit evaluation at the first postpartum visit.

As noted earlier, profound drops in estrogen levels follow removal of the placenta. Reminiscent of the menopause,

postpartum women may experience hot flushes, especially at night. Importantly, the patient's temperature is assessed to differentiate these physiological vasomotor events from infection.

In women with migraines, dramatic hypoestrogenism may trigger headaches. Importantly, severe headaches should be differentiated from postdural puncture headache or hypertensive complications. Care varies depending on headache severity. Mild headaches may respond to analgesics such as ibuprofen or acetaminophen. For more severe headaches, oral or systemic narcotics can be used. Alternatively, a triptan, such as sumatriptan (Imitrex), can relieve headaches by causing intracranial vasoconstriction, and it is breastfeeding compatible.

Perineal Care

The woman is instructed to clean the vulva from anterior to posterior—the vulva toward the anus. A cool pack applied to the perineum may help reduce edema and discomfort during the first 24 hours if there is a perineal laceration or an episiotomy. Most women also appear to obtain a measure of relief from the periodic application of a local anesthetic spray. *Severe perineal, vaginal, or rectal pain always warrants careful inspection and palpation.* Severe discomfort usually indicates a problem, such as a hematoma within the first day or so and infection after the third or fourth day (Chap. 37, p. 657 and Chap. 42, p. 740). Beginning approximately 24 hours after delivery, moist heat as provided by warm sitz baths can reduce local discomfort. Tub bathing after uncomplicated delivery is allowed. The episiotomy incision normally is firmly healed and nearly asymptomatic by the third week.

Rarely, the cervix, and occasionally a portion of the uterine body, may protrude from the vulva following delivery. This is accompanied by variable degrees of anterior and posterior vaginal wall prolapse. Symptoms include a palpable mass at or past the introitus, voiding difficulties, or pressure. Puerperal procidentia typically improves with time as the weight of the uterus lessens with involution. As a temporizing measure for pronounced prolapse, the uterus can be replaced and held in position with a space-filling pessary, such as a donut type.

Rectal veins are often congested at term. Thrombosis of these hemorrhoids is common and may be promoted by second-stage pushing. Treatment includes topically applied anesthetics, warm soaks, and stool-softening agents. Nonprescription topical preparations containing corticosteroids, astringents, or phenylephrine are often used. However, no randomized studies support their efficacy compared with symptomatic care.

Bladder Function

In most delivery units, intravenous fluids are infused during labor and for an hour or so after vaginal delivery. Oxytocin, in doses that have an antidiuretic effect, is typically infused postpartum, and rapid bladder filling is common. Moreover, both bladder sensation and capability to empty spontaneously may be diminished by components of the labor and delivery process. Thus, urinary retention and bladder overdistention is common in the early puerperium. The incidence in more than 5500 women studied with a bladder scanner was 5 percent (Buchanan, 2014). It is much less clinically. Risk factors that increased the likelihood of retention include primiparity, epidural analgesia, cesarean delivery, perineal lacerations, operative vaginal delivery, catheterization during labor, and prolonged second-stage labor (Stephansson, 2016; Wang, 2017).

Prevention of bladder overdistention demands observation after delivery to ensure that the bladder does not overfill and that it empties adequately with each voiding. The enlarged bladder can be palpated suprapubically, or it is evident abdominally indirectly as it elevates the fundus above the umbilicus. Most currently use an automated sonography system to detect high bladder volumes and thus postpartum urinary retention (Buchanan, 2014).

If a woman has not voided within 4 hours after delivery, it is likely that she cannot. If she has trouble voiding initially, she also is likely to have further trouble. First, an examination for perineal and genital-tract hematomas is completed, as these may be contributory. With an overdistended bladder, an indwelling catheter should be placed and left until the factors causing retention have abated. Even without a demonstrable cause, it usually is best to leave the catheter in place for at least 24 hours. This prevents recurrence and allows recovery of normal bladder tone and sensation.

When the catheter is removed, a voiding trial is completed to demonstrate an ability to void appropriately. If a woman cannot void after 4 hours, urine volumes are measured sonographically. If more than 200 mL, the bladder is not functioning appropriately, and the catheter is replaced and remains for another 24 hours. Although rare, if retention persists after a second voiding trial, an indwelling catheter and leg bag can be elected, and the patient returns in 1 week for an outpatient voiding trial. In a study of 27 women with a protracted course, all resumed normal voiding by 3 weeks postpartum (Mevorach Zussman, 2020).

During a voiding trial, if less than 200 mL of urine is obtained, the catheter can be removed and the bladder subsequently monitored clinically and sonographically as described earlier. Harris and coworkers (1977) reported that 40 percent of such women develop bacteriuria, and thus a single dose or short course of antimicrobial therapy against uropathogens is reasonable after the catheter is removed.

Pain, Mood, and Cognition

Discomfort and its causes following cesarean delivery are considered in Chapter 30 (p. 565). During the first few days after vaginal delivery, the mother may be uncomfortable because of afterpains, episiotomy and lacerations, breast engorgement, and at times, postdural puncture headache. Mild analgesics containing codeine, ibuprofen, or acetaminophen, preferably in combinations, are given as frequently as every 4 hours during the first few days.

It is important to screen the postpartum woman for depression (Mangla, 2019). Commonly, mothers exhibit some degree of depressed mood a few days after delivery. Termed *postpartum blues,* this likely is the consequence of several factors. These include the emotional letdown that follows the excitement and fears experienced during pregnancy and delivery, discomforts of the early puerperium, fatigue from sleep deprivation, anxiety over the ability to provide appropriate newborn care, and

body image concerns. In most women, effective treatment includes anticipation, recognition, and reassurance. This disorder is usually mild and self-limited to 2 to 3 days, although it sometimes lasts for up to 10 days. Should these moods persist or worsen, an evaluation for symptoms of major depression is done (Chap. 64, p. 1145).

Last, postpartum hormonal changes in some women may affect brain function. Bannbers and colleagues (2013) observed a functional decline in executive function in postpartum women.

Neuromusculoskeletal Problems

Obstetrical Neuropathies

Pressure on branches of the lumbosacral nerve plexus during labor may manifest as complaints of intense neuralgia or cramplike pains extending down one or both legs as soon as the head descends into the pelvis. If the nerve is injured, pain may continue after delivery, and variable degrees of sensory loss or muscle paralysis can result. In some cases, there is footdrop, which can be secondary to injury at the level of the lumbosacral plexus, sciatic nerve, or common fibular (peroneal) nerve (Bunch, 2014). Components of the lumbosacral plexus cross the pelvic brim and can be compressed by the fetal head or by forceps. The common fibular nerves may be externally compressed when the legs are positioned in stirrups, especially during prolonged second-stage labor.

Obstetrical neuropathy is relatively infrequent. Evaluation of more than 6000 puerperas found that approximately 1 percent had a confirmed nerve injury (Wong, 2003). Lateral femoral cutaneous neuropathies were the most common (24 percent), followed by femoral neuropathies (14 percent). A motor deficit accompanied a third of injuries. Nulliparity, prolonged second-stage labor, and pushing for a long duration in the semi-Fowler position were risk factors. The median duration of symptoms was 2 months, and the range was 2 weeks to 18 months.

Injury of the iliohypogastric and ilioinguinal nerves may occur with cesarean delivery (Rahn, 2010; Yazici Yilmaz, 2018). We have rarely encountered lumbar arachnoiditis following epidural analgesia causing severe bilateral neuropathic pain.

Musculoskeletal Injuries

Pain in the pelvic girdle, hips, or lower extremities may follow stretching or tearing injuries sustained at normal or difficult delivery. MR imaging is often informative when clinical examination is normal (Miller, 2015). Most injuries resolve with antiinflammatory agents and physical therapy. Rarely, there may be septic pyomyositis such as with iliopsoas muscle abscess (Nelson, 2010; Young, 2010).

Separation of the symphysis pubis or one of the sacroiliac synchondroses during labor leads to pain and marked interference with locomotion (Fig. 36-7). Estimates of the frequency of this event vary widely from 1 in 600 to 1 in 30,000 deliveries (Reis, 1932; Taylor, 1986). In our experiences, symptomatic separations are uncommon. Their onset of pain is often acute during delivery, but symptoms may manifest either antepartum or up to 48 hours postpartum (Snow, 1997). Radiography is typically used for evaluation. The normal distance of the symphyseal joint is 0.4 to 0.5 cm, and symphyseal separation >1 cm is diagnostic for diastasis. Treatment is generally conservative, with rest in a lateral decubitus position and an appropriately fitted pelvic binder (Lasbleiz, 2017). Surgery is occasionally necessary in some symphyseal separations >4 cm (Kharrazi, 1997). The recurrence risk is high in subsequent pregnancies, and Culligan and associates (2002) recommend consideration for cesarean delivery.

FIGURE 36-7 Pubic symphyseal separation found on the first postpartum day following vaginal delivery of a 2840-g newborn. The patient had pain over the pubic bone and pain with ambulation. A shuffling gait was noted, and she had difficulty with leg elevation when supine. The patient was treated with physical therapy and analgesics. A pelvic binder was applied, and a rolling walker was provided. She improved quickly and was discharged home on postpartum day 5.

In rare cases, fractures of the sacrum or pubic ramus are caused by even uncomplicated deliveries (Alonso-Burgos, 2007; Speziali, 2015). Discussed in Chapter 61 (p. 1100), the latter is more likely with osteoporosis associated with heparin or corticosteroid therapy. In rare but serious cases, bacterial osteomyelitis—*osteitis pubis*—can be devastating. Lawford and coworkers (2010) reported such a case that caused massive vulvar edema.

Immunizations

The D-negative woman who is not isoimmunized and whose newborn is D-positive is given 300 μg of anti-D immune globulin shortly after delivery (Chap. 18, p. 357). Women who are not already immune to rubella or varicella are excellent candidates for vaccination before discharge (Swamy, 2015). Those who have not received a tetanus/diphtheria (Tdap/Td) or influenza vaccine should be given these (American College of Obstetricians and Gynecologists, 2017e) (Table 10-7, p. 189). The CDC (2021b) recommends the COVID-19 vaccine, and includes breastfeeding women. Morgan and colleagues (2015) reported that implementation of a best-practices alert in the electronic medical record was associated with a Tdap immunization rate of 97 percent at Parkland Hospital. When permissible by law, the American College of Obstetricians and Gynecologists (2019) recommends standing orders for indicated immunizations.

Contraception

During the hospital stay, a concerted effort is made to provide family planning education. Various forms of contraception are discussed throughout Chapter 38 and sterilization procedures in Chapter 39. The immediate puerperium is an ideal time for consideration of long-acting reversible contraception—LARC (American College of Obstetricians and Gynecologists, 2017b).

Women not breastfeeding have return of menses usually within 6 to 8 weeks. At times, however, it is difficult clinically to assign a specific date to the first menstrual period after delivery. A minority of women bleed small to moderate amounts intermittently starting soon after delivery. Ovulation occurs at a mean of 7 weeks but ranges from 5 to 11 weeks (Perez, 1972). That said, ovulation before 28 days has been described (Hytten, 1995). Thus, conception is possible during the early puerperium. *Women who become sexually active during the puerperium and who do not desire to conceive should initiate contraception.* Kelly and associates (2005) reported that by the third month postpartum, 58 percent of adolescents had resumed sexual intercourse, but only 80 percent of these were using contraception. Because of this, many recommend LARC during the puerperium.

Women who breastfeed ovulate much less frequently compared with those who do not, but variation is great. Timing of ovulation depends on individual biological variation and the intensity of breastfeeding. Lactating women may first menstruate as early as the second or as late as the 18th month after delivery. Campbell and Gray (1993) analyzed daily urine specimens in 92 lactating women. Breastfeeding in general delays resumption of ovulation, although it does not invariably forestall it. Other findings in their study included the following:

1. Resumption of ovulation was frequently marked by return of normal menstrual bleeding.
2. Breastfeeding episodes lasting 15 minutes seven times daily delayed ovulation resumption.
3. Ovulation can occur without bleeding.
4. Bleeding can be anovulatory.
5. The risk of pregnancy in breastfeeding women was approximately 4 percent per year.

For the breastfeeding woman, progestin-only contraceptives, such as progestin pills, depot medroxyprogesterone, or progestin implants or IUDs, do not affect the quality or quantity of milk. Not available in the United States, success with the progesterone-releasing vaginal ring also has been described (Carr, 2016). These may be initiated any time during the puerperium. Estrogen-progestin contraceptives likely reduce the quantity of breast milk, but under the proper circumstances, they too can be used by lactating women. These hormonal methods are discussed in Chapter 38 (p. 671).

Hospital Discharge

Following uncomplicated vaginal delivery, hospitalization is seldom warranted for more than 48 hours. Hospital stay length following labor and delivery is now regulated by federal law (Chap. 32, p. 596). Currently, the norms are hospital stays up to 48 hours following uncomplicated vaginal delivery and up to 96 hours following uncomplicated cesarean delivery (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2017; Blumenfield, 2015). Earlier hospital discharge is acceptable for appropriately selected women if they desire it. A woman should receive instructions concerning anticipated normal physiological puerperal changes, including lochia patterns, weight loss from diuresis, and milk let-down. She also should receive instructions concerning fever, excessive vaginal bleeding, or leg pain, swelling, or tenderness. Persistent headaches, shortness of breath, or chest pain warrant immediate concern.

HOME CARE

Coitus

No evidence-based data guide resumption of coitus after delivery, and practices are individualized (Minig, 2009). After 2 weeks, coitus may be resumed *based on desire and comfort.* Wallwiener and colleagues (2017) reported that 60 percent of women resumed sexual activity by 1 week and 80 percent by 4 months. They also reported that a third of these women had sexual dysfunction.

Intercourse too soon may be unpleasant, if not painful, and this may be related to episiotomy incisions or perineal lacerations. In a study of women without an episiotomy, only 0.4 percent of those with a first- or second-degree tear had dyspareunia (Ventolini, 2014). Conversely, in primiparas with an episiotomy, 67 percent had sexual dysfunction at 3 months, 31 percent at 6 months, and 15 percent at 12 months (Chayachinda, 2015). Only 40 percent of women with an anal sphincter injury had resumed intercourse by 12 weeks (Leader-Cramer, 2016). Last, dyspareunia was also common following cesarean delivery (McDonald, 2015).

Postpartum, the vulvovaginal epithelium is thin, and very little lubrication follows sexual stimulation. This stems from the hypoestrogenic state following delivery, which lasts until ovulation resumes. It may be particularly problematic in breastfeeding women who are hypoestrogenic for many months postpartum (Palmer, 2003). For treatment, small amounts of topical estrogen cream can be applied daily for several weeks to vulvar tissues. Additionally, vaginal lubricants may be used with coitus.

This same thinning of the vulvovaginal epithelium can lead to dysuria. Topical estrogen can again be offered once cystitis is excluded.

Follow-Up Care

By discharge, women who had an uncomplicated vaginal delivery can resume most activities, including bathing, driving, and household functions. Despite this, Tulman and Fawcett (1988) reported that only half of mothers regained their usual level of energy by 6 weeks. Women who delivered vaginally were twice as likely to have normal energy levels at this time compared with those with a cesarean delivery. Ideally, the care and nurturing of the infant should be provided by the mother with ample help from the father. Jimenez and Newton (1979) tabulated cross-cultural information on 202 societies from various international geographical regions. Following childbirth, most

societies did not restrict work activity, and approximately half expected a return to full duties within 2 weeks. Wallace and coworkers (2013) reported that 80 percent of women who worked during pregnancy resume work by 1 year after delivery.

Discussed on page 634, during this fourth trimester, the American College of Obstetricians and Gynecologists (2018a) recommends a comprehensive visit within 12 weeks after delivery. This has proved quite satisfactory to identify abnormalities beyond the immediate puerperium and to initiate contraceptive practices.

CHAPTER 37

Puerperal Infection

Women are susceptible to several potentially serious complications during the fourth trimester. Many of these conditions are encountered during pregnancy, and others are unique to the puerperium. Historically, infection was the most important source of postpartum maternal morbidity and mortality, since emphasized by the studies of Semmelweis and Lister (Kadar, 2021). Puerperal infections include pelvic infections, mastitis, and breast abscesses. Discussed in their respective chapters, cardiovascular disease (Chap. 52, p. 915), venous thromboembolism (Chap. 55, p. 980), and hemorrhage (Chap. 42, p. 731) currently are leading noninfectious puerperal complications (Callaghan, 2012; Creanga, 2017). However, the incidence of postpartum hospitalization due to sepsis is rising. Other puerperal issues and their management are discussed in Chapter 36.

PUERPERAL PELVIC INFECTIONS

Traditionally, the term *puerperal infection* describes any bacterial infection of the genital tract after delivery. Infection, preeclampsia, and obstetrical hemorrhage formed the lethal triad of maternal death causes before and during the 20th century. Fortunately, maternal mortality from puerperal infection is uncommon because of effective antibiotics. Creanga and associates (2017) reported results from the Pregnancy Mortality Surveillance System, which contained 4693 pregnancy-related maternal deaths in the United States from 2006 through 2010. Infection caused 13.6 percent of the deaths and was the second leading etiology. In an analysis of the North Carolina population, Berg and colleagues (2005) reported that 40 percent of infection-related maternal deaths were preventable.

Puerperal Fever

Several infective and noninfective factors cause *puerperal fever* defined by a temperature of 38.0°C (100.4°F) or higher. Using this conservative definition, Filker and Monif (1979) reported that only approximately 20 percent of women febrile within the first 24 hours after vaginal delivery were subsequently diagnosed with pelvic infection. This value was 70 percent in those undergoing cesarean delivery. *Most persistent fevers after childbirth are caused by genital tract infection.* Of note, spiking fevers ≥39°C within the first 24 hours postpartum may be associated with virulent pelvic infection caused by group A streptococcus (p. 651).

Other sources of puerperal fever include breast engorgement, urinary infections, episiotomy and abdominal incisions, perineal lacerations, and postcesarean respiratory complications. Approximately 15 percent of women who do not breastfeed develop fever from *breast engorgement*. "Breast fever" rarely exceeds 39°C in the first few postpartum days and usually lasts <24 hours. The incidence of fever is lower in breastfeeding women (Chap. 36, p. 642). Postpartum *urinary infections* are

uncommon because of the normal diuresis. *Acute pyelonephritis* has a variable clinical picture. The first sign of renal infection may be fever, followed later by costovertebral angle tenderness, nausea, and vomiting. *Atelectasis* following general anesthesia for cesarean delivery is caused by hypoventilation and is best prevented by coughing and deep breathing on a fixed schedule following surgery. Fever with atelectasis is due to infection triggered by proliferation of normal flora distal to obstructing mucus plugs.

Uterine Infection

Postpartum uterine infection has been called *endometritis*, *endomyometritis*, and *endoparametritis.* Following vaginal delivery, infection involves not only the decidua but also the myometrium and parametrial tissues. Infection after cesarean delivery is essentially a surgical site infection involving the incised myometrium. In either case, we prefer the inclusive term *metritis with pelvic cellulitis*.

Predisposing Factors

Route of delivery is the single most significant risk factor for the development of uterine infection (Boggess, 2017; Moulton, 2018). In women undergoing cesarean delivery, rehospitalization rates for wound complications and metritis are higher than those with a vaginal birth (Axelsson, 2018; Fein, 2019). In the French Confidential Enquiry on Maternal Deaths, Deneux-Tharaux and coworkers (2006) cited a nearly 25-fold greater infection-related mortality rate with cesarean delivery.

With vaginal delivery, women delivered at Parkland Hospital have a 1- to 2-percent incidence of metritis. This rate rises to 5 to 6 percent in those with ruptured membranes, prolonged labor, and multiple cervical examinations. If intrapartum chorioamnionitis is present, the risk of persistent uterine infection has exceeded 13 percent (DeNoble, 2019; Maberry, 1991). These figures are similar to those reported by the Maternal Fetal Medicine Units Network from a cohort of more than 115,000 women in whom the overall pelvic infection rate approximated 5 percent (Grobman, 2015).

With operative vaginal delivery, women carry higher risks for metritis and perineal infections than spontaneous birth (Mohamed-Ahmed, 2019). Notably, these deliveries are often implemented in the context of prolonged labor, which is a known metritis risk. One study of 3500 such women showed that those receiving a single dose of prophylactic antibiotics had a lower maternal infection rate (Knight, 2019). Infections include those of the urinary tract, uterus, or perineal wound. Labor lengths were not presented, but in approximately 50 percent of participants, "failure to progress" was the operative vaginal delivery indication. Moreover, 10 percent of women had rupture of membranes lengths between 24 and 48 hours. The contribution of these, rather than the delivery mode, will require further investigation before this prophylaxis is widely adopted solely for the indication of operative vaginal delivery.

With cesarean delivery, hysterotomy is associated with significant infectious morbidity. In the 1970s, pelvic infection complicated 50 percent of cesarean deliveries at Parkland Hospital. Fortunately, antimicrobial prophylaxis has done more to decrease the incidence and severity of postcesarean infections than any other intervention in the past 30 years. Thus, a single dose of perioperative antibiotics is recommended for all women undergoing cesarean delivery (American College of Obstetricians and Gynecologists, 2018b). Such practices lower the puerperal pelvic infection risk by 65 to 75 percent (Smaill, 2014). β-lactam antimicrobials are superior to other agents, and elements of this prophylaxis are outlined in Chapter 30 (p. 551) (Harris, 2019). Important risk factors for infection following surgery include prolonged labor, membrane rupture, multiple cervical examinations, and internal fetal monitoring.

Regardless of delivery route, pelvic infection generally is more frequent in women of lower socioeconomic status (Maharaj, 2007). Except in extreme cases usually not seen in developed countries, it is uncommon that anemia or poor nutrition predispose to infection. *Bacterial colonization* of the lower genital tract with certain microorganisms—for example, group B streptococcus, *Chlamydia trachomatis*, *Mycoplasma hominis*, *Ureaplasma urealyticum*, and *Gardnerella vaginalis*—has been associated with an increased postpartum infection risk (Andrews, 1995; Jacobsson, 2002; Watts, 1990). Other factors associated with a greater risk include general anesthesia, significant hysterotomy extension, young maternal age, nulliparity, prolonged labor induction, chorioamnionitis, obesity, and meconium-stained amnionic fluid (Acosta, 2012; Leth, 2011; Patel, 2019; Siriwachirachai, 2014).

Microbiology

Common Pathogens. Most pelvic infections are caused by bacteria indigenous to the genital tract and listed in Table 37-1. Most of these infections are polymicrobial, which enhances bacterial synergy. Other factors that promote virulence are hematomas and devitalized tissue. Although the cervix and vagina routinely harbor bacteria, the uterine cavity is usually sterile before rupture of the amnionic sac. As the consequence of labor and delivery and associated manipulations, anaerobic and aerobic bacteria contaminate the amnionic fluid and uterus.

TABLE 37-1. Bacteria Commonly Responsible for Female Genital Infections

Aerobes

Gram-positive cocci: group A, B, and D streptococci, enterococcus, *Staphylococcus aureus*, *Staphylococcus epidermidis*

Gram-negative bacteria: *Escherichia coli*, *Klebsiella*, *Proteus* spp.

Gram-variable—*Gardnerella vaginalis*

Others

Mycoplasma spp., *Chlamydia trachomatis*, *Neisseria gonorrhoeae*

Anaerobes

Cocci: *Peptostreptococcus*, *Peptococcus* spp.

Others: *Clostridium*, *Bacteroides*, *Fusobacterium*, *Mobiluncus* spp.

Prior to the routine use of antimicrobial prophylaxis, Gilstrap and Cunningham (1979) cultured amnionic fluid obtained at cesarean delivery from women in labor with membranes ruptured more than 6 hours. All had bacterial growth, and an average of 2.5 organisms was identified from each specimen. Anaerobic and aerobic organisms were found in 63 percent, anaerobes alone in 30 percent, and aerobes alone in only 7 percent. Anaerobes included *Peptostreptococcus* and *Peptococcus* species in 45 percent, *Bacteroides* species in 9 percent, and *Clostridium* species in 3 percent. Clostridial species rarely cause puerperal infections, but infections can be severe in those cases (Herrera, 2016). Aerobes included *Enterococcus* in 14 percent, group B *Streptococcus* in 8 percent, and *Escherichia coli* in 9 percent of isolates. Sherman and associates (1999) later showed that bacterial isolates at cesarean delivery correlated with those taken from women with metritis at 3 days postpartum. Group B streptococci, *E coli*, and enterococci are some of the more common blood culture isolates with metritis (Cape, 2013; O'Higgins, 2014). In the past 15 years, skin and soft-tissue infections due to methicillin-resistant *Staphylococcus aureus* (*MRSA*) have become prevalent (Chap. 67, p. 1196). However, *MRSA* is more commonly implicated in abdominal and perineal incisional infections and less often in puerperal metritis (Anderson, 2007; Patel, 2007).

Group A β-hemolytic streptococcal infections have a reported incidence of 1 in 1220 births (Rottenstreich, 2019). During the past 25 years, group A streptococcus has been reported to cause a toxic shock–like syndrome and life-threatening infection (Donders, 2021; Gustafson, 2017; Shinar, 2016). In reviews by Crum (2002) and Udagawa (1999), group A streptococcal infections manifested before, during, or within 12 hours of delivery. Affected women had a maternal mortality rate of almost 90 percent, and the fetal mortality rate exceeded 50 percent.

The role of other organisms in the etiology of these infections is unclear. Observations of Chaim and coworkers (2003) suggest that heavy cervical colonization of *U urealyticum* may contribute to metritis development. To counter this potential pathogen, azithromycin-based extended-spectrum antibiotic prophylaxis reduces postoperative cesarean delivery infections from 12 to 6 percent compared with β-lactam agents alone (Harper, 2017; Tita, 2016). Chlamydial infections have been implicated in late-onset, indolent metritis (Ismail, 1985). Last, Jacobsson and colleagues (2002) reported a threefold higher risk of puerperal infection in a group of Swedish women in whom bacterial vaginosis was identified in early pregnancy (Chap. 68, p. 1216).

Bacterial Cultures. Routine genital tract cultures obtained before treatment serve little clinical use and add significant costs. Women with a temperature >102°F are more likely to have bacteremia (Easter, 2017). Even so, routine blood cultures seldom modify care. In two studies done before perioperative prophylaxis was used, blood cultures were positive in 13 percent of women with postcesarean metritis at Parkland Hospital and in 24 percent of those at Los Angeles County Hospital (Cunningham, 1978; DiZerega, 1979). In a later Finnish study, bacteremia was identified in only 5 percent of women with puerperal sepsis (Kankuri, 2003). Exceptions might be women with exceedingly high temperature spikes that may signify virulent infection with group A streptococci (Chap. 50, p. 890).

Pathogenesis and Clinical Course

Puerperal infection following vaginal delivery primarily involves the placental implantation site, decidua and adjacent myometrium, or cervicovaginal lacerations. The pathogenesis of uterine infection following cesarean delivery is that of an infected surgical incision. Bacteria that colonize the cervix and vagina gain access to the uterus during labor. Postpartum, they invade devitalized uterine tissue. Parametrial cellulitis follows with infection of the pelvic retroperitoneal fibroareolar connective tissue. With early treatment, infection is contained within the parametrial and paravaginal tissue, but it may extend deep into the pelvis.

Fever is the most important criterion for the diagnosis of postpartum metritis. Intuitively, the degree of fever is believed proportional to the extent of infection and sepsis. Temperatures usually are 38 to 39°C, and temperatures >39°C suggest bacteremia or endotoxemia (Easter, 2017; Suffredini, 1989). Women usually complain of abdominal pain, and parametrial tenderness is elicited on abdominal and bimanual examination. Leukocytosis may range from 15,000 to 30,000 cells/μL, but recall that cesarean delivery itself raises the leukocyte count. Although an offensive odor can develop, many women have foul-smelling lochia without evidence for infection, and vice versa. Some other infections, notably those caused by group A β-hemolytic streptococci, may be associated with scant, odorless lochia (Anderson, 2014).

Treatment

If metritis develops following vaginal delivery, treatment with an oral or intramuscular antimicrobial agent may be sufficient (Meaney-Delman, 2015). For moderate to severe infections, however, intravenous therapy with a broad-spectrum antibiotic regimen is indicated. Improvement occurs in 48 to 72 hours in nearly 90 percent of women treated with one of several regimens discussed below. Persistent fever after this interval mandates a careful search for causes of refractory pelvic infection. These include a parametrial phlegmon—an area of intense cellulitis; an abdominal incisional or pelvic abscess or infected hematoma; and septic pelvic thrombophlebitis. In our experience, persistent fever is seldom due to antimicrobial-resistant bacteria or due to drug side effects. The woman may be discharged home after she has been afebrile for at least 24 hours, and further oral antimicrobial therapy is not needed (Mackeen, 2015).

Choice of Antimicrobials. Therapy is empirical and initial treatment is directed against the mixed flora shown in Table 37-1. For infections following vaginal delivery, as many as 90 percent of women respond to regimens such as ampicillin plus gentamicin. In contrast, anaerobic coverage is included for infections following cesarean delivery (Table 37-2).

In 1979, DiZerega and coworkers compared the effectiveness of clindamycin plus gentamicin with that of penicillin G plus gentamicin for treatment of pelvic infections following cesarean delivery. Women given the clindamycin-gentamicin regimen had a 95-percent response rate, and this regimen is still considered by most to be the standard by which others are measured (Mackeen, 2015). Despite this standard therapy, enterococcal cultures may be persistently positive. The addition

TABLE 37-2. Antimicrobial Regimens for Pelvic Infections Following Cesarean Delivery

Regimen	Comments
Clindamycin + gentamicin	"Gold standard," 90–97% efficacy, once-daily gentamicin dosing acceptable ***Plus*** Ampicillin added to regimen with sepsis or suspected enterococcal infection
Clindamycin + aztreonam	Gentamicin substitute for renal insufficiency
Extended-spectrum penicillins	Piperacillin, piperacillin/tazobactam, ampicillin/sulbactam, ticarcillin/clavulanate
Cephalosporins	Cefotetan, cefoxitin, cefotaxime, ceftriaxone
Vancomycin	Added to other regimens for suspected *Staphylococcus aureus* infections
Metronidazole + ampicillin + gentamicin	Metronidazole has excellent anaerobic coverage
Carbapenems	Imipenem/cilastatin, meropenem, ertapenem; all reserved for special indications

of ampicillin, either initially or following no response after 48 to 72 hours, targets enterococci (Brumfield, 2000).

Many authorities recommend periodical monitoring of serum gentamicin levels. At Parkland Hospital, we do not routinely do so if a woman has adequate renal function, which is evidenced by a normal serum creatinine level. Once-daily dosing versus multiple dosing with gentamicin provides adequate serum levels, and either method has similar cure rates (Livingston, 2003). In the event of diminished glomerular filtration, some recommend a combination of clindamycin and a second-generation cephalosporin, because of potential nephrotoxicity and ototoxicity with gentamicin. Instead, others recommend a combination of clindamycin and aztreonam—the latter is a monobactam compound with activity similar to the aminoglycosides.

The spectra of *β-lactam antimicrobials* include activity against many anaerobic pathogens. Some examples include cephalosporins such as cefoxitin, cefotetan, cefotaxime, and ceftriaxone. Extended-spectrum penicillins are piperacillin, ticarcillin, and mezlocillin. β-lactam antimicrobials are inherently safe and, except for allergic reactions, are free of major toxicity. The *β-lactamase inhibitors* clavulanic acid, sulbactam, and tazobactam have been combined with ampicillin, amoxicillin, ticarcillin, and piperacillin to extend their spectra. *Metronidazole* has superior in vitro activity against most anaerobes. This agent given with ampicillin and an aminoglycoside provides coverage against most organisms encountered in serious pelvic infections. It is also used second line to treat some cases of *Clostridioides difficile* colitis.

Imipenem and similar antimicrobials are in the carbapenem family. These offer broad-spectrum coverage against most organisms associated with metritis. Imipenem coupled with *cilastatin* inhibits the antibiotic's renal metabolism. Because of imipenem's higher cost, it is reasonable from both a medical and an economic standpoint to reserve this drug for serious nonobstetrical infections.

Vancomycin is a glycopeptide antimicrobial active against gram-positive bacteria. It is used in lieu of β-lactam therapy for a patient with a type 1 allergic reaction and given for suspected infections due to *S aureus* and to treat *C difficile* colitis (Chap. 57, p. 1019).

Perioperative Prophylaxis

The use of periprocedural techniques for infection prevention is common in obstetrics (Table 37-3). Numerous studies show that prophylactic antibiotics at the time of cesarean delivery reduce wound and postpartum pelvic infection rates (Carter, 2017; Smaill, 2014). The observed benefit applies to both elective and nonelective cesarean delivery. As noted from preliminary data, antimicrobials may decrease pelvic infection rates after operative vaginal delivery (p. 650). However, data are insufficient to suggest prophylactic antimicrobials lower infection rates after spontaneous vaginal delivery, repair of all episiotomies, or manual extraction of the placenta (Bonet 2017a,b; Chongsomchai, 2014). The American College of Obstetricians and Gynecologists (2018a) concluded that a single antibiotic dose with third- and fourth-degree perineal laceration is reasonable and has evidenced-based support.

Single-dose prophylaxis with a 2-g dose of a first-generation cephalosporin is ideal. This regimen has similar efficacy of broad-spectrum agents or multiple-dose regimens (American College of Obstetricians and Gynecologists, 2018b). For obese women, evidence supports a 3-g dose of cefazolin to reach optimal tissue concentrations (Swank, 2015). Some evidence supports addition of azithromycin to lower postcesarean uterine infection rates (Markwei, 2021; Pierce, 2021; Tita, 2016). Women colonized with *MRSA* are given vancomycin

TABLE 37-3. Various Prophylactic Methods for Decreasing Pelvic and Wound Infection Rates Following Delivery

Route	Method	Study Results
Routine delivery	Peripartum antimicrobials	Limited evidence, may reduce risk (Bonet, 2017a)
Episiotomy	Perioperative prophylaxis	Insufficient evidence (Bonet, 2017b)
Operative vaginal delivery	Peripartum antimicrobials	Limited evidence, may reduce risk (Knight, 2019)
Cesarean delivery	Perioperative antimicrobial prophylaxis	Decreased 70–80% (Carter, 2017; Smaill, 2014)
Cesarean delivery	Skin preparation	Decreased incidence (Hadiati, 2018)

in addition to a cephalosporin (Chap. 67, p. 1196). It is controversial whether the infection rate is reduced further if the antimicrobial is given before the skin incision compared with after umbilical cord clamping (Baaqeel, 2013; Macones, 2012; Sun, 2013; Ward, 2016). The American College of Obstetricians and Gynecologists (2018b) has concluded that the evidence favors predelivery administration.

Most women with a stated allergy to penicillin are not prone to developing anaphylaxis. Without a history of anaphylaxis, most of these women can safely be given a cephalosporin (Chap. 30, p. 551). If not, then vancomycin is given along with clindamycin and gentamicin (American College of Obstetricians and Gynecologists, 2018b).

Preoperative abdominal skin preparation decreases the risk for pelvic and wound infections (Hadiati, 2018). Skin preparation with chlorhexidine-alcohol is superior to iodine-alcohol for preventing surgical-site infections (Tuuli, 2016). Additive beneficial effects may be gained by preoperative vaginal cleansing with povidone-iodine rinse or application of metronidazole gel (Caissutti, 2017; Felder, 2019; Haas, 2018).

Other Methods of Prophylaxis. Several studies have addressed the value of prenatal cervicovaginal cultures. These are obtained in the hope of identifying pathogens that might be eradicated to lower incidences of preterm labor, chorioamnionitis, and puerperal infections. Unfortunately, treatment of asymptomatic vaginal infections does not prevent these complications. For asymptomatic bacterial vaginosis, Carey and associates (2000) reported no beneficial effects for women treated. For asymptomatic *Trichomonas vaginalis* infection, a similar postpartum infection rate was found in women treated in the second trimester compared with placebo-treated women (Klebanoff, 2001).

Technical maneuvers done to alter the postcesarean infection rate have been studied (Chap. 30, p. 551). Allowing the placenta to separate spontaneously and exteriorizing the uterus to close the hysterotomy may reduce the infection risk (Jacobs-Jokhan, 2004; Lasley, 1997). However, changing gloves after placental delivery, cleaning the intrauterine cavity, and dilating the lower segment and cervix do not alter the infection rate (Atkinson, 1996; Eke, 2019; Liabsuetrakul, 2018). No differences were found in postoperative infection rates when single- and two-layer uterine closures were compared (Hauth, 1992). Similarly, infection rates are not affected by closure versus nonclosure of the peritoneum (Bamigboye, 2014; Tulandi, 2003). Importantly, closure of subcutaneous tissue in obese women does not lower the wound infection rate, but it does decrease the wound separation incidence (Chelmow, 2004). Similarly, skin closure with staples versus suture has a greater incidence of noninfectious skin separation (Mackeen, 2012; Tuuli, 2011).

Complications of Uterine and Pelvic Infections

Metritis responds to antimicrobial treatment within 48 to 72 hours in more than 90 percent of women. In some of the remainder, any of several complications may arise. These include wound infection, complex pelvic infection such as a phlegmon or an abscess, and septic pelvic thrombophlebitis (Brown, 1999; Jaiyeoba, 2012). As with other aspects of puerperal infections, the incidence and severity of these complications are reduced by perioperative antimicrobial prophylaxis.

Abdominal Incisional Infections

Wound infection is a common cause of persistent fever in women treated for metritis. Incisional infection risk factors include obesity, diabetes, corticosteroid therapy, immunosuppression, anemia, hypertension, and hematoma formation from inadequate hemostasis. If prophylactic antimicrobials are given, the incidence of wound infection following cesarean delivery ranges from 2 to 10 percent depending on risk factors (Andrews, 2003; Chaim, 2000). From our experiences at Parkland Hospital, the incidence is closer to 2 percent, but this risk rises with increasing body mass (Hussamy, 2018).

Incisional abscesses that develop following cesarean delivery usually cause persistent fever or fever that begins on approximately the fourth day. The wound is erythematous and drains pus. Organisms that cause wound infections are generally the same as those isolated from amnionic fluid at cesarean delivery, however, hospital-acquired pathogens also may be causative.

Treatment includes antimicrobials and surgical drainage and debridement of devitalized tissue. This typically requires spinal analgesia or general anesthesia. The fascia is carefully inspected to document integrity. Local wound care thereafter is completed twice daily. Before each dressing change, procedural analgesia is tailored to wound size and location, and oral, intramuscular, or intravenous dosage routes are suitable. Topical lidocaine also may be added. Necrotic tissue is removed, and the wound is repacked with moist gauze. At 4 to 6 days, healthy granulation tissue is typically present, and secondary en bloc closure of the open layers can usually be accomplished (Wechter, 2005). As shown in Figure 37-1, a polypropylene or

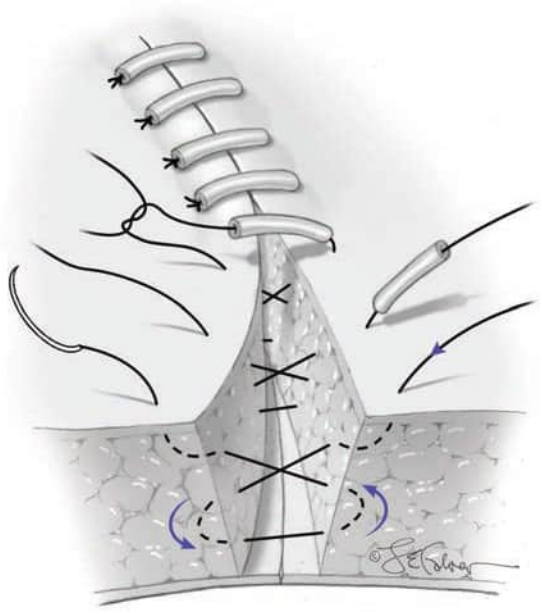

FIGURE 37-1 Secondary abdominal wound closure technique. (Reproduced with permission from Worley KC: Postoperative complications. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al [eds]: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017).

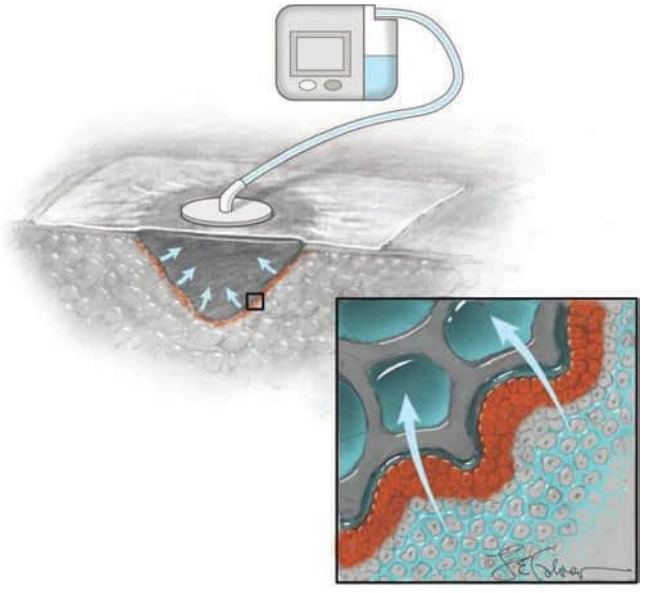

FIGURE 37-2 Theoretical effects of negative-pressure wound therapy include macro- and microdeformation, removal of tissue fluid, and creation of a warm and moist environment. As shown in the inset, tissue fluid is drawn out by suction tubing. It travels through the porous sponge dressing that fills the wound and into an adjacent collection canister. As healing progresses, a layer of granulation tissue (*red*) forms at the wound-sponge interface. (Reproduced with permission from Cunningham FG: Surgical instruments. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al [eds]: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

nylon suture of appropriate gauge enters 2 to 3 cm from one wound edge. It crosses the wound to incorporate the full wound thickness and emerges 3 cm from the other wound edge. These are placed in series to close the opening. In most cases, sutures may be removed on postprocedural day 10.

Vacuum-Assisted Wound Closure

This system promotes healing by applying negative pressure to the wound (Fig. 37-2). The technique is variably referred to as *vacuum-assisted closure (VAC), topical negative pressure (TNP)*, and *negative-pressure wound therapy (NPWT)*. Negative-pressure systems are used for open wounds after infection or for prophylaxis against wound disruption. Mouës and colleagues (2011) confirmed that NPWT enhances blood flow to the wound, promotes angiogenesis, induces cellular proliferation, and shrinks wound size. Several systems are available and widely accepted, despite meager formal evidence for clinical efficacy.

Open abdominal wounds once infection has cleared or an "open surgical abdomen" is a major indication for NPWT. Vacuum therapy is the most efficient method of temporary abdominal closure for patients with open abdominal wounds (Bruhin, 2014; Quyn, 2012). However, no trials have compared vacuum-assisted wound closure with conventional wound care after cesarean delivery. Also, these devices are used for closure of perineal wounds resulting from infected episiotomies, hematomas, or abscesses (Aviki, 2015). Very few randomized trials have compared vacuum-assisted wound closure with conventional wound care (Kawakita, 2021; Yu, 2018).

Prophylaxis. Negative-pressure devices are also marketed to prevent wound infections in incisions closed to heal by primary intention. Such prophylactic use in 441 obese women undergoing cesarean delivery has been evaluated in two large randomized trials. Hussamy and associates (2019) found in obese women that the incidence of wound morbidity was similar in the standard dressing group compared with the NPWT group (Table 37-4). The second trial was a multicenter study from Denmark of 876 obese women (Hyldig, 2019). In the NPWT group, the surgical site infection rate was 4.6 percent compared with 9.2 percent in the group of women treated with standard dressing. Similarly, a systematic review found use of prophylactic NPWT reduced wound complications (Yu, 2018). The cost effectiveness of these systems is inconclusive in multiple studies (Echebiri, 2015; Lewis, 2014). Smid and coworkers (2017) questioned the effectiveness of such therapy. Because of these uncertainties, we agree with Tuuli (2019) that routine use of prophylactic NPWT needs more evaluation before its widespread acceptance.

Fascial Dehiscence

This separation of the fascial layer is a serious complication, and bowel evisceration can be comorbid. Wound infection and obesity are prominent risk factors (Poole, 1985; Subramaniam, 2014). For example, McNeeley and associates (1998) reported a fascial dehiscence rate of approximately 1 per 300 operations in almost 9000 women undergoing cesarean delivery. Two thirds of the 27 fascial dehiscences in this study were associated with concurrent fascial infection and tissue necrosis.

Fascial dehiscence generally presents within the first 7 to 10 postoperative days. Superficial disruption of the subcutaneous layer and extensive leakage of peritoneal fluid or purulent drainage are indicative. In unclear cases, CT scanning may be elected preoperatively, if obtained expeditiously.

Dehiscence is a surgical emergency. If abdominal contents have eviscerated, sterile towels or gauze soaked in saline can be used early to cover and gently replace bowel or omentum. Broad-spectrum antibiotics are generally recommended to minimize ensuing peritonitis.

Given the high mortality risk associated with fascial dehiscence and bowel evisceration, examination under anesthesia to estimate the extent of separation is often warranted. Surgery aims to assess bowel health, debride necrotic wound tissue, and close the fascia, if possible. For closure, an interrupted mass closure using a no. 2 permanent suture is recommended typically (Fig. 37-3). In cases with infection, the subcutaneous layers are left to close secondarily. General surgery consultation is considered if bowel ischemia or difficult fascial closure is anticipated.

■ Necrotizing Fasciitis

This uncommon severe wound infection is associated with high mortality rates. In obstetrics, necrotizing fasciitis may involve abdominal incisions, or it may complicate episiotomy or other perineal lacerations. As the name implies, tissue necrosis is significant. Of the risk factors for fasciitis summarized by Owen and Andrews (1994), diabetes, obesity, and hypertension are increasingly common in gravidas. Like pelvic infections, this wound complication usually is polymicrobial and caused by

TABLE 37-4. Randomized Trial of Prophylactic Incisional Negative-Pressure Wound Therapy (iNPWT) Versus Standard Surgical Dressing for Morbidly Obese Women Undergoing Cesarean Delivery

Factor	iNPWT (N = 222)	Standard (N = 219)	Significance
BMI at delivery	46.6 ± 6.0	45.8 ± 5.8	NS
Cesarean delivery			
Primary	43%	37%	$p = 0.18$
Secondary	57%	63%	$p = 0.18$
Scheduled	32%	33%	$p = 0.99$
Unscheduled	68%	67%	$p = 0.99$

Incision			
Depth	5.5 ± 1.7	5.3 ± 1.8	$p = 0.19$
Length	14.5 ± 2.5	14.6 ± 2.9	$p = 0.74$
Wound morbidity			
Cellulitis	32%	38%	RR = 0.7 (95% CI, 0.3 – 1.7)
Superficial SSI	54%	61%	RR = 0.8 (95% CI, 0.4 – 1.5)
Dehiscence	11%	2%	RR = 3.9 (95% CI, 0.4 – 194)
Composite outcome	17%	19%	RR = 0.9 (95% CI, 0.5 – 1.4)
Readmission	5%	4%	RR = 1.3 (95% CI, 0.5 – 3.5)
Reoperation	6%	5%	RR = 1.4 (95% CI, 0.6 – 3.5)

BMI = body mass index; CI, confidence interval; NS = not significant; RR = relative risk; SSI = surgical site infection.
Data from Hussamy, 2018, 2019.

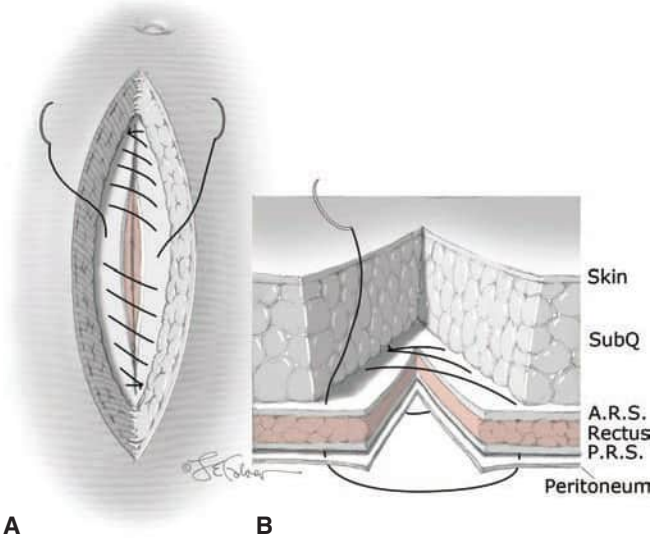

FIGURE 37-3 Mass closure: each stitch is placed 1.5 to 2 cm from the wound edge **(A)** and incorporates the peritoneum, rectus muscle, and rectus sheath **(B)**. Stitches are spaced 1 cm apart along the length of the incision. A.R.S. = anterior rectus sheath; P.R.S. = posterior rectus sheath; SubQ = subcutaneous layer. (Reproduced with permission from Cundiff GW: Incisions and closures. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al [eds]: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

organisms that make up the normal vaginal flora. In some cases, however, infection is caused by a single virulent bacterial species such as group A β-hemolytic streptococcus (Anderson, 2014; Rimawi, 2012). Occasionally, rarely encountered pathogens cause necrotizing infections (Chong, 2016; Swartz, 2004).

Goepfert and coworkers (1997) described nine cases of necrotizing fasciitis in more than 5000 cesarean deliveries. The infection was fatal in two women—one with metastatic breast cancer and the other with sepsis. In another report, Schorge and colleagues (1998) described five women with fasciitis following cesarean delivery. None of these women had predisposing risk factors, and none died.

Infection may involve skin, superficial and deep subcutaneous tissues, and any of the abdominopelvic fascial layers. In some cases, muscle also is involved—*myofasciitis*. Most of these necrotizing infections do not cause symptoms until 3 to 5 days after delivery. Some virulent infections develop earlier. Clinical findings vary, and it is frequently difficult to differentiate more innocuous superficial wound infections from a deep fascial one. If myofasciitis progresses, the woman may become ill from septicemia. A high index of suspicion, with surgical exploration if the diagnosis is uncertain, may be lifesaving (Goh, 2014). We aggressively pursue early exploration (Chap. 50, p. 890).

Successful treatment of necrotizing soft-tissue infections involves early diagnosis, source control by surgical

debridement, antimicrobials, and intensive care (Gallup, 2002; Goh, 2014; Society for Maternal-Fetal Medicine, 2019). Surgery includes thorough debridement of all infected tissue, leaving wide margins of healthy bleeding tissue. This may include extensive abdominal or vulvar debridement and excision of abdominal, thigh, or buttock fascia. Death is virtually universal without surgical treatment, and rates approach 50 percent even if exhaustive debridement is performed (Johnson, 2020). With substantial resection, synthetic mesh may ultimately be required later to close the fascial incision once infection is cleared (Gallup, 2002; McNeeley, 1998).

■ Peritonitis and Adnexal Abscesses

Following cesarean delivery, peritonitis is infrequent. It almost always is preceded by metritis, especially cases with uterine incisional necrosis and dehiscence. However, it may stem from a ruptured adnexal abscess or an inadvertent intraoperative bowel injury. Perforative appendicitis also can cause peritonitis (Chap. 57, p. 1024). In these cases, prompt surgical treatment is usually indicated.

After vaginal delivery, peritonitis is rarely encountered, and many such cases are due to virulent strains of group A β-hemolytic streptococci or similar organisms. Importantly, abdominal rigidity may not be prominent with puerperal peritonitis because of physiological abdominal wall laxity from pregnancy. Pain may be severe, but frequently, the first symptoms of peritonitis are those of *adynamic ileus.* Marked bowel distention may develop, which is unusual after vaginal birth. Normally, if the infection begins in an intact uterus and extends into the peritoneum, antimicrobial treatment alone suffices.

An *ovarian abscess* rarely develops in the puerperium. These are presumably caused by bacterial invasion through an opening in the ovarian capsule (Wetchler, 1985). The abscess is usually unilateral, and women typically present 1 to 2 weeks after delivery. Rupture is common, and peritonitis may be severe.

■ Parametrial Phlegmon

For some women in whom metritis develops following cesarean delivery, parametrial cellulitis is intense and forms an area of induration—a *phlegmon*—within the leaves of the broad ligament (Fig. 37-4). These infections are considered when fever persists longer than 72 hours despite intravenous antimicrobial therapy (Brown, 1999; DePalma, 1982).

Phlegmons are usually unilateral, and they frequently are limited to the parametrium at the base of the broad ligament. If the inflammatory reaction is more intense, cellulitis extends along natural lines of cleavage. The most common form of extension is laterally along the broad ligament, with a tendency to extend to the pelvic sidewall. Occasionally, posterior extension may involve the rectovaginal septum, producing a firm mass posterior to the cervix. In most women, clinical improvement follows continued treatment with a broad-spectrum antimicrobial regimen. Typically, fever resolves in 5 to 7 days.

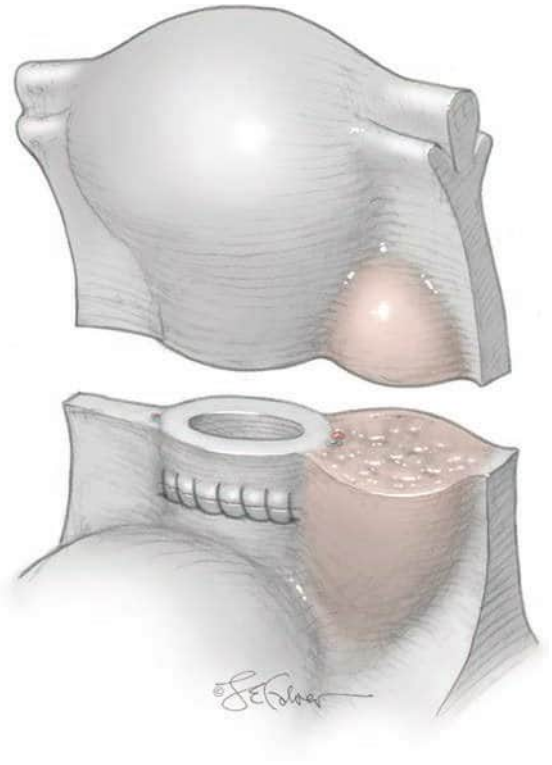

FIGURE 37-4 Left-sided parametrial phlegmon: cellulitis causes induration in the parametrium adjacent to the hysterotomy incision. (Reproduced with permission from Worley KC: Postoperative complications. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al [eds]: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017).

Severe cellulitis of the uterine incision may ultimately lead to necrosis and separation (Treszezamsky, 2011). Extrusion of purulent material causes intraabdominal abscess formation and peritonitis as described above. Surgery is reserved for women in whom uterine incisional necrosis is suspected. For most, hysterectomy and surgical debridement are needed. These cases are difficult because the cervix and lower uterine segment are involved with an intense inflammatory process that extends to the pelvic sidewall. The adnexa are seldom involved, and one or both ovaries can usually be conserved. Blood loss is often appreciable, and transfusion is common.

Imaging Studies

Persistent puerperal infections can be evaluated using computed tomography (CT) or magnetic resonance (MR) imaging (Wang, 2020). Brown and associates (1991) used CT imaging in women in whom pelvic infection was refractory to antimicrobial therapy given for 5 days. They found at least one abnormal radiological finding in 75 percent of these women, and most were nonsurgical lesions. Fishel Bartal and colleagues (2018) reported abnormal CT findings in almost 60 percent of women with refractory fever persisting >3 days. Pelvic fluid collections were seen in 22 percent, and surgical intervention was prompted in 8 percent. Thus, imaging can be used to dissuade surgical exploration in most cases.

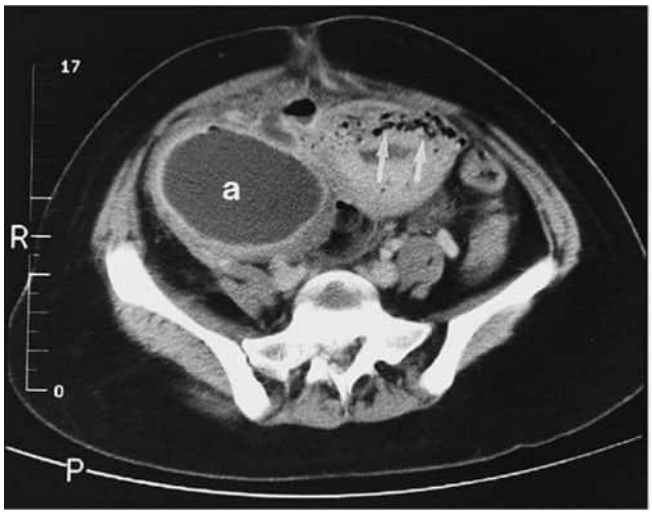

FIGURE 37-5 Pelvic computed tomography scan showing necrosis of the uterine incision with gas in the myometrium (*arrows*). A large abscess (*a*) fills the right parametrium.

Uterine incisional dehiscence such as shown in Figure 37-5 can sometimes be confirmed based on CT images. These findings must be interpreted within the clinical context because apparent uterine incisional defects thought to represent edema can be seen even after uncomplicated cesarean delivery. Shown in Figure 37-6 is a necrotic hysterotomy incision, which had leaked into the peritoneal cavity.

Occasionally, a parametrial phlegmon may suppurate, forming a fluctuant broad ligament abscess that may point above the inguinal ligament. These abscesses can dissect anteriorly and be amenable to CT-directed needle drainage. A *psoas abscess* is rare, and despite antimicrobial therapy, percutaneous drainage may be required to effectively treat it (Shahabi, 2002; Swanson, 2008). If a phlegmon involving the rectovaginal septum suppurates, surgical drainage is easily effected by colpotomy. Absorption of the induration may require several days to weeks.

FIGURE 37-6 Necrotic hysterotomy infection. Severe cellulitis of the uterine incision resulted in dehiscence with subsequent leakage into the peritoneal cavity. Hysterectomy was required for sufficient debridement of necrotic tissue. (Reproduced with permission from Dr. Denisse Holcomb.)

Septic Pelvic Thrombophlebitis

Suppurative thrombophlebitis was a frequent complication in the preantibiotic era, and septic embolization was common. However, with the advent of antimicrobial therapy, the mortality rate and need for surgical therapy for these infections diminished. Septic phlebitis arises as an extension along venous routes and may cause thrombosis. Lymphangitis often coexists. The ovarian veins may then become involved because they drain the upper uterus and therefore the placental implantation site. The experiences of Witlin and Sibai (1995) and Brown and coworkers (1999) suggest that puerperal septic thrombophlebitis is likely to involve one or both ovarian venous plexuses. In a fourth of women, the clot extends into the inferior vena cava and occasionally to the renal vein.

The incidence of septic phlebitis varies in several reports. In a 5-year survey of 45,000 women who were delivered at Parkland Hospital, Brown and workers (1999) found an incidence of 1 case per 9000 vaginal births and 1 per 800 cesarean deliveries. In a cohort of 16,650 women undergoing primary cesarean delivery, Rouse and coworkers (2004) reported an incidence of 1 case per 400 surgeries. Incidences approximated 1 per 175 cesarean deliveries if chorioamnionitis was antecedent, but only 1 per 500 if there was no intrapartum infection.

Except for chills and occasional lower quadrant pain, women with septic thrombophlebitis usually lack symptoms (Wouterlood, 2021). The diagnosis can be confirmed by pelvic CT or MR imaging (Fig. 37-7). Using either, Brown and coworkers (1999) found that 20 percent of 69 women with persistent fever following >5 days of antimicrobial therapy for metritis had septic pelvic thrombophlebitis. In a later study, Fischel Bartal and associates (2018) reported that 6 percent of women with refractory fever ≥3 days had septic phlebitis. These women normally have symptomatic improvement with antimicrobial treatment, however, they continue to have fever.

Treatment with heparin is controversial. In a randomized study of 14 women, the addition of heparin to antimicrobial therapy for septic pelvic thrombophlebitis did not hasten recovery or improve outcome (Brown, 1999). We and others are of the opinion that heparin is unnecessary (Witlin, 1995). Others, however, continue to recommend anticoagulation (Klima, 2008; Lenz, 2017). Certainly, no evidence supports long-term anticoagulation (Brown, 2018).

Perineal Infections

Episiotomy infections are uncommon, because the operation is now performed less frequently (American College of Obstetricians and Gynecologists, 2018a; Dillon, 2019). Reasons for this are discussed in Chapter 27 (p. 510). In an older study, Owen and Hauth (1990) described only 10 episiotomy infections in 20,000 women delivered vaginally. With infection, however, dehiscence is a concern. Ramin and colleagues (1992) reported an episiotomy dehiscence rate of 0.5 percent at Parkland Hospital, and 80 percent of these were infected. Uygur and associates (2004) reported a 1-percent dehiscence rate and attributed two thirds to infection.

When the anal sphincter is disrupted at delivery, the subsequent infection rate is higher and is likely influenced by intrapartum antimicrobial treatment (Buppasiri, 2014; Stock, 2013).

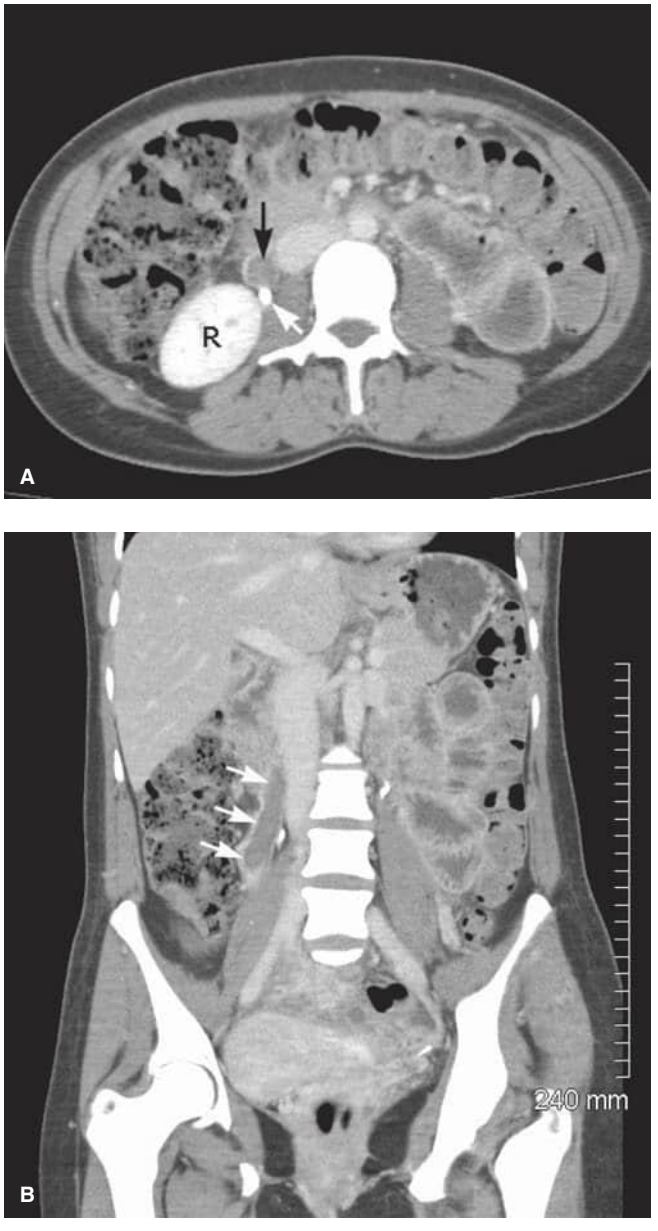

FIGURE 37-7 Septic ovarian vein thrombosis—contrast-enhanced computed tomography scan: **A.** Enlarged right ovarian vein filled with low-density thrombus (*black arrow*). Contrast is seen in ureter (*white arrow*). *R* = lower pole, right kidney. **B.** Coronal image demonstrates enlarged right ovarian vein filled with low-density thrombus (*arrows*). (B: Reproduced with permission from Dr. April Bailey in Worley KC: Postoperative complications. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al [eds]: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

Lewicky-Gaupp and colleagues (2015) reported a 20-percent infection rate when the sphincter was torn. Goldaber and coworkers (1993) described fourth-degree lacerations in 390 parturients, of whom 5.4 percent had morbidity. In these women, 2.8 percent had infection and dehiscence, 1.8 percent had only dehiscence, and 0.8 percent only infection.

Pathogenesis and Clinical Course

As noted, perineal laceration infection may be complicated by dehiscence. Other factors for separation include coagulation disorders, smoking, and human papillomavirus infection (Ramin, 1994). No data suggest that dehiscence is related to faulty repair.

With infection, local pain and dysuria, with or without urinary retention, are frequent symptoms. Ramin and colleagues (1992) reported that the most common findings were pain in 65 percent, purulent discharge in 65 percent, and fever in 44 percent. In extreme cases, the entire vulva may become edematous, ulcerated, and covered with exudate. Although life-threatening, septic shock or necrotizing fasciitis is rare (p. 654).

Vaginal lacerations may also become infected directly or by extension from the perineum. The epithelium becomes red and swollen and may then become necrotic and slough. Parametrial extension can lead to lymphangitis. Cervical lacerations are seldom noticeably infected, but instead may manifest as metritis. Deep lacerations that extend directly into the base of the broad ligament may become infected and cause lymphangitis, parametritis, and bacteremia.

Treatment

Infected episiotomies are managed similar to other infected surgical wounds. In women with obvious cellulitis but no purulence, close observation and broad-spectrum antimicrobial therapy alone may be appropriate. With purulence, drainage is established, and in most cases, sutures are removed and the infected wound debrided. With dehiscence, local wound care is coupled with intravenous antimicrobials. Hauth and associates (1986) were the first to advocate for early episiotomy repair after infection subsided. Hankins and colleagues (1990) described successful early repair in 94 percent of women, and the average duration from dehiscence to repair was 6 days. The two women with failures developed a pinpoint rectovaginal fistula that was treated with a small rectal flap. Other studies have shown similar high rates with early repair (Ramin, 1992; Uygur, 2004).

Before performing early repair, diligent preparation is essential (Table 37-5). The surgical wound must be properly cleaned and cleared of infection. Once the surface of the wound is free

TABLE 37-5. Preoperative Protocol for Early Repair of Episiotomy Dehiscence

Open wound, remove sutures, begin intravenous antimicrobials
Initiate wound care:
Institute sitz bath several times daily or hydrotherapy
Provide adequate analgesia or anesthesia—regional analgesia or general anesthesia may be necessary for initial debridements
Scrub wound twice daily with a povidone-iodine solution
Debride necrotic tissue
Close wound when afebrile and pink, healthy granulation tissue present
Provide enemas prior to fourth-degree repair
Institute postoperative stool softeners; normal diet, nothing per vagina or rectum

of exudate and covered by pink granulation tissue, secondary repair can be accomplished. The tissue must be adequately mobilized, with special attention to identify and mobilize the anal sphincter muscle. A tension-free suture line is essential to avoid repeated dehiscence. Secondary closure of the wound is accomplished in layers, as described for primary episiotomy closure (Chap. 27, p. 510). Postoperative care includes local wound care, stool softeners, and nothing per vagina or rectum until healed. Hard stools risk wound disruption, but liquid stool can seep between sutures to reincite infection. Thus, soft formed stools are the goal.

■ Toxic Shock Syndrome

This acute febrile illness with severe multisystem derangement has a case-fatality rate of 10 to 15 percent. Usual findings are fever, headache, mental confusion, diffuse macular erythematous rash, nausea, vomiting, watery diarrhea, and marked hemoconcentration. Renal failure followed by hepatic failure, disseminated intravascular coagulation, and circulatory collapse may progress in rapid sequence. During recovery, the rash-covered areas desquamate. In early investigations of toxic shock syndrome (TSS), *Staphylococcus aureus* was recovered from almost all afflicted persons. Specifically, a staphylococcal exotoxin, termed *toxic shock syndrome toxin 1 (TSST-1)*, was found to cause the clinical manifestations by provoking profound endothelial injury. A very small amount of TSST-1 can activate T cells to create a "cytokine storm" (Heying, 2007; Que, 2005). Toxic shock syndrome has also been reported with *MRSA* (Deguchi, 2018).

Subsequent investigations have also implicated virulent group A β-hemolytic streptococcal infection (Anderson, 2014; Rottenstreich, 2019; Shinar, 2016). Heavy colonization or infection is complicated in some cases by *streptococcal toxic shock syndrome,* which is produced when pyrogenic exotoxin is elaborated. Serotypes M1 and M3 are particularly virulent (Beres, 2004; Okumura, 2004). Last, almost identical findings of toxic shock have been reported in pregnant women with *Clostridium sordellii* and *novyi* colonization (Herrera, 2016; Robbie, 2000).

Thus, in some cases of toxic shock syndrome, infection is not apparent, and colonization of a mucosal surface is the presumed source (Olp, 2020). At least 10 to 20 percent of pregnant women have vaginal colonization with *S aureus.* And *Clostridium perfringens* and *sordellii* are cultured from 3 to 10 percent of asymptomatic women (Chong, 2016). Thus, it is not surprising that the disease develops in postpartum women when growth of vaginal bacteria is abundant (Chen, 2006; Guerinot, 1982).

Delayed diagnosis and treatment are associated with maternal mortality (Schummer, 2002). Crum and colleagues (2002) described a neonatal death following antenatal toxic shock syndrome. Principal therapy is supportive, while allowing reversal of capillary endothelial injury. Antimicrobial therapy includes coverage against staphylococcal and streptococcal species. With evidence of pelvic infection, antimicrobial therapy must also include agents used for polymicrobial infections. Women with these infections may require wound debridement and possibly hysterectomy. Because the toxin is so potent, the mortality rate is correspondingly high (Hotchkiss, 2003).

BREAST INFECTIONS

Parenchymal infection of the mammary glands is a rare antepartum complication, but the postpartum incidence of mastitis approximates 3 percent (Lee, 2010). No evidence supports use of prophylactic measures to prevent breast infection (Crepinsek, 2012). Risk factors include nursing difficulties, cracked nipples, and oral antibiotic therapy (Branch-Elliman, 2012; Mediano, 2014).

Symptoms of suppurative mastitis seldom appear before the end of the first week postpartum and usually are not seen until the third or fourth week. Infection almost invariably is unilateral, and marked engorgement usually precedes inflammation. Symptoms include chills or actual rigors, which are soon followed by fever and tachycardia. Pain is severe, and the breast(s) becomes hard and red. Approximately 10 percent of women with mastitis develop an abscess. Detection of fluctuation may be difficult, and sonography is usually diagnostic (Fig. 37-8). Although rare, toxic shock syndrome from mastitis caused by *S aureus* has been reported (Demey, 1989; Fujiwara, 2001).

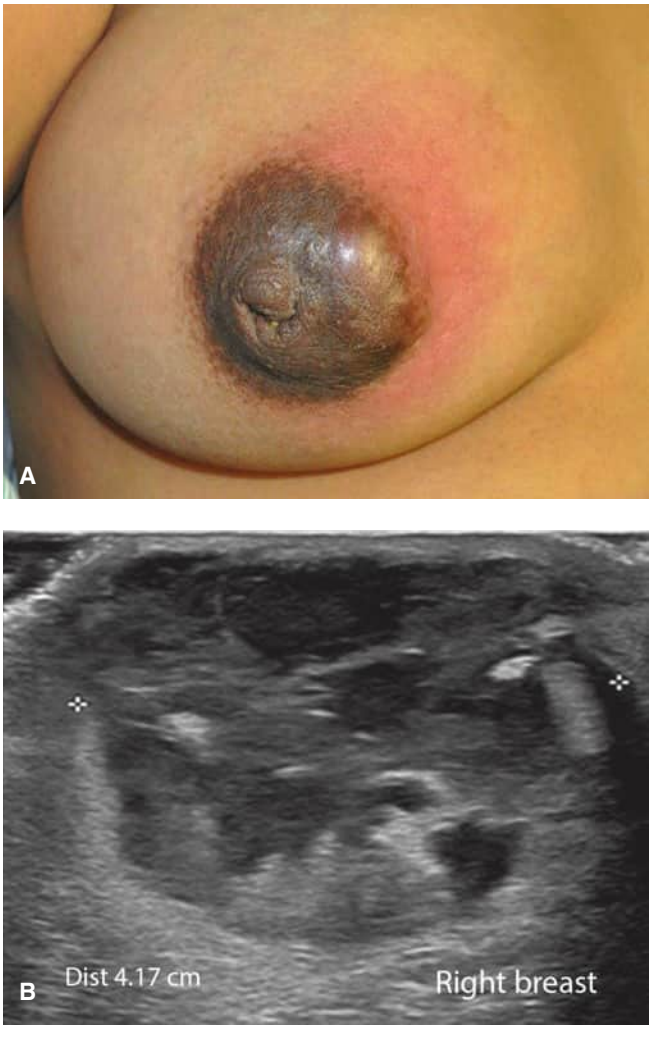

FIGURE 37-8 Puerperal mastitis with breast abscess. **A.** Indurated, erythematous skin overlies the area of right-sided breast infection. **B.** Sonographic picture of this 5-cm abscess.

Etiology

S aureus, especially *MRSA*, is the most commonly isolated organism in breast infections. Matheson and coworkers (1988) found it in 40 percent of women with mastitis. Other commonly isolated organisms are coagulase-negative staphylococci and viridans streptococci. The immediate source of mastitis-causing organisms is almost always the newborn's nose and throat. Bacteria enter the breast through the nipple at fissures or small abrasions. The infecting organism can usually be cultured from milk.

At times, suppurative mastitis reaches epidemic levels among nursing mothers. Such outbreaks most often coincide with the appearance of a new strain of antibiotic-resistant staphylococcus. A contemporaneous example is *MRSA*, which has rapidly become the most commonly isolated staphylococcal species in some areas (Berens, 2010; Klevens, 2007). At Parkland Hospital from 2000 to 2004, Laibl and associates (2005) reported that a fourth of community-acquired *MRSA* isolates were from pregnant or postpartum women with mastitis. Hospital-acquired *MRSA* may cause mastitis when the newborn becomes colonized after contact with nursery personnel who are colonized (Centers for Disease Control and Prevention, 2006). Stafford and colleagues (2008) found a higher incidence of recurrent abscess in those with *MRSA*-associated mastitis.

Management

Provided that appropriate therapy for mastitis is started before suppuration begins, the infection usually resolves within 48 hours. Many recommend that milk be expressed from the affected breast onto a swab and cultured before beginning therapy. Bacterial identification and antimicrobial sensitivities can provide information for a successful program of nosocomial infection surveillance (Lee, 2010).

The most effective treatment has not been clarified (Jahanfar, 2013). Thus, the initial antimicrobial choice is influenced by current experience with staphylococcal infections at a given institution. Dicloxacillin, 500 mg orally four times daily, may be started empirically. Erythromycin is given to women who are penicillin sensitive. If the infection is caused by resistant, penicillinase-producing staphylococcus species or if resistant organisms are suspected while awaiting the culture results, then vancomycin, clindamycin, or trimethoprim-sulfamethoxazole is given (Sheffield, 2013). Although clinical response may be prompt, treatment is recommended for 10 days.

Marshall and coworkers (1975) demonstrated the importance of continued breastfeeding. They reported that of 65 women with mastitis, the only three who developed abscesses were among the 15 women who quit breastfeeding. Vigorous milk expression may be sufficient treatment alone (Thomsen, 1984). Sometimes the infant will not nurse on the inflamed breast. This probably is not related to any changes in the milk taste but is secondary to engorgement and edema, which can make the areola harder to grip. Pumping can alleviate this. When nursing bilaterally, it is best to begin suckling on the uninvolved breast. This allows let-down to commence before moving to the tender breast.

In resource-poor countries, breastfeeding in women infected with the human immunodeficiency virus (HIV) is not contraindicated. However, in the setting of mastitis or breast abscess, it is recommended to stop feeding from the infected breast. This is because HIV RNA levels rise in affected breast milk. These levels return to baseline after symptoms resolve (Semrau, 2013).

Breast Abscess

In a population-based study of nearly 1.5 million Swedish women, the incidence of breast abscess was 0.1 percent (Kvist, 2005). An abscess should be suspected when defervescence does not follow within 48 to 72 hours of treatment or when a mass is palpable. Again, sonographic imaging is valuable. Breast abscesses can be large, and in one case report, 2 L of pus were released (Martic, 2012). Traditional therapy has been surgical drainage, which usually requires general anesthesia. The incision ideally is placed along Langer skin lines for a cosmetic result (Stehman, 1990). In early cases, a single incision over the most dependent portion of fluctuation is usually sufficient. Multiple abscesses require several incisions and disruption of loculations. The resulting cavity is loosely packed with gauze, which should be replaced at the end of 24 hours by a smaller pack.

More recently, sonographically guided needle aspiration using local analgesia has become favored (Patani, 2018). This has an 80- to 90-percent success rate (Geiss, 2014). In a randomized trial, Naeem and colleagues (2012) compared surgical drainage with aspiration. At 8 weeks, they found 93 percent undergoing aspiration were healed compared with 77 percent undergoing surgical drainage. Sonographic findings, initial choice of antimicrobials, and infecting organism do not predict aspiration failure (David, 2018).

Other etiologies should be considered in the setting of a nonhealing abscess. Rarely, *granulomatous mastitis* presents as puerperal mastitis (Ding, 2021 Freeman, 2017). Cancer or tuberculosis are other considerations (Wu, 2020).

CHAPTER 38

Contraception

The puerperium offers an excellent opportunity to provide effective contraception. For mothers who are nursing exclusively, ovulation during the first 10 weeks after delivery is unlikely. Nursing, however, is not a reliable method of family planning for women whose infants breastfeed only during the day. Moreover, waiting for first menses involves a risk of pregnancy, because ovulation usually antedates menstruation. Certainly, after the first menses, contraception is essential unless the woman desires pregnancy.

Nearly half of all pregnancies each year in the United States are unintended (Finer, 2016). These may follow contraceptive method failure or stem from lack of contraceptive use. For those seeking contraception, effective options are available (Table 38-1). Among these, estimated failure rates of perfect and typical use during the first year differ widely (Trussell, 2018). Efficacy tiers reflect these failure rates, and implants and intrauterine devices (IUDs) are found in the top tier (Steiner, 2006). They effectively drop unintended pregnancy rates and are considered long-acting reversible contraception (LARC). Clinicians provide counseling on *all* options and encourage LARC for appropriate candidates (American College of Obstetricians and Gynecologists, 2019d).

No contraceptive method is completely without side effects, but contraception usually poses less risk than pregnancy. However, some disorders or medications can raise the risks of certain contraceptives. The World Health Organization (2015) has provided guidelines for the use of effective reversible contraceptive methods by women with various health conditions. Individual countries have subsequently modified these guidelines. The *United States Medical Eligibility Criteria (US MEC)* was updated in 2016 by the Centers for Disease Control and Prevention and is available at their website (Curtis, 2016b).

In the US MEC, reversible contraceptive methods are organized into six groups: levonorgestrel-releasing intrauterine system (LNG-IUS), copper intrauterine devices (Cu-IUDs), implants, depot medroxyprogesterone acetate (DMPA), progestin-only pills (POPs), and combination hormonal contraceptives (CHCs). This last group includes combination oral contraceptives (COCs), rings, and patches. For a given health condition, each method is categorized 1 through 4. The score describes the safety profile for a typical woman with that condition: (1) no restriction of method use, (2) method advantages outweigh risks, (3) method risks outweigh advantages, and (4) method poses an unacceptable health risk.

Alternatively, depending on the underlying disorder or patient desire, male or female sterilization may be a preferred or recommended permanent contraceptive method. These options are discussed in Chapter 39.

INTRAUTERINE DEVICES

The five IUDs currently approved for use in the United States are *chemically active* and continually elute either copper or a progestin. All have a flexible, T-shaped, polyethylene frame

TABLE 38-1. Contraceptive Failure Rates of Reversible Methods During the First Year and Use Rates[a]

Method	Perfect Use	Typical Use	Percent Use[b]
Top tier (most effective)			
Intrauterine devices:			11.8
52-mg LNG-IUS	0.1	0.1	–
T380A Cu-IUD	0.6	0.8	–
Etonogestrel implant	0.1	0.1	2.6
Female sterilization	0.5	0.5	21.8
Male sterilization	0.1	0.15	6.5
Second tier (very effective)			
Combination pill	0.3	7	24.9
Vaginal ring	0.3	7	2.4
Patch	0.3	7	0.2
DMPA	0.2	4	3.9
Progestin-only pill	0.3	7	0.4
Third tier (effective)			
Condom			14.6
Male	2	13	–
Female	5	21	–
Diaphragm + spermicides[c]	16	24	–
Fourth tier (least effective)			
Spermicides[c]	18	28	–
Sponge[c]			–
Multiparas	20	27	–
Nulliparas	9	14	–

[a]Among women in the United States using contraception.
[b]This sum totals less than 100% as withdrawal (8.1%) and natural family planning (2.2%) values are not presented in the table.
[c]Combined into "other method" category, which has a use rate of 0.6%.
Cu-IUD = copper-containing intrauterine device; DMPA = depot medroxyprogesterone acetate; LNG-IUS = levonorgestrel-releasing intrauterine system.
From Guttmacher Institute, 2020; Hall, 2012; Kavanaugh, 2018; Steiner, 2006; Trussell, 2018.

compounded with barium to render them radiopaque. The progestin-eluting devices are similarly shaped, but each differs by size, string color, longevity, and presence or absence of a silver band at the junction of the stem and arms (Table 38-2). Among these, smaller-sized devices are thought to better fit a nulliparous uterus (Gemzell-Danielsson, 2012). In contrast, the copper device, the T380A IUD named *ParaGard,* contains a thin copper strand wound around its stem and a copper bracelet on each arm.

■ Contraceptive Action

The contraceptive mechanism of IUDs is not precisely defined, but prevention of fertilization is now favored. Within the uterus, an intense local endometrial inflammatory response is induced, especially by the Cu-IUD. Inflammatory fluid fills the uterine cavity and fallopian tubes to decrease sperm and egg viability (Ortiz, 2007). Also, in the unlikely event that fertilization does occur, the same inflammatory actions are directed against the blastocyst. With the LNG-IUS, progestin release atrophies the endometrium to hinder normal implantation and creates scant viscous cervical mucus to obstruct sperm motility (Apter, 2014; Silverberg, 1986). The above effects are considered primary because ovulation inhibition is inconsistent with the LNG-IUS and lacking with the Cu-IUD (Nilsson, 1984).

■ Method-specific Adverse Effects

Ectopic Pregnancy

In the past, IUDs were perceived to increase the risk of ectopic pregnancy, but this has since been clarified. Specifically, IUDs provide effective contraception and lower the absolute number of ectopic pregnancies by half compared with the rate in noncontracepting women (World Health Organization, 1985). But, the IUD mechanisms of action are more effective in preventing *intrauterine* implantation. Thus, if an IUD fails, a higher proportion of pregnancies are likely to be ectopic (Furlong, 2002; Teal, 2019).

Lost Device

Expulsion of an IUD from the uterus is most common during the first month. Thus, women are examined approximately 4 to 6 weeks following IUD insertion, usually after menses, to identify the tails trailing from the cervix. Following this, a woman is instructed to palpate the strings each month after menses. Regardless of IUD type, the cumulative 3-year expulsion rate

TABLE 38-2. Properties of Intrauterine Devices

Active Agent	Quantity of Active Agent	Width × Height (mm)	Inserter Tube Diameter (mm)	FDA-approved Duration of Use (yr)	String Color	Silver Ring	Brand Name
LNG	52 mg	32 × 32	4.4	5	Tan	No	Mirena
LNG	52 mg	32 × 32	4.8	6	Blue	No	Liletta
LNG	19.5 mg	28 × 30	3.8	5	Blue	Yes	Kyleena
LNG	13.5 mg	28 × 30	3.8	3	Tan	Yes	Skyla, Jaydess
Copper	380 mm^3	32 × 36	4.4	10	White	No	ParaGard

FDA = U.S. Food and Drug Administration; LNG = levonorgestrel.

approximates 10 percent following nonpuerperal insertion (Madden, 2014; Simonatto, 2016).

If the tail of an IUD cannot be visualized, the device may have been expelled, may have perforated the uterus, or may be malpositioned. Alternatively, the device may be normally positioned with its tail folded within the endocervical canal or uterine cavity. To investigate, after excluding pregnancy, a cytological brush can be twirled within the endocervical canal to entangle the strings and bring them gently into the vagina. If unsuccessful, the uterine cavity is probed gently with a Randall stone clamp or with a specialized rod with a terminal hook to retrieve the strings.

One should not assume that a device has been expelled unless it was seen. Thus, if tails are not visible and the device is not felt by gentle probing of the uterine cavity, transvaginal sonography (TVS) can be used to ascertain if the device lies within the uterus. Although traditional TVS will document IUD position adequately in most cases, three-dimensional TVS offers improved views (Moschos, 2011). If sonography is inconclusive or if no device is seen, a plain radiograph of the abdominopelvis is taken. Computed tomography (CT) scanning or magnetic resonance (MR) imaging is an alternative depending on coexisting pregnancy and study access. MR imaging at 1.5 or 3 Tesla with an IUD in place is safe (Ciet, 2015).

Perforation

During sounding or IUD insertion, the uterus may be perforated, which is identified by the tool traveling farther than expected based on initial bimanual uterine examination. Rates approximate 1 case per 1000 insertions, and risks include puerperal insertion and breastfeeding (Barnett, 2017; Kaislasuo, 2012).

With acute perforation, the fundus is the more common site, and bleeding is often minimal due to myometrial contraction around the puncture site. If no brisk bleeding is noted from the os following removal of the wounding tool, patient observation alone is reasonable. Rarely, lateral perforations may lacerate the uterine artery, and subsequent heavy bleeding prompts laparoscopy or laparotomy for control.

With occult perforation, a device can penetrate the myometrium to varying degrees. Abdominal pain, uterine bleeding, or missing strings are clues, and imaging described in the last section is a primary step (Kaislasuo, 2013). A device with an arm partially embedded can sometimes be removed transcervically with steady traction. Otherwise, IUDs with a mainly intrauterine location are usually removed hysteroscopically. Devices that have nearly or completely perforated through the uterine wall are more easily extracted laparoscopically. Devices often embed on posterior cul-de-sac structures and omentum, but bowel and bladder perforations are possible (Şengül, 2014; Zeino, 2011).

Menstrual Changes

Dysmenorrhea and irregular bleeding can complicate IUD use. These can be treated with some degree of success by nonsteroidal antiinflammatory drugs (NSAIDs) or tranexamic acid, which is an antifibrinolytic (Friedlander, 2015). Of IUD types, heavy bleeding more often complicates Cu-IUD use and may cause iron-deficiency anemia, for which oral iron salts are given. With the LNG-IUS, irregular spotting for up to 6 months after placement often gives way to progressive amenorrhea, which is reported by approximately 10 percent of women after year 1 and 35 percent after 3 years (Goldthwaite, 2019). This is frequently associated with improved dysmenorrhea.

Infection

The risk of upper genital tract device-related infection is greatest during the first 3 weeks following IUD insertion (Farley, 1992; Turok, 2016). Pathogens include *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and vaginal flora. Women at risk for sexually transmitted diseases (STDs) should be screened either before or at the time of IUD insertion (Centers for Disease Control and Prevention, 2015). That said, device insertion need not be delayed while awaiting STD or Pap test results in asymptomatic women (Birgisson, 2015). If these bacteria are subsequently found, the IUD may remain and treatment may be prescribed. Routine antimicrobial prophylaxis before insertion is not recommended (Grimes, 2012). Bacterial endocarditis prophylaxis is not needed with insertion (Nishimura, 2017).

After the first month, infection risk is not elevated in IUD users who would otherwise be at low risk of STDs. Correspondingly, IUDs cause little, if any, increase in infertility rates in these low-risk patients (Hubacher, 2001). The American College of Obstetricians and Gynecologists (2020a) recommends that women at low risk for STDs, including adolescents, be considered good candidates for IUDs. The IUD is also safe and effective in women with immunosuppression, including human immunodeficiency virus (HIV) infection (Tepper, 2016a). Moreover, IUD use does not appear to raise HIV acquisition rates (Curtis, 2020).

If infection does develop, it may take several forms and typically requires broad-spectrum antibiotics. *Pelvic inflammatory disease (PID)* without abscess is treated with antibiotics. There are theoretical concerns that a coexistent IUD may worsen the infection or delay resolution. A provider may choose to remove an IUD in this setting, although growing evidence supports allowing device retention during treatment in those with mild or moderate PID (Curtis, 2016a; Tepper, 2013). If infection fails to improve during 48 to 72 hours of treatment, the device is removed. *Tuboovarian abscess* can complicate PID and is treated aggressively with intravenous broad-spectrum antibiotics and IUD removal. Last, *septic abortion* mandates immediate uterine evacuation and antibiotics.

Actinomyces israelii is a gram-positive, slow-growing, anaerobic, indigenous vaginal bacterium. It is frequently identified in the vaginal flora or on the Pap smears of IUD users (Curtis, 1981; Kim, 2014). If found, an asymptomatic woman may retain her IUD and does not require antibiotics (Lippes, 1999; Westhoff, 2007a). However, with infection in a woman who harbors *Actinomyces* species, the device is removed and antibiotics with gram-positive coverage are given. Early findings with infection include fever, weight loss, abdominal pain, and abnormal uterine bleeding or discharge.

Pregnancy with an IUD

For women who become pregnant despite an IUD, ectopic pregnancy and pelvic infection each must be excluded. Pregnant women with a retained IUD and infection are treated with broad-spectrum antibiotics and prompt uterine evacuation.

For those with intrauterine pregnancy without infection, the IUD tail can be grasped, and the IUD removed by gentle outward traction. This action reduces rates of subsequent abortion, chorioamnionitis, and preterm birth (Brahmi, 2012). Specifically, in one cohort, a 54-percent abortion rate and 17-percent preterm delivery rate was noted if the device remained in situ. More favorably, rates of 25 percent and 4 percent, respectively, resulted from prompt Cu-IUD removal (Tatum, 1976). Few data guide management with the LNG-IUS, and most practice extrapolates from copper devices.

If the tail is not visible, attempts to locate and remove the device may result in abortion. Some case reports and small series describe sonography or hysteroscopy to assist difficult device removals, but this is not our practice (Pérez-Medina, 2014; Schiesser, 2004). In women who give birth with a device in place, appropriate steps should be taken at delivery to identify and remove the IUD.

Intrauterine Device Insertion

Timing

Before insertion, IUD contraindications are sought (Table 38-3). Candidates are counseled, and written consent obtained.

To reduce expulsion rates, IUD insertion traditionally has followed complete uterine involution and is termed *interval* placement. Instead, immediately following miscarriage, surgical abortion, or delivery, an IUD may be inserted in the absence of overt infection (Roe, 2019; Whitaker, 2018). Also, early insertion 1 week after mifepristone and completed medical abortion has been described (Sääv, 2012; Shimoni, 2011). Compared with interval insertion, the IUD expulsion rate is slightly higher with *immediate* placement, defined as the first 10 minutes after placenta delivery. The highest rates are with *early* placement, defined as later than 10 minutes but within the first month postpartum (Jatlaoui, 2018). The higher US MEC scores seen in Table 38-4 reflect these early-placement expulsion risks.

TABLE 38-3. Contraindications to IUD Use

Both IUD Types
Pregnancy or suspicion of pregnancy
Distorted uterine cavity
Acute PID
Postpartum/postabortal endometritis in past 3 months
Uterine bleeding of unknown etiology
Acute untreated LGT infection
Conditions linked to pelvic infection risk[a]
Allergy to device components
Coexisting retained IUD

Specific to Cu-IUD
Known or suspected uterine or cervical cancer
Wilson disease

Specific to LNG-IUS
Prior PID unless a subsequent IUP has occurred
Known or suspected uterine or cervical neoplasia
Acute liver disease or benign/malignant liver tumor
Known or suspected current or prior breast cancer or other progestin-sensitive cancer

[a]These include multiple sexual partners, severe immune compromise, intravenous drug use, and recent PID or endometritis.
Cu-IUD = copper-containing intrauterine device; IUD = intrauterine device; IUP = intrauterine pregnancy; LGT = lower genital tract; LNG-IUS = levonorgestrel-releasing intrauterine system; PID = pelvic inflammatory disease.
Bayer HealthCare Pharmaceuticals, 2017; CooperSurgical, 2020.

TABLE 38-4. U.S. Medical Eligibility Criteria Category of Contraceptive Methods Related to Breastfeeding and Time After Delivery

Method CHCs[a]	Cat.	DMPA, POPs, Implants	Cat.	LNG-IUS	Cat.	Cu-IUD	Cat.
Breastfeeding		Breastfeeding		± Breastfeeding[c]		± Breastfeeding[c]	
<21 d	4	<1 month	2	<10 mins	2	<10 min	1
21 d to <30 d	3	≥1 month	1	10 mins to ≤4 wks	2	10 min to ≤4 wks	2
30–42 d[b]	2			≥4 wks	1	≥4 wks	1
>42 d	2			Puerperal sepsis	4	Puerperal sepsis	4
Nonbreastfeeding		Nonbreastfeeding	1				
<21 d	4						
21–42 d[b]	2						
>42 d	1						

[a]Combined hormonal contraceptive (CHC) group includes pills, vaginal ring, and patch.
[b]Associated risks that increase puerperal category score include: age ≥35, transfusion at delivery, body mass index ≥30, postpartum hemorrhage, cesarean delivery, smoking, preeclampsia.
[c]With or without breastfeeding.
Cat. = category; Cu-IUD = copper-containing intrauterine device; DMPA = depot medroxyprogesterone acetate; LNG-IUS = levonorgestrel-releasing intrauterine system; POPs = progestin-only pills.
From Curtis, 2016b; Kapp, 2009b.

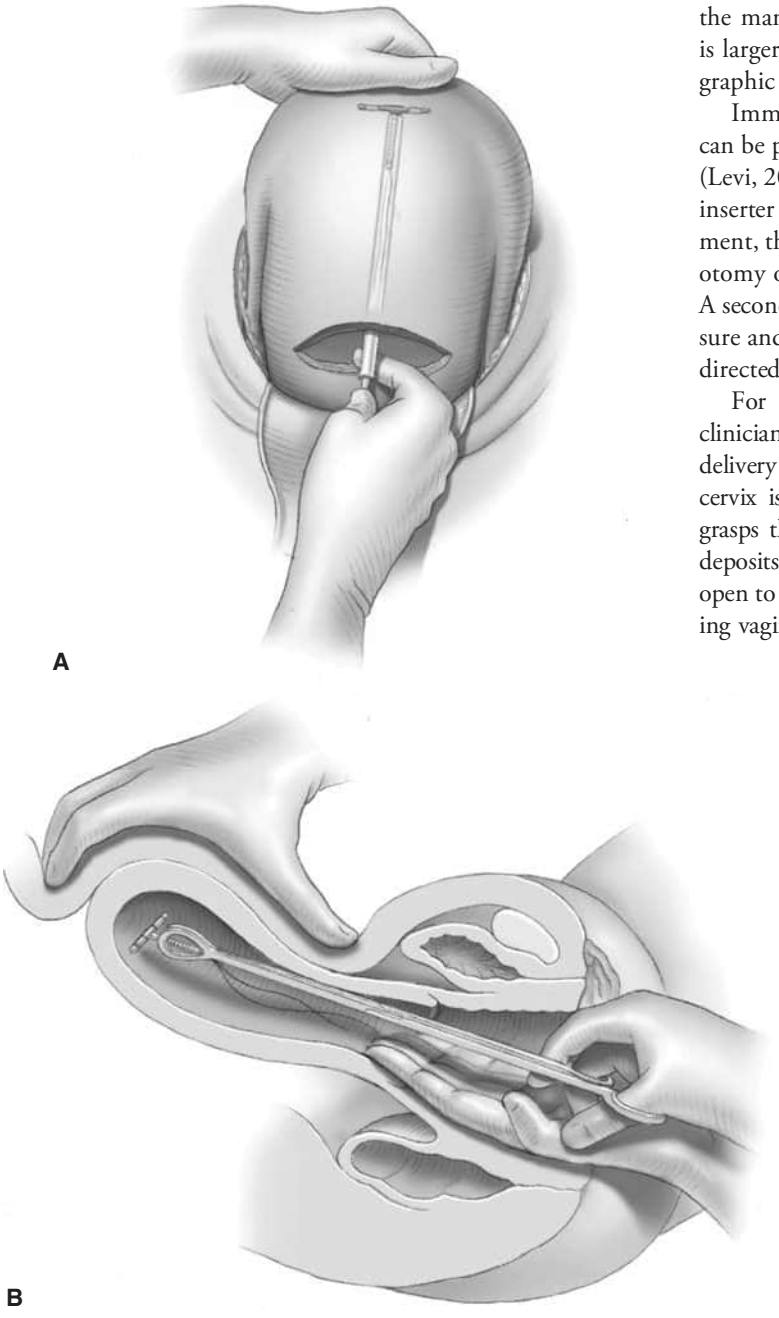

FIGURE 38-1 A. Intrauterine device (IUD) insertion at cesarean delivery. The device inserter guides the device to the uterine fundus. A hand at the fundus can provide back pressure to stabilize the uterus during insertion. **B.** IUD insertion after vaginal delivery. Ring forceps direct the device to the uterine fundus. Back pressure against the fundus by an abdominal hand can help guide positioning. (Reproduced with permission from Stuart GS, Hoffman BL: Puerperal sterilization. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw Hill; 2017.)

However, the number of women in immediate-placement groups who ultimately receive and retain an IUD is greater than in groups scheduled for interval placement, because some fail to return for insertion (Bednarek, 2011; Chen, 2010).

Postpregnancy Insertion Techniques

With immediate insertion, techniques depend on uterine size. After first-trimester evacuation, the IUD can be placed using the manufacturer's standard instructions. If the uterine cavity is larger, the IUD can be placed using ring forceps with sonographic guidance (Fox, 2011).

Immediately following vaginal or cesarean delivery, an IUD can be placed by a hand, by its inserter tube, or by ring forceps (Levi, 2015). The arms of the IUD need not be folded into the inserter tube prior to insertion. During cesarean delivery placement, the hand or inserter travels through the unsutured hysterotomy opening to deposit the device at the fundus (Fig. 38-1). A second hand cupping the outer fundus can provide back pressure and stabilize the uterus during insertion. Strings are gently directed but not pulled toward the cervix.

For instrumented insertion following vaginal delivery, the clinician resterilizes the vulva and changes gloves after placental delivery but before perineal repairs. The anterior lip of the floppy cervix is held with ring forceps. A second ring forceps gently grasps the IUD stem, guides it up into the uterine cavity, and deposits it at the fundus. During forceps removal, the jaws remain open to avoid ensnaring the strings. For manual insertion following vaginal delivery, the provider holds the IUD between fingers to deposit the device. In either case, back pressure against the fundus by an abdominal hand can guide fundal positioning (Stuart, 2017).

Interval Insertion Technique

For placement not related to pregnancy, insertion near the end of normal menstruation, when the cervix is usually softer and somewhat more dilated, may be easier and also helps exclude early pregnancy. However, for the woman who is sure she is not pregnant and does not want to be pregnant, insertion is done at any time.

To ease insertional pain, applying lidocaine-prilocaine cream locally or placing paracervical blockade can be helpful (Akers, 2017; Samy, 2019). Bimanual pelvic examination delineates uterine position and size. Abnormalities are evaluated, as they may contraindicate insertion. Mucopurulent cervicitis or significant vaginitis is appropriately treated and resolved before IUD insertion.

The ectocervix is cleansed with an antiseptic solution, and sterile instruments are used. A tenaculum is placed on the cervical lip, and the endocervical canal and uterine cavity are straightened by applying gentle outward traction. A uterine sound is guided into the cavity to identify its direction and depth. Specific steps of Cu-IUD and LNG-IUS insertions are outlined in their respective package inserts.

Following insertion, only the threads should be visible trailing from the cervix. These are trimmed to allow 3 to 4 cm to protrude into the vagina, and their length is recorded. An oral NSAID can be used for cramping after insertion (Ngo, 2015).

If improper device positioning is suspected, placement should be confirmed, using sonography if necessary. If the IUD is not positioned completely within the uterus, it is removed and replaced with a new device. An expelled or partially expelled device should not be reinserted.

PROGESTIN-ONLY CONTRACEPTIVES

Actions and Side Effects

Progestin-only contraceptives include implants, injectables, and pills. These suppress luteinizing hormone (LH) to block ovulation, cervical mucus thickens to retard sperm passage, and atrophy renders the endometrium unfavorable for implantation. Fertility is restored rapidly following cessation except for DMPA, described later (Mansour, 2011).

After placenta delivery, progesterone withdrawal may contribute to lactogenesis, and early progestin use theoretically could hinder breastmilk establishment. Although studies support the safety of early puerperal use of progestins, this theoretical risk is still reflected in their higher US MEC score (see Table 38-4) (Carmo, 2017; Phillips, 2016).

For all progestin-only methods, irregular uterine bleeding is the most frequent adverse event prompting discontinuation. Often, counseling and reassurance is sufficient. In others, troublesome bleeding may be improved by combining the progestin method with a 2-week course of estrogen or with a short course of NSAIDs (Abdel-Aleem, 2013). A few cycles of COCs combined with DMPA or an implant is another option. Fortunately, with prolonged use, progestins induce endometrial atrophy, which can lead to sustained amenorrhea. For the informed patient, this is often an advantage. Iron-deficiency anemia is also less likely.

Most progestin-only contraceptive methods do not significantly affect lipid metabolism, glucose levels, hemostatic factors, liver function, thyroid function, or blood pressure (Dorflinger, 2002). However, the increased low-density lipoprotein (LDL) cholesterol and decreased high-density lipoprotein (HDL) cholesterol levels seen with DMPA are less desirable for women with cardiovascular disease risks (Kongsayreepong, 1993).

Risks for genital tract, liver, or breast neoplasia are not increased with progestin-only methods (Samson, 2016; Wilailak, 2012; World Health Organization, 1991a,b, 1992). Weight gain and bone fracture are not prominent side effects of this contraceptive group, except for DMPA, discussed later (Lopez, 2012, 2013). Functional ovarian cysts are seen more often in women using progestin-only agents, although intervention is not usually required (European Society of Human Reproduction and Embryology, 2001). Last, concern for a higher depression rate is not supported by recent studies (Skovlund, 2016; Worly, 2018).

Progestin Contraindications

Current pregnancy, breast cancer, acute liver disease, liver tumors, and undiagnosed abnormal genital bleeding are absolute contraindications. For Nexplanon and DMPA, their manufacturers also add current or past history of thromboembolic disorders (Merck, 2019; Pfizer, 2017). However, for women with these disorders, the US MEC considers progestin-containing methods category 2 (Curtis, 2016b).

Progestin Implants

These thin, pliable, progestin-containing cylinders can be implanted in the upper arm to release contraceptive hormone over several years. Implants are an effective, top-tier method (Mommers, 2012; Sivin, 1998; Steiner, 2010).

These systems are placed subdermally on the inner arm approximately 8 cm from the elbow. Implants vary in their insertion technique, and manufacturer instructions should be consulted. After their expiration date, implants are removed, and may be replaced at the same site or in the opposite arm.

Nexplanon is a single-rod etonogestrel implant that releases at least 30 µg of hormone daily and may be used for 3 years. The inserter design assists with subdermal positioning and averting deeper placement. Nexplanon replaced *Implanon*, which is still approved by the Food and Drug Administration (FDA) but no longer distributed by the manufacturer.

Levonorgestrel implants are two-rod systems available outside the United States and contain a total LNG dose of 150 mg. *Jadelle* provides contraception for 5 years. It is approved by the FDA but not marketed in the United States. *Sino-implant II* provides 3 years of contraception (Steiner, 2019).

Method-specific Adverse Effects

In addition to the hormonal side effects listed earlier, the implants themselves can cause adverse events. These complicate approximately 1 percent of implant insertions and 5 percent of removals (Creinin, 2017; Reed, 2019). Of serious events, branches of the medial antebrachial cutaneous nerve and median nerve can be injured during an implant insertion that is too deep or during exploration for implant removal (Laumonerie, 2018). Thus, implants found deep in muscle or near neurovascular structures are best removed by surgeons with a clear understanding of upper arm anatomy (American College of Obstetricians and Gynecologists, 2019a).

Nonpalpable devices are not uncommon and require imaging for localization prior to attempted removal. Nexplanon is radiopaque and can be imaged by two-dimensional x-ray views. Implanon is not radiopaque, and sonography using a 10- to 15-MHz linear array transducer or MR imaging is needed (Correia, 2012; Shulman, 2006). Rarely, an implant can migrate to distant sites such as the lung (Kang, 2017). If imaging fails to locate an implant, etonogestrel blood levels can help verify that the implant is indeed in situ. This assay must be coordinated with the manufacturer (877-888-4231).

Implant Insertion

The etonogestrel implant is ideally inserted within 5 days of menses onset. With LNG-releasing implants, contraception is established within 24 hours if inserted within the first 7 days of the menstrual cycle. For transitioning methods, an implant is placed on the day of the first placebo COC pill; on the day that the next DMPA injection would be due; or within 24 hours of the last POP (Merck, 2019). In women certain that they are not pregnant, insertion at other times of the cycle is followed by an additional method that serves as a back-up method for 7 days. Postabortion or postpartum, an implant may be inserted before discharge home (Madden, 2012; Sothornwit, 2017).

For insertion, the supine patient positions her nondominant arm against the bed so that the arm is abducted and the elbow is flexed. With a sterile pen, the insertion site is marked 8 to 10 cm proximal to the humerus' medial condyle and 3 to

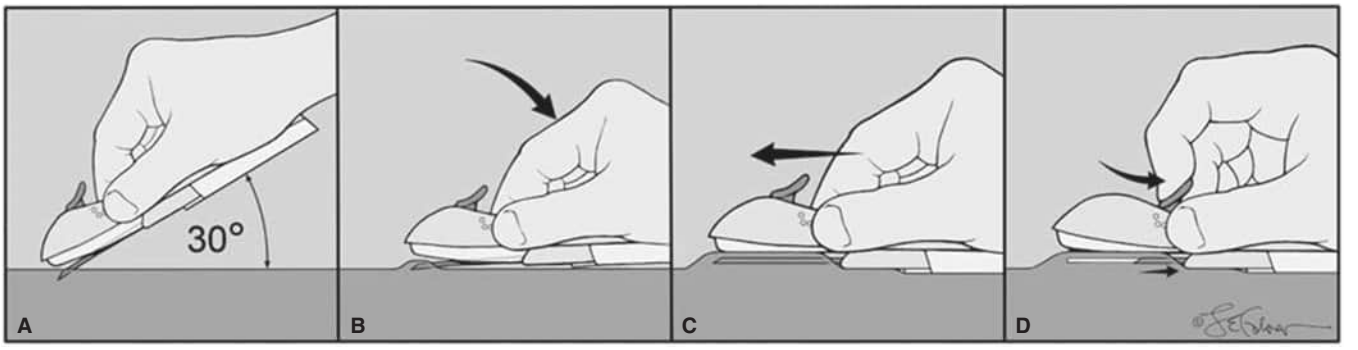

FIGURE 38-2 Nexplanon insertion. A sterile pen marks the insertion site, which is 8 to 10 cm proximal to the medial humeral condyle. A second mark is placed 4 cm proximally along the arm's long axis. The area is cleaned aseptically, and a 1-percent lidocaine anesthetic track is injected along the planned insertion path. **A.** The insertion device is grasped at its gripper bubbles found on either side, and the needle cap is removed outward. The device can be seen within the needle bore. The needle bevel then pierces the skin at a 30-degree angle. **B.** Once the complete bevel is subcutaneous, the needle is quickly angled downward to lie horizontally. **C.** Importantly, the skin is tented upward by the needle as the needle is slowly advanced horizontally and subdermally. **D.** Once the needle is completely inserted, the lever on the top of the device is pulled backward toward the operator. This retracts the needle and thereby deposits the implant. The device is then lifted away from the skin. After placement, both patient and operator should palpate the 4-cm implant.

5 cm posterior to the groove between biceps and triceps muscles (Iwanaga, 2019). A second mark is placed 4 cm proximal to the first and serves as a guide for the insertion path along the arm's long axis. The Nexplanon is inserted using sterile technique. The area is cleansed aseptically, and a 1-percent lidocaine anesthetic track is injected beneath the skin along the planned insertion path. The implant is then placed as shown in Figure 38-2. After placement, both patient and provider should palpate and identify both ends of the 4-cm implant. To minimize bruising at the site, a pressure bandage is created around the arm and is removed the following day.

With implant extraction, the removal site is first cleansed with antiseptic. The proximal end of the implant is depressed with a finger to allow the distal end to lift up toward the skin. After anesthetizing the skin over this bulge, the skin is incised 2 mm toward the elbow along the arm's long axis. The implant's proximal butt is then pushed toward this incision. Once visible, the implant's distal end is grasped with a hemostat and removed. Superficial adhesions surrounding an implant are common and are dissected away with hemostat tips.

■ Injectable Progestin Contraceptives

DMPA, 150 mg every 3 months, and norethisterone enanthate, 200 mg every 2 months, are two intramuscular injectable progestin-only contraceptives used worldwide. Of the two, DMPA is available in the United States and marketed as *Depo-Provera*. DMPA is injected into the deltoid or gluteus muscle, but massage is avoided to ensure that the drug is released slowly. A subcutaneous version, *depo-subQ provera 104*, is injected into the subcutaneous tissue of the anterior thigh or abdomen every 3 months. This form may be self-administered (Curtis, 2021).

Initial injection is given within the first 5 days following menses onset. Serum levels sufficient for contraception are present by 24 hours. Thus, no additional contraceptive method is required for initiation within this window. Limited data support a *quick start*, or initiation of DMPA regardless of cycle day. If so implemented, investigators recommend an initial negative pregnancy test result before injection, a supplemental contraceptive method during the 7 days following injection, and a second pregnancy test after 3 to 6 weeks to identify an early pregnancy (Sneed, 2005). Conceptions during DMPA use do not have higher fetal anomaly rates (Katz, 1985).

Method-specific Adverse Effects

Unique to DMPA, prolonged anovulation can follow discontinuation and results in delayed fertility resumption (Paulen, 2009). After injections are stopped, a fourth of patients do not resume regular menses for up to 1 year (Gardner, 1970). Thus, DMPA may be less ideal for women who plan to use birth control only briefly before attempting conception.

As with other progestins, DMPA is not associated with cardiovascular events or stroke in otherwise healthy women. However, in those with severe hypertension, a higher risk of stroke has been found in DMPA users (World Health Organization, 1998). The US MEC authors express concerns regarding DMPA's hypoestrogenic effects and reduced HDL levels for women with vascular disease or multiple cardiovascular disease risks (Curtis, 2016b).

Weight gain is generally attributed to DMPA, and ranges from 1 to 3 kg in the first year (Dianat, 2019). In long-term users, bone density loss is also greater than in nonusers (Petitti, 2000; Scholes, 1999). It is somewhat reassuring that bone loss appears to slowly reverse after cessation (Clark, 2006; Scholes, 2002). In 2004, the FDA added a black box warning to DMPA labeling, which notes that this concern is probably most relevant for adolescents, who are building bone mass, and perimenopausal women, who will soon have increased bone loss during menopause. Despite this, DMPA should not be restricted in those high-risk groups (American College of Obstetricians and Gynecologists, 2019b).

■ Progestin-only Pills

Also called *mini-pills*, this group contains norethindrone-only, desogestrel-only, and drospirenone-only pills. Of these, each

norethindrone-only pill provides 0.35 mg of hormone and is taken daily and continuously. This specific drug does not reliably inhibit ovulation. Efficacy stems from cervical mucus thickening and endometrial atrophy. Because mucus changes are not sustained, these pills are best taken at the same time each day. If the pill is taken even 3 hours late (missed-pill window), a backup form of contraception is used for the next 48 hours.

In contrast, the drospirenone-only pill marketed as *Slynd* delivers 4 mg of hormone and is taken for 24 consecutive days out of a 28-day cycle. Progestin withdrawal during the last 4 days aims to minimize irregular bleeding (Archer, 2015). Both drospirenone and desogestrel pills alter mucus and endometrium *plus* reliably inhibit ovulation. *Slynd* offers a 24-hour missed-pill window, which mirrors that of COC pills (Duijkers, 2016).

Drospirenone is structurally similar to spironolactone. It displays antiandrogenic activity, provides an antialdosterone action to minimize water retention, and has antimineralocorticoid properties that may, in theory, cause potassium retention and hyperkalemia (Krattenmacher, 2000). Thus, contraindications are renal or adrenal insufficiency in addition to traditional progestin contraindications, listed earlier (p. 669). Serum potassium level monitoring is recommended in the first month for patients chronically treated with any drug associated with potassium retention. These include NSAIDs, angiotensin-converting enzyme (ACE) inhibitors, angiotensin II antagonists, heparin, aldosterone antagonists, and potassium-sparing diuretics.

Last, desogestrel-only pills contain 0.075 mg of hormone and are used daily and continuously. Its missed-pill window is 12 hours. These are not available in the United States.

TABLE 38-5. Estrogen and Progestins Used in FDA-Approved Combination Oral Contraceptive Pills

Estrogen Type (Pill Dose)	Paired Progestin[a]
Ethinyl estradiol 10 μg	Norethindrone acetate
Ethinyl estradiol 20 μg	Desogestrel Drospirenone Levonorgestrel Norethindrone acetate
Ethinyl estradiol 25 μg	Desogestrel Norgestimate
Ethinyl estradiol 30–35 μg	Desogestrel Drospirenone Ethynodiol diacetate Levonorgestrel Norethindrone Norethindrone acetate Norgestimate Norgestrel
Ethinyl estradiol 50 μg	Ethynodiol diacetate Norgestrel
Estradiol valerate 2 mg Estetrol 14.2 mg Mestranol 50 μg	Dienogest Drospirenone Norethindrone

[a]Progestins are listed alphabetically.
FDA = U.S. Food and Drug Administration.

COMBINATION HORMONAL CONTRACEPTIVES

Mechanism of Action

The most important contraceptive effect of both the estrogen and progestin components of CHCs is suppression of hypothalamic gonadotropin-releasing factors to inhibit ovulation. The progestin also thickens cervical mucus to retard sperm passage and renders the endometrium unfavorable for implantation. Estrogen stabilizes the endometrium, which prevents intermenstrual bleeding—also known as *breakthrough bleeding*. This benefit is termed *cycle control*. The net effect is an extremely effective yet highly reversible contraceptive method.

Combination Oral Contraceptive Pills

Composition

COCs are marketed in various estrogen and progestin combinations (Table 38-5). Ethinyl estradiol is the most common estrogen present in formulations in the United States. Less frequently, mestranol, estetrol, or estradiol valerate is used. Unwanted effects most often attributed to the estrogen component are breast tenderness, weight gain, nausea, and headache.

COCs contain one of several progestins that are structurally related to progesterone, testosterone, or spironolactone. Thus, these progestins bind variably to progesterone, androgen, glucocorticoid, and mineralocorticoid receptors. These affinities explain many pill-related side effects and are often used to compare one progestin with another. However, the advantage of one progestin over another is less apparent clinically (Lawrie, 2011; Moreau, 2007).

To minimize adverse effects, estrogen and progestin content in COCs has dropped remarkably. Currently, the lowest acceptable dose is limited by the ability to prevent pregnancy yet maintain cycle control. Thus, the daily estrogen content varies from 10 to 50 μg of ethinyl estradiol, and most contain ≤35 μg.

In a few COCs, inert placebo pills have been replaced by tablets containing iron. These have the suffix Fe added to their name. Instead, *Beyaz* and *Sayfral* have a form of folate—*levomefolate calcium*—within both its active and placebo pills.

With COCs termed *monophasic*, the progestin dose remains constant. In others, the dose frequently is varied, and term *biphasic, triphasic,* or *quadriphasic* is used depending on the number of dose changes within one cycle. In some formulations, the estrogen dose also varies. In general, phasic pills aim to reduce the total progestin content and associated side effects per cycle without sacrificing contraceptive efficacy or cycle control. The theoretical advantage of this approach, however, has not been borne out clinically (Moreau, 2007). Cycle control also appears similar among mono-, bi-, and triphasic pills (van Vliet, 2011a,b,c).

Administration

Hormones are taken daily for a specified time (21 to 81 days) and then replaced by placebo for a specified time (4 to 7 days), which is called the *pill-free interval*. During these pill-free days, bleeding prompted by hormonal withdrawal is expected.

With the trend toward lower estrogen doses, follicular growth and ovulation may occur. To counter this, the active-pill duration in some formulations is extended to 24 days. In comparison, these 24/4 regimens perform similarly to 21/7 regimens (Anttila, 2011; Marr, 2012).

Longer durations of active hormone are designed to minimize the number of withdrawal bleeding episodes. This practice has similar efficacy and safety profiles compared with traditional administration (Edelman, 2014). These *extended-cycle* products produce a 13-week cycle, that is, 12 weeks of hormone use, followed by a week for withdrawal menses. Instead, the product *Amethyst* provides continuous active hormone pills for 365 days each year. These extended-cycle and continuous regimens may be especially suited for women with significant menstrual symptoms (Mendoza, 2014).

Women ideally begin COCs on the first day of a menstrual cycle. In such cases, a back-up method is unnecessary. With the more traditional "Sunday start," women begin pills on the first Sunday that follows menses onset, and a back-up method is added for 1 week. If menses begin on a Sunday, pills are begun that day and no back-up method is required. Alternatively, with a quick start, COCs are started on any day, commonly the day prescribed. A back-up method is added for 1 week (Westhoff, 2007b). If the woman is unknowingly already pregnant, COCs are not teratogenic (Rothman, 1978; Savolainen, 1981). A missed menses after COC initiation should prompt pregnancy testing. Similar initiation methods are used for contraceptive vaginal rings or patches.

For maximum efficiency, pills are best taken at the same time each day. If one dose is missed, the missed pill is taken immediately; the scheduled dose for that day is taken on time; and then daily pills are continued. If two or more doses are missed, the most recent missed pill is taken immediately; the scheduled dose for that day is taken on time; and a back-up method is used for 7 days while daily pills are then continued (Curtis, 2016a). If withdrawal bleeding fails to occur during the pill-free interval, a woman should continue her pills but exclude pregnancy.

With COC initiation, spotting or bleeding is common. It does not reflect contraceptive failure and typically resolves within one to three cycles. If unscheduled bleeding persists, those with bleeding during the first part of a pill pack may benefit from an increase in the estrogen dose, whereas those with bleeding during the second part may improve with a higher progestin dose (Nelson, 2011).

Method-specific Effects

Altered Drug Efficacy

Some drugs decrease COC effectiveness, and choosing another contraceptive method is preferable. Most notable are rifampin/rifabutin, but other antibiotics are not implicated (Simmons, 2018). Cytochrome P450–inducing anticonvulsants are another group and include phenytoin, phenobarbital, primidone, carbamazepine, oxcarbazepine, topiramate, rufinamide, and felbamate (American College of Obstetricians and Gynecologists, 2020b). Some antiretroviral drugs, mainly among the protease inhibitor group, can interact with COCs. A rapidly evolving list is provided by the U.S. Department of Health and Human Services (2019).

In obese women, COCs are effective (Simmons, 2016). With the *Ortho Evra* transdermal patch, however, obesity may alter pharmacokinetics and lower efficacy (p. 674).

On the other hand, some COCs lower the actions of certain drugs. Notably, lamotrigine efficacy is lowered by COCs (Gaffield, 2011).

Metabolic Changes, Risks, and Benefits

The hormones in COCs can induce metabolic changes that may aggravate underlying medical conditions. Most of the contraindications to COCs reflect these metabolic alterations (Table 38-6).

Hepatic angiotensinogen synthesis is augmented by COCs. Its conversion by renin to angiotensin I may be associated with pill-induced hypertension. Thus, patients return 8 to 12 weeks after COC initiation for evaluation of blood pressure and other symptoms. However, women using low-dose COC formulations rarely develop clinically significant hypertension (Chasan-Taber, 1996).

In women with well-controlled hypertension, COC use is linked to greater risks than in nonusers for stroke, acute myocardial infarction, and peripheral arterial disease, and in these women, COCs are considered US MEC category 3 (Curtis, 2016b). Severe forms of hypertension, especially those with end-organ involvement, preclude COC use.

The estrogen component of COCs boosts hepatic production of fibrinogen and many of the clotting factors. Deep-vein thrombosis and pulmonary embolism rates are increased in women who use COCs (Stadel, 1981). These events are estrogen-dose related, and rates have substantively declined with lower-dose formulations containing 10 to 35 μg of ethinyl estradiol. The general-population risk of venous thromboembolism (VTE) is 4 to 5 events per 100,000 woman-years. The incidence of VTE with COC use increases three- to fivefold compared with nonusers (Shaw, 2013; van Hylckama Vlieg,

TABLE 38-6. Contraindications to the Use of Combination Oral Contraceptive Pills

Pregnancy
Uncontrolled hypertension
Smokers older than 35 years
Diabetes with vascular involvement
Cerebrovascular or coronary artery disease
Migraines with associated focal neurologic deficits
Thrombophlebitis or thromboembolic disorders
History of deep-vein thrombophlebitis or thrombotic disorders
Thrombogenic heart arrhythmias
Thrombogenic cardiac valvulopathies
Undiagnosed abnormal genital bleeding
Known or suspected breast carcinoma
Cholestatic jaundice of pregnancy or jaundice with pill use
Hepatic adenomas and carcinomas
Cirrhosis or active liver disease with abnormal liver function
Known or suspected estrogen-dependent neoplasia

2009). Obesity raises the general VTE risk, which is compounded by COCs (Horton, 2016; Suchon, 2016). Accordingly, in an obese woman, COCs are considered a US MEC category 2. VTE rates are also significantly increased in women smokers older than 35 years, and COCs are not recommended. Those most at risk for VTE include women with thrombophilias (ESHRE Capri Workshop Group, 2013). Moreover, COC use during the month before a major operative procedure appears to double the risk for postoperative VTE (Robinson, 1991). Thus, the American College of Obstetricians and Gynecologists (2021) recommends balancing the risks of VTE and the degree of postoperative immobility with the risk of unintended pregnancy during the 4 to 6 weeks required to reverse the thrombogenic effects of COCs before surgery. In the early puerperium, VTE risks are also increased, and COCs are not recommended early (see Table 38-4).

Certain progestins within COC are also linked with greater VTE rates. A slightly higher VTE risk with drospirenone-containing COCs has been shown in two studies. In response, an assessment of benefits and VTE risks in users of these pills has been emphasized (Food and Drug Administration, 2012; Jick, 2011; Parkin, 2011). Desogestrel and gestodene are also implicated and carry similarly elevated risks (Stegeman, 2013; Vinogradova, 2015).

For women with prior myocardial infarction, COCs should not be considered. Also, for women with multiple cardiovascular risk factors, which include smoking, hypertension, older age, dyslipidemias, and diabetes, the risk for myocardial infarction outweighs the benefits of this method. For women with no cardiovascular risks, low-dose oral contraceptives are not associated with an increased risk of myocardial infarction (Margolis, 2007; World Health Organization, 1997).

For nonsmoking women younger than 35, stroke is rare (World Health Organization, 1996). COCs are associated with a small increased risk for ischemic stroke (Chan, 2004; Lidegaard, 2012). Rates rise significantly for women who have hypertension, who smoke, or who have migraine headaches with visual aura or other focal neurological changes *and* use COCs (MacClellan, 2007; Tepper, 2016b). The evidence for stroke risk in migraineurs without aura is less clear (Etminan, 2005; Schürks, 2009). COC initiation may be considered for women with preexisting migraines without aura if they are otherwise healthy, younger, normotensive nonsmokers. For women with prior stroke, COCs should not be considered to avoid repeat events.

Regarding carbohydrate metabolism, the risk of developing diabetes is not increased with COC use (Kim, 2002). For diabetic women, COCs may be used in nonsmokers with disease duration <20 years and without associated vascular disease, nephropathy, retinopathy, or neuropathy (Curtis, 2016b). In general, COCs raise serum triglycerides and total and HDL cholesterol levels but lower LDL cholesterol concentrations. Last, studies do not support a connection between COCs and weight gain (Gallo, 2014).

Regarding neoplasia, COCs offer a protective effect against ovarian and endometrial cancers (Collaborative Group on Epidemiological Studies of Ovarian Cancer, 2008; Tsilidis, 2011). As an exception, the relative risk of cervical dysplasia and cervical cancer is higher in current COC users, but this declines after use is discontinued. Following 10 or more years, risk returns to that of never users (International Collaboration of Epidemiological Studies of Cervical Cancer, 2007). It is unclear whether COCs contribute to breast cancer development. Major studies show no risk or a small risk among current users, which drops with time following cessation (Collaborative Group on Hormonal Factors in Breast Cancer, 1996; Hannaford, 2007; Marchbanks, 2002).

COCs are not a risk for liver tumors (Heinemann, 1998; Maheshwari, 2007). For women with known tumors, COCs may be used in those with focal nodular hyperplasia, but avoided in those with benign hepatic adenoma and hepatocellular carcinoma (Kapp, 2009c). Rates of colorectal cancer appear to be reduced in ever users (Bosetti, 2009; Luan, 2015).

Of other potential effects, cholestasis and cholestatic jaundice are uncommon and resolve when COCs are discontinued. In women who have active hepatitis, COCs should not be initiated, but these may be continued in women who experience a flare of their liver disease while already taking COCs. Use of progestin-only contraception in these women is not restricted. Moreover, COCs are suitable for women who have recovered. Mild compensated cirrhosis does not limit the use of COCs or progestin-only methods. With severe decompensated disease, all hormonal methods are avoided (Kapp, 2009a).

Chloasma, which is hyperpigmentation of the face and forehead, is more likely in women who demonstrated such a change during pregnancy. This is less common with low-dose estrogen formulations.

Previously, COCs were used to treat functional ovarian cysts. However, data do not support use of current low-dose COC formulations to resolve or prevent these (European Society of Human Reproduction and Embryology, 2001; Grimes, 2014).

Last, many noncontraceptive benefits are associated with COC use (American College of Obstetricians and Gynecologists, 2018). COCs are often selected for these effects, even in those without contraceptive needs. First, dysmenorrhea and heavy menstrual bleeding declines. COCs also elevate hepatic production of sex hormone–binding globulin. This binds bioavailable testosterone to diminish the action of androgens. Thus, conditions such as acne and hirsutism can improve. For women with premenstrual dysphoric disorder, drospirenone-containing COCs can lessen symptoms (Pearlstein, 2005; Yonkers, 2005).

Intravaginal Rings

NuvaRing is a flexible clear intravaginal ring that measures 54 mm in diameter and 4 mm in cross section. Its core releases ethinyl estradiol and etonogestrel, which are absorbed across the vaginal epithelium. *Annovera* is a new ring that releases ethinyl estradiol and segesterone acetate. Colored white, it measures 56 mm in diameter and 8.4 mm in cross section.

For both, the ring is inserted within 5 days of menses onset and, after 3 weeks of use, is removed for 1 week to allow withdrawal bleeding. *Nuvaring* is single use, and after menses, a new ring is placed. In contrast, after removal and washing, the same *Annovera* ring is reinserted for another 3 weeks. One ring can function for 13 such cycles (Nelson, 2019).

With insertion, the ring is compressed and advanced into the vagina, but no specific final orientation within the vagina is

required. Patient satisfaction is high with this method, although vaginitis, ring-related events, and leukorrhea are more common than with COCs (Gemzell-Danielsson, 2019; Oddsson, 2005). A ring may be used concurrently with vaginal medications or with a tampon (Verhoeven, 2004a,b). However, with *Annovera*, miconazole suppositories raised hormone levels. These were not altered with miconazole cream, and thus cream or oral antifungals are preferable (Simmons, 2018). Partners may feel the ring during intercourse (Dieben, 2002). If this is bothersome, the ring may be removed for intercourse but should be replaced within 3 hours for *Nuvaring* and within 2 hours for *Annovera* to maintain efficacy.

Transdermal Patches

The *Ortho Evra* patch and its generic *Xulane* each contain ethinyl estradiol and norelgestromin. A newer patch, *Twirla*, releases ethinyl estradiol and levonorgestrel. Either patch may be applied to the buttocks, upper outer arm, lower abdomen, or upper torso, but the breasts are avoided. Rates of application-site skin reaction are low (Kaunitz, 2015; Smallwood, 2001). If a patch is so poorly adhered that it requires reinforcement with tape, it should be replaced. Women can wear the patch in saunas and whirlpools without decreased efficacy (Abrams, 2001; Archer, 2013). However, with *Twirla*, swimming is limited to 30 minutes.

Initiation of the patch is the same as for COCs, and a new patch is applied weekly for 3 weeks, followed by a patch-free week to allow withdrawal bleeding. In general, the transdermal patches and vaginal rings produce metabolic changes, side effects, and efficacy rates comparable to those with COC pills.

However, the *Ortho Evra* patch has been associated with a higher VTE risk in some but not all studies (Cole, 2007; Jick, 2010; Lidegaard, 2011). Labeling for the patch states that the risk for VTE may be increased compared with COCs, and relative risk estimates range from 1.2 to 2.2. In addition, obesity—90 kg or greater—may be associated with a higher risk for patch contraceptive failure (Zieman, 2002).

In contrast, the LNG-containing patch showed comparable VTE rates compared with COCs in one randomized trial (Kaunitz, 2015). Moreover, efficacy was similar between obese and normal-weight users.

BARRIER METHODS

Male Condom

For many years, male and female condoms, vaginal diaphragms, and periodic abstinence have been used for contraception with variable success. When used properly, condoms provide considerable but not absolute protection against a broad range of STDs, including HIV (Eaton, 2014). Contraceptive efficacy of the male condom is enhanced by a reservoir tip and by the addition of a spermicide. Adjunct lubricant and spermicides should be water-based because oil-based products degrade latex.

For individuals sensitive to latex, condoms made from lamb intestines are effective, but they do not provide infection protection. Instead, nonallergenic condoms made of polyurethane or of synthetic elastomers are available. Polyurethane condoms are effective against STDs but have a higher breakage and slippage rate compared with latex condoms (Gallo, 2015).

Female Condom

The only female condom available in the United States is marketed as the *FC2 Female Condom*. It contains a nitrile sheath and outer ring and a flexible polyurethane inner ring. Its open ring remains outside the vagina, whereas its closed internal ring is fitted under the symphysis like a diaphragm (Fig. 38-3). The inner and outer sheath are covered with silicone-based lubricant, and other-based lubricants can be added. Male condoms should not be used concurrently because simultaneous use creates friction that leads to condom slipping, tearing, and displacement. Following use, the female condom outer ring should be twisted to seal the condom so that no semen spills. As an added value, the female condom may offer some protection against STDs (Minnis, 2005).

Diaphragm plus Spermicide

The diaphragm consists of a latex dome of various diameters supported by a circular latex-covered metal spring. It is effective when used in combination with water-based spermicidal jelly or cream, which is applied into the dome cup and along the device rim. The diaphragm is then positioned so that the cup faces the cervix and the cervix is partitioned effectively from the remainder of the vagina and the penis. In this fashion, the centrally placed spermicide is held against the cervix. When appropriately positioned, one rim is lodged deep in the posterior vaginal fornix, and the opposite rim fits behind the inner surface of the symphysis and immediately below the urethra. If a diaphragm is too small, it will not remain in place. If it is too large, it is uncomfortable when forced into position. Coexistent pelvic organ prolapse typically leads to instability and expulsion. Because size and spring flexibility must be individualized, the diaphragm is fitted by providers and available only by prescription.

The diaphragm and spermicide can be inserted hours before intercourse. If more than 6 hours elapse, the diaphragm can remain but additional spermicide is placed in the vagina for maximum protection. Spermicide is reapplied before each coital episode. The diaphragm is not removed for at least 6 hours after intercourse. Because toxic shock syndrome has been described following its use, it may be worthwhile to remove the diaphragm at 6 hours, or at least the next morning, to minimize this rare event. Diaphragm use is associated with a slightly greater rate of urinary infections, presumably from urethral irritation by the ring under the symphysis.

Cervical Cap

FemCap is the only cervical cap currently available in the United States. Made of silicone rubber, it has a sailor-cap shape with a dome that covers the cervix and a flared brim, which allows the cap to be held in place by the upper vagina's muscular walls. Available in 22-, 26-, and 30-mm sizes, it is used with a spermicide applied once at insertion to both

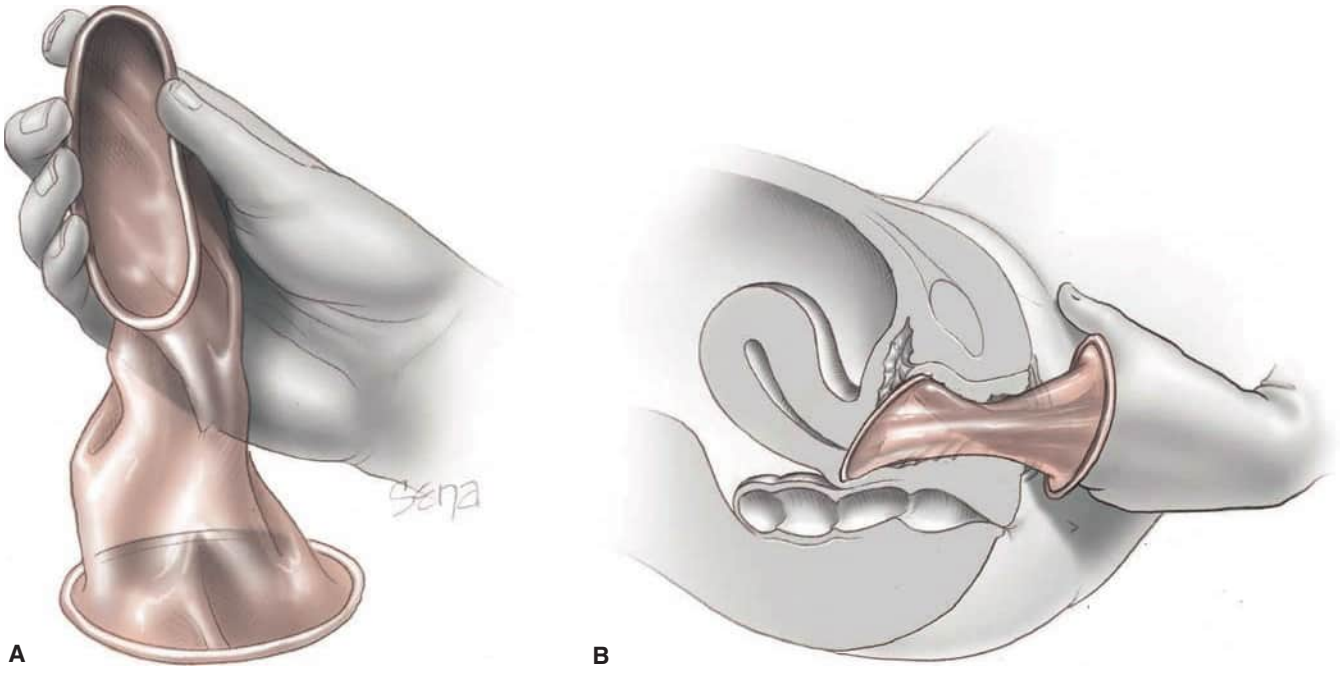

FIGURE 38-3 *FC2 Female Condom* insertion and positioning. **A.** The inner ring is squeezed for insertion. The sheath is inserted similarly to a diaphragm. **B.** The inner ring is pushed inward with an index finger.

sides of the dome cup. For contraception, it should remain in place for 6 hours following coitus and may remain for up to 48 hours. Even with proper fitting and correct use, pregnancy rates with this method are higher than those with the diaphragm (Gallo, 2012).

FERTILITY AWARENESS–BASED METHODS

These attempt to identify the fertile days each cycle and advise sexual abstinence during these days. Fertility awareness–based methods (FABMs) as a group have a 15-percent pregnancy rate with typical use (Trussell, 2018). Some smartphone applications aim to assist these practices (Berglund Scherwitzl, 2017; Jennings, 2019).

The *Standard Days Method* counsels women to avoid unprotected intercourse during cycle days 8 through 19. For successful use, women must have regular monthly cycles of 26 to 32 days. Those who use this method can mark a calendar or can use *Cycle-Beads*, which is a ring of counting beads, to keep track of their days.

The *TwoDay Method* relies on awareness of vaginal wetness, which reflects changes in the amount and quality of cervical mucus at different times in the menstrual cycle. Intercourse is considered safe if a woman did not note mucus on the day of planned intercourse or the day prior.

The *Symptothermal Method* combines changes in cervical mucus—onset of the fertile period; changes in basal body temperature—end of the fertile period; and calculations to estimate ovulation. A sustained 0.4°F rise in the basal body temperature usually precedes ovulation. For maximum efficacy, the woman must abstain from intercourse from the first day of menses through the third day after the temperature increase. Overall, this method is more complex to learn and apply, and it does not appreciably improve efficacy.

SPERMICIDES

Most spermicides contain nonoxynol-9 and are sold over-the-counter as creams, jellies, suppositories, films, and foams. They are a less effective method but provide a chemical spermicidal action and a physical barrier to sperm penetration. Their duration of maximal effectiveness is usually no more than 1 hour, and these do not offer STD protection. If pregnancy does occur, nonoxynol-9 is not teratogenic (Briggs, 2017).

In 2020, a vaginal contraceptive gel containing lactic acid, citric acid, and potassium bitartrate was FDA approved as *Phexxi*. As an acidifying agent, it resists the buffering effect of semen and thereby allows the vagina's normally acidic pH to work as a spermicide (Garg, 2001; Nelson, 2018). This pH effect also has potential as a microbicide, which warrants additional study.

Ideally, either agent is deposited high in the vagina up to 1 hour before coitus. Thereafter, each must be reinserted before repeat intercourse.

■ Contraceptive Sponge

The *Today* contraceptive sponge is an over-the-counter, one-size-fits-all device. The nonoxynol-9–impregnated polyurethane disc is 2.5 cm thick and 5.5 cm wide. One side has a dimple that faces the cervix, and the other has a satin loop for removal. The sponge can be inserted up to 24 hours prior to intercourse, and while in place, it provides contraception regardless of coital frequency. It should remain in place for 6 hours after intercourse. Pregnancy is prevented primarily by the spermicide and to a lesser extent by covering the cervix and absorbing semen.

Although the sponge is possibly more convenient than the diaphragm or condom, it is less effective than either (Kuyoh, 2013). Most common causes for method discontinuance are pregnancy, discomfort, or vaginitis (Beckman, 1989). Although toxic shock syndrome has been reported with the contraceptive sponge, it is rare, and evidence suggests that the sponge may actually limit production of the responsible staphylococcal exotoxin (Remington, 1987). Still, it is recommended that the sponge not be used during menses or the puerperium.

EMERGENCY CONTRACEPTION

Following unprotected sexual intercourse, several emergency contraception (EC) regimens substantially lower the likelihood of an unwanted pregnancy. Current methods include COCs, a progestin, a selective progesterone-receptor modulator (SPRM), and the Cu-IUD (Table 38-7). Notably, the single-dose LNG pill is available over-the-counter without a prescription to all reproductive-aged individuals. Patients can obtain information regarding EC by calling 888-NOT-2-LATE or accessing The Emergency Contraception Website: http://not-2-late.com. Although not yet adopted as EC, early efficacy data find the LNG-IUS not inferior to the Cu-IUD for EC (Turok, 2021).

Hormonal Emergency Contraception

Except for allergy to a particular component, no conditions in the US MEC contraindicate hormonal EC methods. Moreover, clinical examination or pregnancy testing is not required before EC provision (American College of Obstetricians and Gynecologists, 2019c). With all methods, dosing begins as early as possible and ideally within 72 hours of unprotected coitus. It may be given up to 120 hours after coitus (Fine, 2010; Rodrigues, 2001; von Hertzen, 2002).

The major mechanism with all hormonal regimens is inhibition or delay of ovulation. Of oral methods, failure rates are lowest with ulipristal (1 to 2 percent) and greatest with the Yuzpe method (2 to 3.5 percent) (Cleland, 2014). If EC fails to prevent pregnancy or is mistimed, no associations with major congenital malformation or pregnancy complications have been noted with these hormonal methods (Jatlaoui, 2016; Levy, 2014). With EC administration, nausea and vomiting can be an important side effect. Accordingly, an oral antiemetic may be prescribed at least 1 hour before each dose (Rodriguez, 2013). If a woman vomits within 2 hours of a dose, the dose is repeated.

For subsequent coitus, a barrier method is recommended until long-term contraception is begun. If not, EC can be repeated within a given menstrual cycle. Quick start initiation of contraceptive methods is suitable and is discussed in the respective method sections. Notably, because ulipristal competes at the progesterone receptor, a 5-day delay is recommended before starting progestin-containing contraceptives.

Copper-containing Intrauterine Devices

For women who are candidates, Cu-IUD insertion is the most effective EC method and provides an effective 10-year form of contraception. If an IUD is placed up to 5 days after unprotected coitus, the pregnancy rate approximates only 0.1 percent (Cleland, 2012; Wu, 2010).

TABLE 38-7. Emergency Contraception Methods and Some Brand-Name Examples

Method	Formulation	Pills per Dose	Number of Doses[a]
Progestin-only Pill			
Plan B One-Step	1.5 mg LNG	1	1
PRM Pill			
Ella	30 mg ulipristal acetate	1	1
COC Pills[b]			
Ogestrel	50 μg EE + 0.5 mg norgestrel[c]	2	2
Cryselle, Low-Ogestrel	30 μg EE + 0.3 mg norgestrel[c]	4	2
Enpresse (orange), Trivora (pink)	30 μg EE + 0.125 mg LNG	4	2
Levora, Seasonale	30 μg EE + 0.15 mg LNG	4	2
Aviane, LoSeasonique (orange)	20 μg EE + 0.1 mg LNG	5	2
Copper-containing IUD			
Paragard T380A			

[a]Doses taken 12 hours apart.
[b]COCs method, also known as the Yuzpe method, aims to provides a minimum of 100 μg of EE and 0.5 mg of LNG or 1.0 mg of norgestrel in each of the two doses. A listing of other suitable COCs and dosing is found at https://ec.princeton.edu/questions/dose.html#dose.
[c]Norgestrel contains two isomers, and only one of these isomers is bioactive, namely levonorgestrel. Thus, the amount of norgestrel needed for efficacy is twice that of the levonorgestrel-based regimens.
COC = combination oral contraceptive; EE = ethinyl estradiol; IUD = intrauterine device; LNG = levonorgestrel; PRM = progesterone-receptor modulator.

CHAPTER 39

Sterilization

Among women using contraception in the United States, 28 percent rely on either male or female sterilization (Kavanaugh, 2018). Tubal interruption or excision is suitable for those requesting sterilization and who clearly understand its permanence and its difficult and often unsuccessful reversal. Alternative contraceptive choices also should be presented. Ultimately, following provision of information, patient autonomy and her decision for sterilization should be respected (American College of Obstetricians and Gynecologists, 2017, 2019).

Female sterilization is usually accomplished by occlusion, excision, or division of the fallopian tubes. *Puerperal sterilization* procedures follow cesarean or vaginal delivery and approximately 7 percent of all live births in the United States (Moniz, 2017). *Nonpuerperal tubal sterilization* is done at a time unrelated to recent pregnancy and is also termed *interval sterilization*. More recently, consideration of total salpingectomy for sterilization and for ovarian cancer risk reduction is now recommended (p. 682).

PUERPERAL TUBAL STERILIZATION

Timing

Several days postpartum, the uterine fundus lies at the level of the umbilicus, and fallopian tubes are accessible directly beneath the abdominal wall. Moreover, abdominal laxity allows easy repositioning of the incision over each uterine cornu.

On our service, puerperal tubal ligation is performed the morning after delivery by a surgical team designated solely to this role. This timing minimizes hospital stay but lowers the likelihood that postpartum hemorrhage would complicate recovery following surgery. The status of the newborn also can be better ascertained before surgery. In contrast, some prefer to perform sterilization immediately following delivery and use neuraxial analgesia already placed for labor. Designating these postpartum surgeries as nonelective can help lessen barriers. This is especially so for high-volume labor and delivery units, which typically prioritize their limited operating-room availability for intrapartum procedures (American College of Obstetricians and Gynecologists, 2021). From one large series, postpartum tubal ligation was a safe, reasonable option, regardless of body mass index (Byrne, 2020).

Method Selection

In general for postpartum sterilization, a midtubal segment of tube is excised, and the severed ends seal by fibrosis and peritoneal regrowth. Commonly used methods include the Parkland, Pomeroy, and modified Pomeroy techniques. Less often, Filshie clips are used, and evidence points to slightly decreased efficacy (Madari, 2011; Rodriquez, 2011, 2013). Also, in the absence of uterine or other pelvic disease, hysterectomy solely for sterilization is difficult to justify because of its significantly higher risk for surgical morbidity compared with tubal sterilization.

Most pelvic serous cancers are thought to originate from the distal fallopian tube (Erickson, 2013). Because of this, although currently theoretical, evidence suggests that bilateral salpingectomy may lower these ovarian cancer rates (Falconer, 2015; Lessard-Anderson, 2014). With this knowledge, the Society of Gynecologic Oncologists (Walker, 2015) and American College of Obstetricians and Gynecologists (2019b) recommend consideration of salpingectomy to lower these

cancer risks. Specifically, for women at average risk of ovarian cancer, risk-reducing salpingectomy should be discussed and considered with abdominopelvic surgery, with hysterectomy, or in lieu of tubal ligation.

In the discussion of salpingectomy, several points are instructive. First, the lifetime risk for ovarian cancer approximates 1 percent (National Cancer Institute, 2019). Data from epidemiologic studies show that tubal interruption alone offers an approximate 30-percent decline in ovarian cancer rates (Rice, 2012; Sieh, 2013). Salpingectomy may reduce the risk by 42 to 78 percent (Gockley, 2018). However, no prospective studies of sufficient size or duration have yet been done to demonstrate the true risk and benefit ratio for women at low risk of ovarian cancer. Also, few data describe the effects on ovarian reserve from tubal blood supply disruption. In small studies comparing the two surgeries, no differences in antimüllerian hormone levels, which are a measure of ovarian reserve, were found (Findley, 2013; Ganer Herman, 2017). In other comparisons, total salpingectomy at cesarean delivery takes 5 to 10 minutes longer than partial salpingectomy (Ferrari, 2019; Powell, 2017). Blood loss rates are comparable or slightly higher but do not lead to higher transfusion rates or greater postsurgical declines in hematocrit values. Only a few small studies have evaluated salpingectomy following vaginal delivery (Danis, 2016; Powell, 2017).

Technique

Spinal analgesia is typically selected for cases scheduled on the first postpartum day. General anesthesia may be less desirable due to residual pregnancy-related aspiration risks (Bucklin, 2003). If done more proximate to delivery, the same epidural catheter used for labor analgesia can be used for sterilization analgesia. Generally, with thrombocytopenia-related conditions, platelet levels should be >70,000 for spinal blockade (Chap. 25, p. 478). The bladder is emptied before surgery to avoid its laceration. A full bladder can also push the fundus and tubes above the umbilicus and incision. Considered a clean case, antibiotic prophylaxis is not required.

To begin, a small infraumbilical incision is ideal for several reasons. As noted, the fundus in most cases lies near the umbilicus. Second, the umbilicus usually remains the thinnest portion of the anterior abdominal wall and requires less subcutaneous dissection to reach the linea alba fascia. Third, an infraumbilical incision offers fascia with sufficient integrity to provide a closure with minimal risk for later incisional hernia. Last, incisions that follow the natural curve of the lower umbilical skin fold yield suitable cosmesis. A 2- to 3-cm transverse or vertical skin incision is usually sufficient for normal-weight women. For obese women, a 4- to 5-cm incision may be needed for adequate abdominal access.

Beneath this incision, the subcutaneous tissue is bluntly separated to reach the linea alba fascia. For this, an Allis clamp can be opened and closed as downward pressure is exerted. Similarly, the blades of two army-navy retractors both pulling in downward yet opposite directions can part the subcutaneous layer. Clearing this fatty tissue away from the fascia isolates the fascia for incision and for later closure without intervening fat, which may impede wound healing.

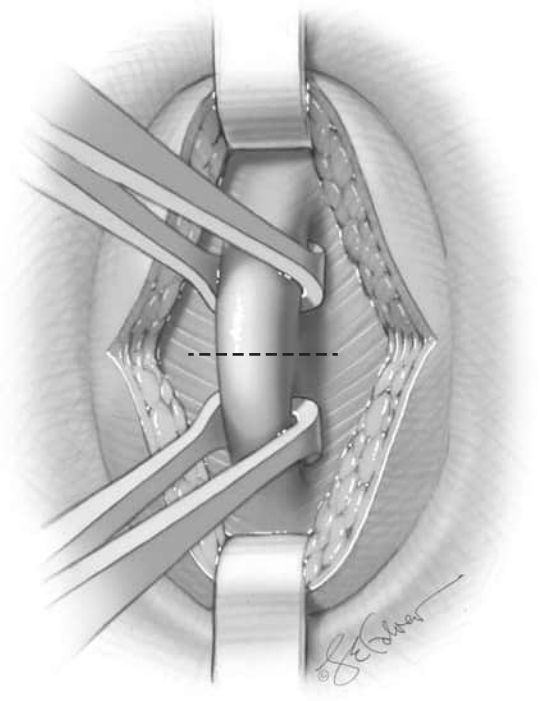

FIGURE 39-1 Fascia is grasped by two Allis clamps and elevated away from viscera beneath. Planned fascial incision is marked by dashed line. (Modified and reproduced with permission from Kho KA: Diagnostic and operative laparoscopy. In Yeomans ER, Hoffman BL, Gilstrap, III, et al [eds]: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

The fascial incision may be transverse or vertical and follows the same orientation of the skin incision. For this, once the linea alba is reached, it is grasped with two Allis clamps—one placed on either side of the planned fascial incision (Fig. 39-1). The purchase of tissue with each clamp should be substantial and creates a small roll of fascia to be incised. Often, the peritoneum is incorporated simultaneously and entered. If not, the peritoneum is grasped with two hemostats and sharply cut. Others may prefer to bluntly enter with a single index finger. Notably, if the initial fascial incision is too small, it can be extended with curved Mayo scissors.

Adequate exposure is critical, and army-navy or appendiceal retractors are suitable. For obese women, a slightly larger incision and narrow deeper retractors may be needed. If bowel or omentum is obstructing, Trendelenburg position can help displace these cephalad. Digitally packing with a single, moist, fanned-out piece of surgical gauze also can be used, but a hemostat should always be attached to the distal end to avert its intraabdominal retention. At times, mechanically tilting the entire table to the opposite side of the tube being exposed also can assist tube isolation.

The fallopian tube is identified and grasped at its midportion with a Babcock clamp. A second slightly more distal clamp grasps the tube, which is similarly lifted. This allows the fimbriated end to be seen. Such confirmation prevents confusing the round ligament for the fallopian tube. A common reason for sterilization failure is ligation of the wrong structure, typically the round ligament. If the tube is inadvertently dropped, it is mandatory to repeat this identification process. Surgical steps for ligation are outlined in Figures 39-2 and 39-3.

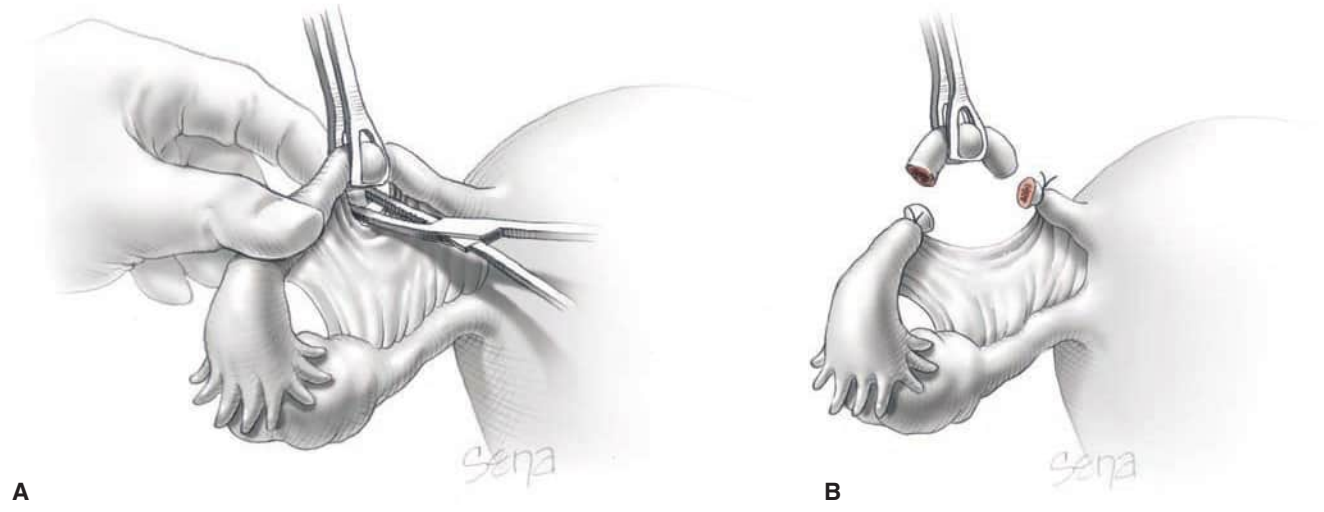

FIGURE 39-2 Parkland method. **A.** An avascular site in the mesosalpinx adjacent to the fallopian tube is perforated with a small hemostat. The jaws are opened to separate the fallopian tube from the adjacent mesosalpinx for approximately 2.5 cm. **B.** The isolated tubal portion is ligated proximally and distally with 0-chromic suture. The intervening segment of approximately 2 cm is excised, and the excision site is inspected for hemostasis. This method was designed to avoid the initial intimate proximity of the cut ends of the fallopian tube inherent with the Pomeroy procedure. (Reproduced with permission from Hoffman BL, Hamid CA, Corton MM: Surgeries for benign gynecologic conditions. In Hoffman BL, Schorge JO, Halvorson LM, et al: Williams Gynecology, 4th ed. New York, NY: McGraw Hill; 2020.)

For total salpingectomy, the umbilical incision generally will need to be larger to allow an adequate view of the tube and mesosalpinx and to place clamps (Fig. 39-4). The entire mesosalpinx must be divided to free the fallopian tube. Thus, risks include bleeding from the often large, congested mesosalpingeal veins, control of which requires extension of the laparotomy incision or even an adnexectomy. Some prefer to use a bipolar electrosurgical coagulation device (LigaSure, ENSEAL), which seals and divides the mesosalpinx simultaneously. This may add speed but also expense.

After surgery, diet is given as tolerated, and walking is encouraged. Ileus is infrequent and should prompt concern for bowel injury, albeit rare. Most women have an uncomplicated course and are discharged on the first postoperative day.

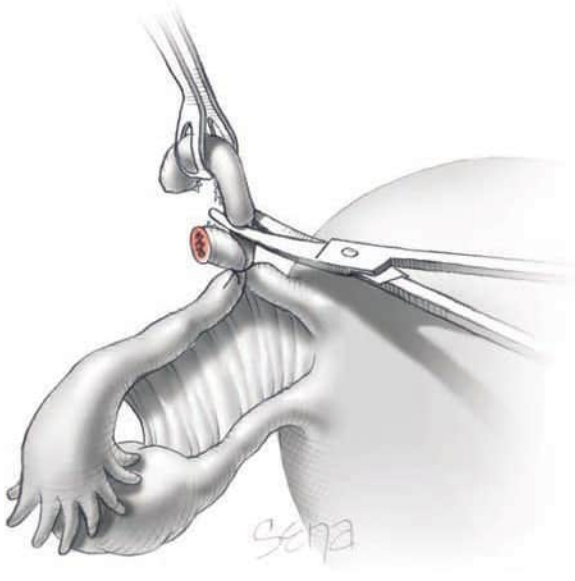

FIGURE 39-3 Pomeroy method. During ligation of a midsegment tubal loop, plain catgut is used to ensure prompt absorption of the ligature and subsequent separation of the severed tubal ends. (Reproduced with permission from Hoffman BL, Hamid CA, Corton MM: Surgeries for benign gynecologic conditions. In Hoffman BL, Schorge JO, Halvorson LM, et al: Williams Gynecology, 4th ed. New York, NY: McGraw Hill; 2020.)

NONPUERPERAL TUBAL STERILIZATION

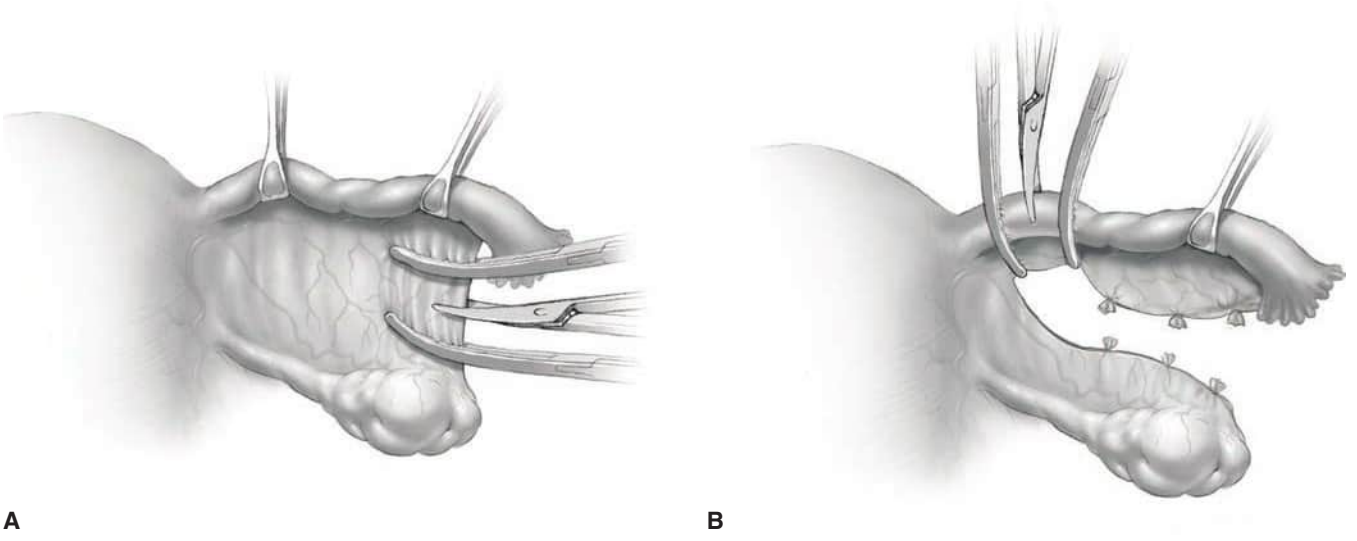
These techniques and other modifications basically consist of (1) ligation and resection at laparotomy as described earlier for puerperal sterilization; (2) application of permanent rings, clips, or inserts to the fallopian tubes by laparoscopy or hysteroscopy; or (3) electrocoagulation of a tubal segment, usually through a laparoscope. A detailed description and illustration of these can be found in *Williams Gynecology*, 4th edition (Kho, 2020).

In the United States, a laparoscopic approach to interval tubal sterilization is the most common. The procedure is frequently performed in an ambulatory surgical setting under general anesthesia. In almost all cases, the patient can be discharged within several hours. Minilaparotomy using a 3-cm suprapubic incision also is popular, especially in resource-poor countries. Major morbidity is rare with either minilaparotomy or laparoscopy. Although not often used, the peritoneal cavity can be entered through the posterior vaginal fornix via colpotomy to perform tubal interruption.

LONG-TERM COMPLICATIONS

Contraceptive Failure

Pregnancy following sterilization is infrequent. The Collaborative Review of Sterilization (CREST) study followed 10,863 women



A B

FIGURE 39-4 A. With salpingectomy, the mesosalpinx is sequentially clamped, cut, and ligated. **B.** At the cornu, clamps are placed across the fallopian tube and its adjacent mesosalpinx prior to tubal transection. (Reproduced with permission from Stuart GS: Puerperal sterilization. In Yeomans ER, Hoffman BL, Gilstrap, III, et al [eds]: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

who had undergone tubal sterilization from 1978 through 1986 (Peterson, 1996). The cumulative failure rate for the various tubal procedures was 18.5 per 1000 or approximately 0.5 percent. The study found puerperal sterilization to be highly effective. The 5-year failure rate was 5 per 1000, and at 12 years, it was 7 per 1000.

Puerperal sterilization fails for two major reasons. First, surgical errors include transection of the round ligament or only partial transection of the tube. For this reason, both tubal segments are submitted for pathological confirmation. Second, a fistulous tract or spontaneous reanastomosis may form between the severed tubal stumps.

Approximately 30 percent of pregnancies that follow failed tubal sterilization are ectopic. This rate is 20 percent for those following a postpartum procedure (Peterson, 1996, 1997). Thus, any symptoms of pregnancy in a woman after tubal sterilization must be investigated to exclude ectopic pregnancy.

Other Effects

Women who have undergone tubal sterilization are highly unlikely to subsequently have salpingitis (Levgur, 2000). Most studies also find that rates of heavy menstrual or intermenstrual bleeding are not increased following the procedure (DeStefano, 1985; Peterson, 2000; Shy, 1992). Moreover, in the CREST study, Costello (2002) found that tubal ligation did not change sexual interest or pleasure in 80 percent of women. In most of the 20 percent of women who did report a change, positive effects were 10 to 15 times more likely.

Invariably, some women express regrets regarding sterilization, and this is especially true if it is performed at a younger age (Curtis, 2006; Kelekçi, 2005). In the CREST study, Jamieson (2002) reported that 7 percent of women who had undergone tubal ligation had regrets by 5 years. This is not limited to their own sterilization, because 6.1 percent of women whose husbands had undergone vasectomy had similar regrets.

Tubal Sterilization Reversal

No woman should undergo tubal sterilization believing that subsequent fertility is guaranteed either by surgery or by assisted reproductive technologies. Both approaches are technically difficult, expensive, and not always successful. In general, pregnancy rates after tubal reversal favor women with 7 cm of remaining tube, with age younger than 35 years, with a short time from antecedent sterilization, and with isthmic–isthmic repairs. With reanastomosis via laparotomy, rates of live births range from 44 to 82 percent (Deffieux, 2011; Malacova, 2015). The rate of ectopic pregnancy is 2 to 10 percent after reanastomosis (American Society for Reproductive Medicine, 2015). With reanastomosis to reverse *Essure* sterilization, the subsequent live birth rates range from 0 to 27 percent (Fernandez, 2014; Monteith, 2014).

TRANSCERVICAL STERILIZATION

A transcervical approach to reach the tubal ostia can be used for sterilization. However, no methods using this approach are currently approved in the United States.

Mechanical methods employ insertion of a device into the proximal fallopian tubes via hysteroscopy. Both the Essure system and the Adiana Permanent Contraception system have been removed from the U.S. market. The Adiana is a cylindrical, nonabsorbent silicone elastomer matrix that once inserted stimulates tissue ingrowth to occlude the tubal lumen (Hologic, 2012).

The Essure Permanent Birth Control System is a long, slender, coiled, metallic tubal insert. Once placed, fibroblastic proliferation within the device similarly causes tubal occlusion. With this method, contraceptive failure rates range from <1 percent to 5 percent (Gariepy, 2014; Munro, 2014).

Chronic pelvic pain after hysteroscopic sterilization may develop in 2 to 6 percent of those with Essure inserts (Chudnoff, 2015; Kamencic, 2016; Yunker, 2015). Pain may stem

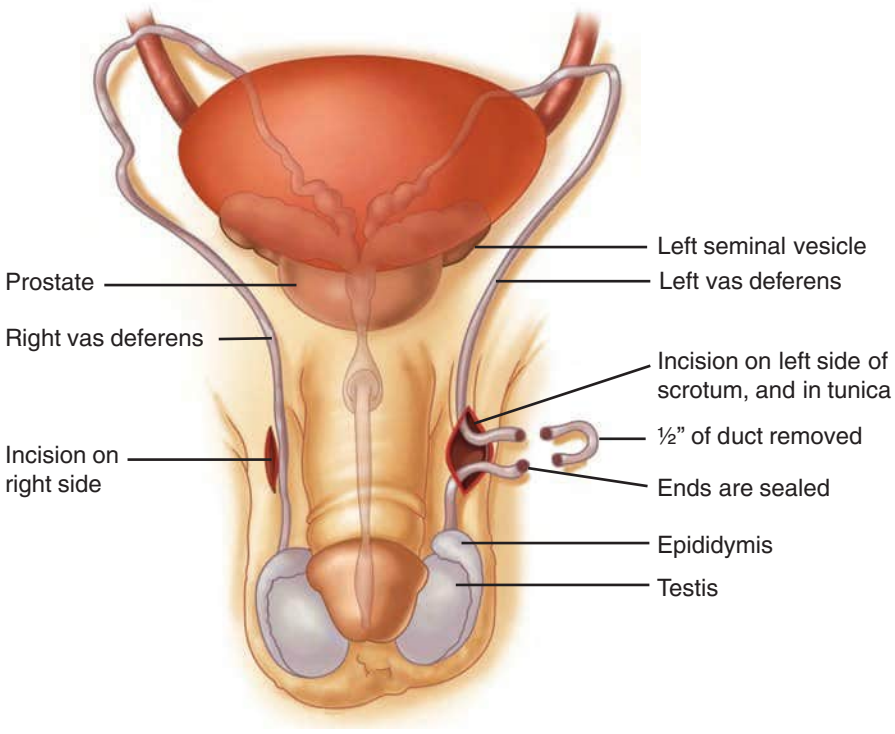


FIGURE 39-5 Anatomy of male reproductive system showing procedure for vasectomy.

from tubal perforation, device migration, or the device itself (Adelman, 2014). For those desiring removal, proximal linear salpingostomy and device removal is feasible (Kho, 2020). Importantly, device removal is not curative in all symptomatic patients (Clark, 2017; Maassen, 2019). Other cited adverse events include abnormal bleeding and allergy or hypersensitivity reaction to its components (Al-Safi, 2013; Mao, 2015).

Chemical agents may also be placed into the uterine cavity or tubal ostia to incite an inflammatory response to cause tubal occlusion. Used in lower-resource areas, one method employs an intrauterine device–type inserter to place quinacrine pellets into the uterine fundus. From randomized trials, pregnancy rates were 1 and 12 percent at 1 and 10 years, respectively (Sokal, 2008). The World Health Organization (2009) has recommended against quinacrine use because of carcinogenesis concerns. Evidence is contradictory, and some consider it a potential option for resource-poor countries (Lippes, 2015).

VASECTOMY

Currently, up to a half million men in the United States undergo vasectomy each year (Barone, 2006; Eisenberg, 2010). And, 5 percent of women rely on this method for contraception (Daniels, 2015). For sterilization, the vas deferens lumen is disrupted to block the passage of sperm from the testes (Fig. 39-5).

Vasectomy is safer than female tubal sterilization because it is less invasive and is performed with local analgesia (American College of Obstetricians and Gynecologists, 2019a). In a review that compared the two, female tubal sterilization had a 20-fold higher complication rate and a 10- to 37-fold higher failure rate (Hendrix, 1999).

One disadvantage is that sterilization following vasectomy is not immediate. Sperm stored in the reproductive tract beyond the interrupted vas deferens takes approximately 3 months or 20 ejaculations for complete release. The American Urological Association recommends a postprocedural semen analysis at 8 to 16 weeks to document sterility (Sharlip, 2012). Before azoospermia is documented, another form of contraception should be used.

The failure rate for vasectomy during the first year is 9.4 per 1000 procedures but only 11.4 per 1000 at 2, 3, and 5 years (Jamieson, 2004). Failures result from unprotected intercourse too soon after ligation, incomplete vas deferens occlusion, or recanalization (Awsare, 2005; Deneux-Tharaux, 2004).

Reanastomosis of the vas deferens can be completed most effectively using microsurgical techniques. Conception rates following reversal are adversely affected by longer duration from vasectomy, poor sperm quality found at reversal, and type of reversal procedure required (American Society for Reproductive Medicine, 2008).

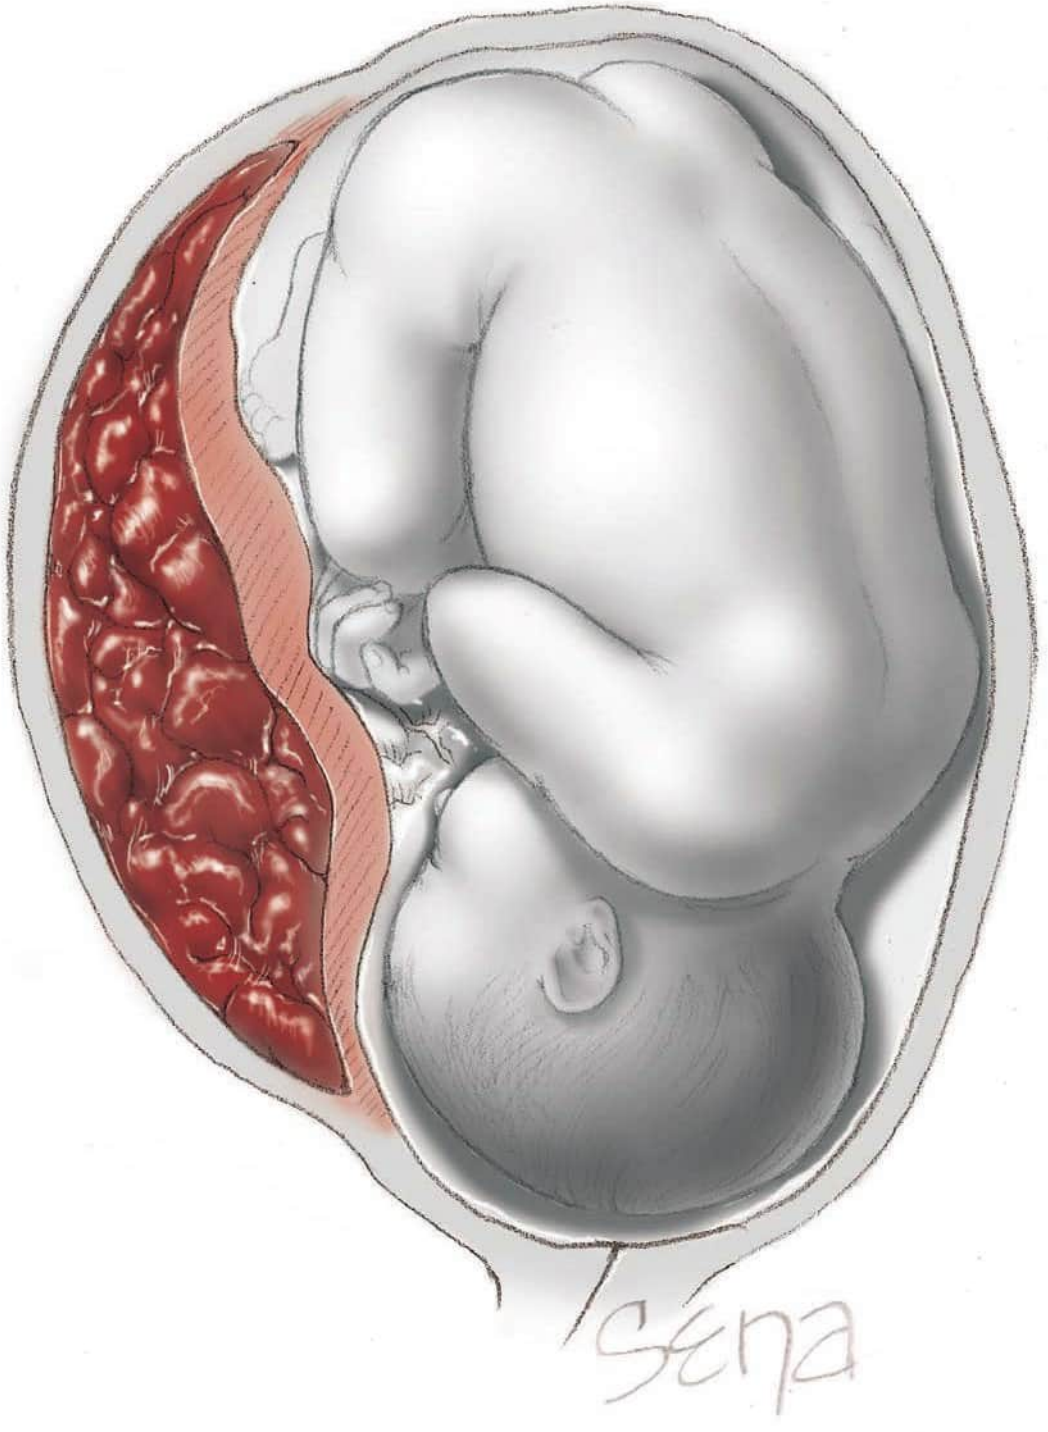
SECTION 11

OBSTETRICAL COMPLICATIONS



CHAPTER 40

Preeclampsia Syndrome

Hypertensive disorders include preeclampsia, gestational hypertension, and chronic hypertension and complicate up to 10 percent of pregnancies. As a group, they are one member of the deadly triad—along with hemorrhage and infection—that contributes greatly to maternal morbidity (Judy, 2019).

Preeclampsia, either alone or superimposed on chronic hypertension, is the most dangerous. In the United States from 2011 to 2015, 7 percent of pregnancy-related maternal deaths were caused by preeclampsia or eclampsia (Petersen, 2019). Most hypertension-related deaths are deemed preventable (Katsuragi, 2019). In response, Joint Commission (2019) accredited hospitals are now required to track their recognition and timely treatment of hypertension.

In 2018, a workshop to study preeclampsia was convened by the National Heart, Lung, and Blood Institute. This builds on the prior work of the American College of Obstetricians and Gynecologists' Task Force on Hypertension in Pregnancy (2013). Its purpose was to review topics regarding all aspects of preeclampsia and to recommend future research areas. Many of these topics are discussed throughout this chapter and Chapter 41.

TERMINOLOGY AND DIAGNOSIS

To codify the classification of hypertensive disorders of pregnancy, the American College of Obstetricians and Gynecologists (2013, 2020) describes four types of hypertensive disease:

1. Preeclampsia and eclampsia syndrome
2. Chronic hypertension of any etiology
3. Preeclampsia superimposed on chronic hypertension
4. Gestational hypertension, in which definitive evidence for the preeclampsia syndrome does not develop and hypertension resolves by 12 weeks postpartum.

This classification aims to differentiate preeclampsia syndrome, which is potentially more ominous, from other hypertensive disorders.

Diagnosis of Hypertensive Disorders

Hypertension is diagnosed empirically when systolic and diastolic blood pressures exceed 140 mm Hg and 90 mm Hg, respectively. Korotkoff phase V is used to define diastolic pressure.

Previously for pregnant women, increases of 30 mm Hg systolic or 15 mm Hg diastolic above blood pressure values taken at midpregnancy had also been used as diagnostic criteria, even when absolute values were <140/90 mm Hg. These incremental changes are no longer used to define hypertension. However, blood pressure surveillance in these gravidas is reasonable because eclamptic seizures develop in some whose blood pressures have stayed below 140/90 mm Hg (Alexander, 2006).

In other cases, mean arterial pressures that suddenly rise but that still lie in normal range—"delta hypertension"—may signify preeclampsia (Macdonald-Wallis, 2012; Zeeman, 2007). We use this term to describe a relatively acute rise in blood pressure in individual patients, albeit some still with pressures <140/90 mm Hg (Fig. 40-1). Some of these

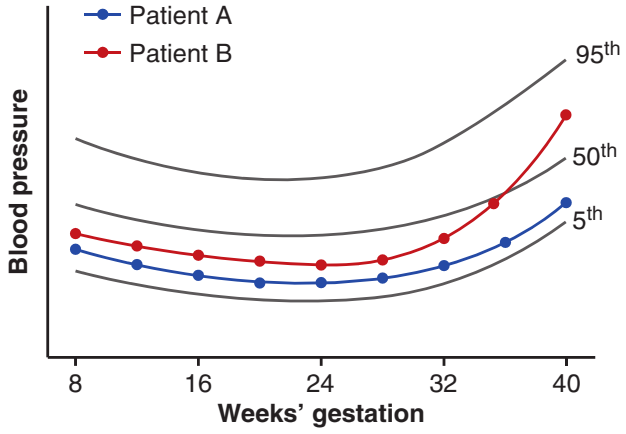


FIGURE 40-1 Schematic of normal reference ranges for mean arterial blood pressure changes across pregnancy. Patient A (*blue*) has mean blood pressures near the 20th percentile throughout pregnancy. Patient B (*red*) has a similar pattern with mean pressures at the 25th percentile until approximately 36 weeks' gestation, at which time her blood pressure begins to rise. By term, it is substantively higher and in the 75th percentile, but she is still considered "normotensive." This increase from the 25th to 75th percentile can be termed "delta hypertension."

women will go on to have obvious preeclampsia, and some even develop eclamptic seizures or hemolysis, elevated liver enzyme levels, and low platelet count (HELLP) syndrome.

Historically, systolic and diastolic blood pressure levels of 140/90 mm Hg have been arbitrarily used since the 1950s to define "hypertension" in nonpregnant individuals. However, these levels were selected by insurance companies to characterize a population of middle-aged men. It seems more realistic to define normal-range blood pressures for specific populations—such as young, healthy, pregnant women (Lu, 2019; Reddy, 2020). To provide such data, >1000 women were recently studied longitudinally through pregnancy (Green, 2020). Data of this type may shape future thresholds.

Gestational Hypertension

Women with gestational hypertension have blood pressures that reach 140/90 mm Hg or greater for the first time after midpregnancy but lack proteinuria. Almost half of affected women subsequently develop preeclampsia (Jim, 2017). Even so, when blood pressure rises appreciably, it is dangerous to both mother and fetus to ignore this elevation only because proteinuria has not yet developed (Fishel Bartal, 2020). As Chesley (1985) emphasized, 10 percent of eclamptic seizures develop before overt proteinuria can be detected. Gestational hypertension is reclassified by some as *transient hypertension* if preeclampsia does not develop and blood pressure returns to normal by 12 weeks postpartum.

Preeclampsia Syndrome

Preeclampsia is best described as a pregnancy-specific syndrome that can affect virtually every organ system. Although preeclampsia is more than simply gestational hypertension with proteinuria, the appearance of protein remains a primary diagnostic criterion. It is an objective marker and reflects the system-wide endothelial leak that characterizes the preeclampsia syndrome. Last, preeclampsia can be divided into early onset, <34 weeks; late onset, ≥34 weeks; preterm onset, <37 weeks; and term onset, ≥37 weeks (Burton, 2019; Poon, 2019).

In some women with preeclampsia, neither overt proteinuria nor fetal-growth restriction are features (Sibai, 2009). Because of this, the Task Force (2013) suggests other diagnostic criteria, some of which are shown in Table 40-1. Multiorgan involvement may be reflected by thrombocytopenia, renal dysfunction, hepatocellular necrosis, central nervous system perturbations, or pulmonary edema.

The markers listed in Table 40-1 help also to classify preeclampsia syndrome severity. Although many use a dichotomous "mild" and "severe" classification, the Task Force (2013) discourages the use of "mild preeclampsia." It is problematic

TABLE 40-1. Classification and Diagnosis of Pregnancy-Associated Hypertension

Condition	Criteria Required
Gestational hypertension	BP >140/90 mm Hg after 20 weeks in previously normotensive women
Preeclampsia: Hypertension plus	
Proteinuria	≥300 mg/24h, or Urine protein: creatinine ratio ≥0.3, or Dipstick 1+ persistent[a]
	or
Thrombocytopenia	Platelets <100,000/μL
Renal insufficiency	Creatinine >1.1 mg/dL or doubling of baseline[b]
Liver involvement	Serum transaminase levels[c] twice normal
Cerebral symptoms	Headache, visual disturbances, convulsions
Pulmonary edema	—

[a]Recommended only if sole available test.
[b]No prior renal disease.
[c]Aspartate transaminase (AST) or alanine transaminase (ALT).
BP = blood pressure.

TABLE 40-2. Indicators of Severity of Gestational Hypertensive Disorders[a]

Abnormality	Nonsevere[b]	Severe
Diastolic BP	<110 mm Hg	≥110 mm Hg
Systolic BP	<160 mm Hg	≥160 mm Hg
Proteinuria[c]	None to positive	None to positive
Headache	Absent	Present
Visual disturbances	Absent	Present
Upper abdominal pain	Absent	Present
Oliguria	Absent	Present
Convulsion (eclampsia)	Absent	Present
Serum creatinine	Normal	Elevated
Thrombocytopenia (<100,000/μL)	Absent	Present
Serum transaminase elevation	Minimal	Marked
Fetal-growth restriction	Absent	Present
Pulmonary edema	Absent	Present
Gestational age	Late	Early

[c]Most disregard degrees of proteinuria to classify as nonsevere or severe.
BP = blood pressure.

that there are criteria for the diagnosis of "severe" preeclampsia, but the binary default classification is either implied or specifically termed "mild," "less severe," or "nonsevere" (Alexander, 2003; Lindheimer, 2008). No consensus criteria define "moderate" preeclampsia, which is an elusive third category. We use the criteria recommended by the American College of Obstetricians and Gynecologists (2020), some of which are listed in Table 40-2 and categorize disease as "severe" versus "nonsevere."

Some symptoms are considered ominous. *Headaches* or *visual disturbances* can precede *eclampsia*, which is a convulsion in a woman with preeclampsia that is not attributable to another cause. The seizures are generalized and may appear before, during, or after labor. The proportion that develops seizures later—after 48 hours postpartum—approximates 10 percent (Sibai, 2005; Zwart, 2008). Another symptom, *epigastric or right upper quadrant pain*, frequently accompanies hepatocellular necrosis, ischemia, and hepatic edema. Elevated serum hepatic transaminase levels can be one marker. Last, *thrombocytopenia* also signifies worsening preeclampsia. It represents platelet activation and aggregation and microangiopathic hemolysis. Other factors indicative of severe preeclampsia include renal or cardiac involvement. When these signs and symptoms are profound, they likely cannot be temporized, and delivery will more likely be required. Importantly, differentiating nonsevere and severe gestational hypertension or preeclampsia can be misleading because what might be apparently mild disease may progress rapidly to severe disease.

Preeclampsia Superimposed on Chronic Hypertension

Any chronic hypertensive disorder predisposes a woman to develop superimposed preeclampsia syndrome. Chronic underlying hypertension is diagnosed in women with documented blood pressures ≥140/90 mm Hg before pregnancy or before 20 weeks' gestation, or both. Thus, in women who are not first seen until after midpregnancy, hypertensive disorders can be difficult to classify. For example, a woman with previously undiagnosed chronic vascular disease who is seen before 20 weeks frequently has blood pressures within normal range. During the third trimester, however, as blood pressures return to their originally hypertensive levels, it may be difficult to determine whether hypertension is chronic or induced by pregnancy. Even a careful search for evidence of preexisting end-organ damage may be futile, as many of these women have mild disease and no evidence of ventricular hypertrophy, retinal vascular changes, or renal involvement.

In 20 to 50 percent of women with chronic hypertension, blood pressure rises to obviously abnormal levels, typically after 24 weeks' gestation. If new-onset or worsening baseline hypertension is accompanied by new-onset proteinuria or other findings listed in Table 40-1, superimposed preeclampsia is diagnosed (American College of Obstetricians and Gynecologists, 2019a). Compared with "pure" preeclampsia, superimposed preeclampsia commonly develops earlier in pregnancy. It tends to be more severe and more often is accompanied by fetal-growth restriction. The same criteria shown in Table 40-2 also further characterize the severity of superimposed preeclampsia.

INCIDENCE AND RISK FACTORS

Preeclampsia is identified in 5 to 8 percent of all pregnancies (Jim, 2017; Poon, 2019). Young and nulliparous women are particularly vulnerable, whereas older women are at greater risk for chronic hypertension with superimposed preeclampsia (Sheen, 2020). In one review of global studies, the incidence of preeclampsia in nulliparas ranged from 3 to 10 percent (Staff, 2015). In multiparas, the incidence ranges from 2 to 5 percent (Jim, 2017; Poon, 2019).

The incidence of preeclampsia is also influenced by race, ethnicity, and genetic predisposition. In one study by the Maternal–Fetal Medicine Units (MFMU) Network, the incidence of preeclampsia was 5 percent in white, 9 percent in Hispanic, and 11 percent in African American nulliparas (Myatt, 2012a,b). In addition, black women carry higher risk for associated severe adverse outcomes (Gyamfi-Bannerman, 2020).

For several clinical factors, Bartsch and associates (2016) extracted data from more than 25 million pregnancies and calculated relative risks (Table 40-3). Major risks include older age, nulliparity, obesity, diabetes, and chronic hypertension. Another is preeclampsia and especially HELLP syndrome in a prior pregnancy (Malström, 2020). Underlying metabolic syndrome, hyperhomocysteinemia, or chronic kidney disease are others (Masoudian, 2016; Wiles, 2020).

Of lesser factors, human immunodeficiency virus (HIV) seropositivity, sleep-disordered breathing, and a male fetus

TABLE 40-3. Selected Clinical Risk Factors for Preeclampsia

Risk Factor	Pooled Unadjusted Relative Risk[a]
Nulliparity	2.1 (1.9–2.4)
Age >35	1.2 (1.1–1.3)
BMI >30	2.8 (2.6–3.1)
Multifetal gestation	2.9 (2.6–3.1)
Prior abruption	2.0 (1.4–2.7)
Diabetes	3.7 (3.1–4.3)
Prior preeclampsia	8.4 (7.1–9.9)
CHTN	5.1 (4.0–6.5)
Prior stillbirth	2.4 (1.7–3.4)
Chronic kidney disease	1.8 (1.5–2.1)
ART	1.8 (1.6–2.1)
SLE	2.5 (1.0–6.3)
APA	2.8 (1.8–4.3)

[a]95% confidence interval.
APA = antiphospholipid antibody; ART = assisted reproductive technology; BMI = body mass index; CHTN = chronic hypertension; SLE = systemic lupus erythematosus.

pose a slightly higher risk (Facco, 2017; Jaskolka, 2017; Sansone, 2016). Previously affected family members are another, and maternal and fetal genetics are assuming greater predictive importance (Burton, 2019; Gray, 2018; Phipps, 2019). Last, preeclampsia frequently complicates the "mirror syndrome" (Chap. 18, p. 364) (Trad, 2021). Although smoking during pregnancy causes various adverse pregnancy outcomes, ironically, it lowers the risk for hypertension during pregnancy.

For eclampsia, seizure incidence has declined in areas where health care is more readily available. In countries with adequate resources, the incidence averages 1 case in 2000 to 3000 deliveries (Jaatinen, 2016; O'Connor, 2013; Schaap, 2019). At Parkland Hospital, the incidence has declined appreciably during the past decade and approximates 1 case in 2000 births (Fig. 40-2). This frequency may be related to improved access to prenatal care and our active management approach (Chap. 41, p. 717).

ETIOPATHOGENESIS

The mechanisms by which pregnancy incites or aggravates hypertension remain unsolved. Any satisfactory theory concerning the origins of preeclampsia must account for the observation that gestational hypertensive disorders are more likely to develop in women with the following characteristics:

- Exposure to chorionic villi for the first time
- Exposure to a superabundance of chorionic villi, as with twins or hydatidiform mole
- Preexisting conditions associated with endothelial cell activation or inflammation
- Genetic predisposition to hypertension developing during pregnancy.

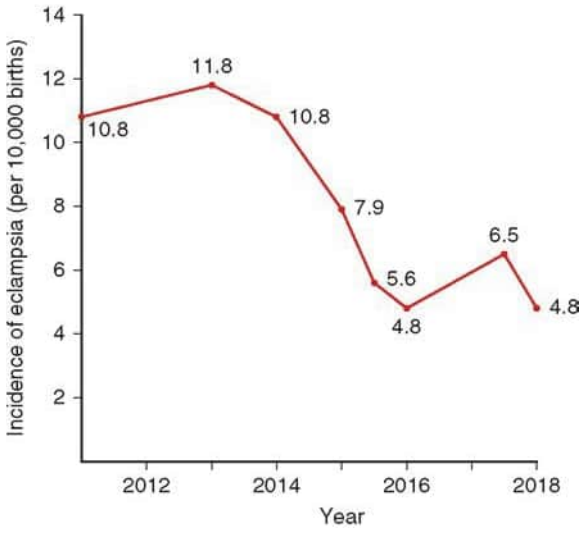

FIGURE 40-2 Incidence of eclampsia per 10,000 deliveries at Parkland Hospital ($p < 0.05$ for trend).

A fetus is not a requisite for preeclampsia to develop. Although chorionic villi are essential, they need not be intrauterine. For example, preeclampsia can develop with an advanced abdominal pregnancy (Worley, 2008). Regardless of precipitating etiology, the cascade of promoting events leads to systemic vascular endothelial damage, vasospasm, plasma transudation, and ischemic and thrombotic sequelae.

Phenotypic Expression

This varies widely for preeclampsia, and phenotype is affected by the degree of remodeling of uterine spiral arterioles by endovascular trophoblasts. This process underlies the "two-stage disorder" theory of preeclampsia pathogenesis. According to Redman and coworkers (2015), stage I—the placental syndrome—is caused by faulty endovascular trophoblastic remodeling that downstream causes stage II—the maternal syndrome. Importantly, stage II can be modified by maternal conditions that also manifest endothelial cell activation or inflammation. These include chronic hypertension, renal disease, obesity, immunological or connective tissue disorders, and diabetes.

Such staging is artificial, and preeclampsia syndrome presents a spectrum of disease (Burton, 2019). Moreover, "isoforms" likely exist and are discussed subsequently. Differences include maternal and fetal characteristics, placental findings, genetic factors, and early- versus late-onset disease (Gray, 2018; Phipps, 2019; Poon, 2019).

Etiology

Of suggested mechanisms to explain the cause of preeclampsia, primary ones include:

- Placental implantation with abnormal trophoblastic invasion of uterine vessels
- Dysfunctional immunological tolerance between maternal, paternal (placental), and fetal tissues

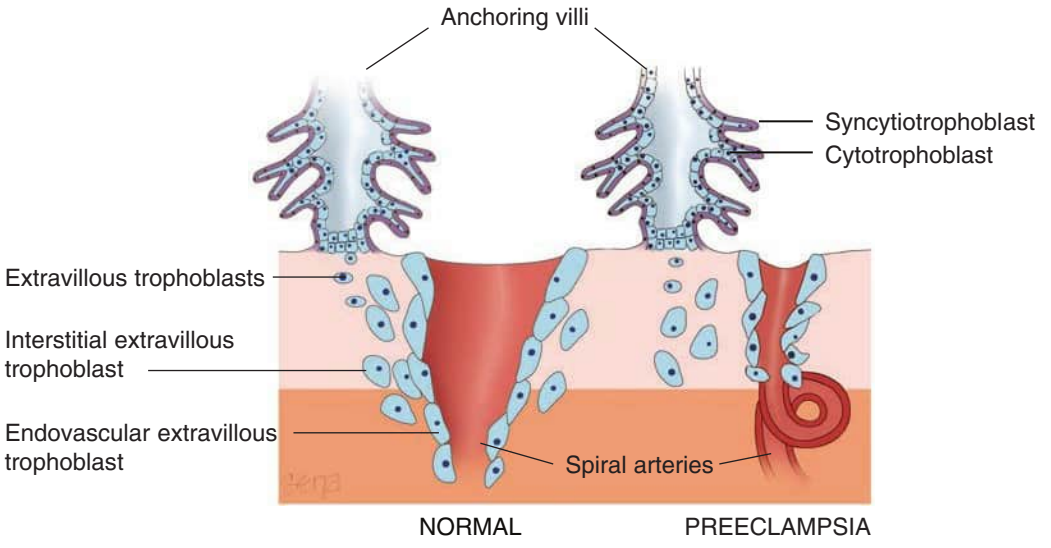

FIGURE 40-3 Schematic representation of normal placental implantation shows proliferation of extravillous trophoblasts from an anchoring villus. These trophoblasts invade the decidua and extend into the walls of the spiral arteriole to replace the endothelium and muscular wall to create a dilated low-resistance vessel. With preeclampsia, there is defective implantation characterized by incomplete invasion of the spiral arteriolar wall by extravillous trophoblasts. This results in a small-caliber vessel with high resistance to flow.

- Maternal maladaptation to cardiovascular or inflammatory changes of normal pregnancy
- Genetic factors that include predisposing genes and epigenetic influences.

Stage I—Placental Syndrome

Normal placental implantation, as discussed in Chapter 5 (p. 90), is characterized by extensive remodeling of the spiral arterioles within the decidua basalis (Fig. 40-3). In this "placental bed," endovascular trophoblasts replace the vascular endothelial and muscular linings. This advantageously enlarges arteriole diameter (Brosens, 2019). Veins are invaded only superficially. In some preeclampsia cases, but not all, trophoblastic invasion may be incomplete. With this, decidual vessels, but not myometrial vessels, become lined with endovascular trophoblasts. The deeper myometrial arterioles thus do not lose their endothelial lining and musculoelastic tissue. As a result, their mean external diameter is only half that of corresponding vessels in normal placentas (Fisher, 2015). This mechanism is more prevalent in women with early-onset preeclampsia (Khodzhaeva, 2016). Evidence suggests a critical role for soluble antiangiogenic growth factors in this faulty endovascular remodeling (McMahon, 2014).

From placental electron microscopy studies, early preeclamptic changes include endothelial damage, insudation of plasma constituents into vessel walls, myointimal cell proliferation, and medial necrosis (De Wolf, 1980). Hertig (1945) referred to lipid accumulation in myointimal cells and macrophages as *atherosis*. These findings are more common in placentas from women diagnosed with preeclampsia before 34 weeks' gestation (Nelson, 2014). Acute placental vascular atherosis may also identify a group of women at greater risk for atherosclerosis and cardiovascular disease later in life (Staff, 2015) (Chap. 41, p. 726). In pregnancy, abnormally narrow spiral arteriole lumens likely impair placental blood flow, reduce perfusion, and create a hypoxic environment (Burton, 2019).

At this point, these changes incite a systemic inflammatory response, which is stage II or the maternal syndrome. Defective placentation is posited to further predispose affected women to gestational hypertension, preeclampsia syndrome, preterm delivery, fetal growth-restriction, and placental abruption (Brosens, 2019; Labarrere, 2017; Nelson, 2014).

Immunological Factors

Maternal immune tolerance to paternally derived placental and fetal antigens is discussed in Chapter 5 (p. 85). Loss of this tolerance is another cited theory for preeclampsia (Erlebacher, 2013). Certainly, histological changes at the maternal–placental interface in those with preeclampsia suggest acute graft rejection.

Tolerance dysregulation might also explain the elevated risk when the paternal antigenic load is increased. One example is complete molar pregnancies, which have diploid complement of chromosomes solely from the father. Those with later-stage moles, have a high incidence of early-onset preeclampsia.

Women with a trisomy 13 fetus also have a 30- to 40-percent incidence of preeclampsia. The gene for one preeclampsia-linked factor, *soluble fms-like tyrosine kinase 1*, is on chromosome 13 (Bdolah, 2006). These women have elevated serum levels of antiangiogenic factors, which can affect the placenta (p. 694). Last, women previously exposed to paternal antigens, such as a prior pregnancy with the same partner, may be "immunized" against preeclampsia. Conversely, multiparas impregnated by a new partner have a greater risk of preeclampsia (Mostello, 2002).

Burton and colleagues (2019) reviewed the possible role of immune maladaptation in preeclampsia pathophysiology. In women destined to have preeclampsia, extravillous trophoblasts early in pregnancy express reduced amounts of immunosuppressive nonclassic human leukocyte antigen G (HLA-G). Black women more commonly have the 1597ΔC gene allele,

which is associated with incomplete HLA-G expression and may predispose to preeclampsia (Loisel, 2013). This immune maladaptation may contribute to the defective placental vascularization seen with preeclampsia.

As discussed in Chapter 4 (p. 61), T-helper (Th) lymphocytes during normal pregnancy are produced so that type 2 activity is increased in relation to type 1. This is the so-called *type 2 bias* (Phipps, 2019; Redman, 2015). Th2 cells promote humoral immunity, whereas Th1 cells stimulate inflammatory cytokine secretion (Ma, 2019). Beginning in the early second trimester in women who develop preeclampsia, Th1 action is increased.

Genetic Factors

Preeclampsia appears to be a multifactorial, polygenic disorder. In one study of almost 1.2 million Swedish births, a genetic association was found for gestational hypertension and for preeclampsia (Nilsson, 2004). Ward and Taylor (2015) cite an incident risk for preeclampsia of 20 to 40 percent for daughters of preeclamptic mothers; 11 to 37 percent for sisters of preeclamptic women; and 22 to 47 percent for twins. Ethnoracial factors are important and evidenced by the high incidence of preeclampsia in African American women. Latina women have a lower incidence because of interactions of American Indian and white race genes (Shahabi, 2013).

The hereditary predisposition for preeclampsia likely stems from interactions of literally hundreds of inherited genes—both maternal and paternal—that control many enzymatic and metabolic functions throughout every organ system (Burton, 2019; Triche, 2014). Plasma-derived factors may induce some of these genes in preeclampsia (Leseva, 2020; Mackenzie, 2012). Thus, the clinical manifestation in any given woman with the preeclampsia syndrome will reflect a spectrum. In this regard, phenotypic expression will differ among similar genotypes depending on interactions with environmental components (Yang, 2013).

Hundreds of genes have been studied for their possible association with preeclampsia (Buurma, 2013; Sakowicz, 2016; Ward, 2015). However, because of the complex phenotypic expression of preeclampsia, it is doubtful that any one candidate gene will be found responsible. Last, a preeclampsia predisposition has also been linked to genes of the fetus (Burton, 2019; Gray, 2018; Leseva, 2020).

■ Stage II—Maternal Syndrome

Endothelial Cell Activation

Inflammatory changes are believed to be a continuation of the placental syndrome. In response to ischemia or other inciting causes, placental factors are released and initiate a series of events (Burton, 2019; Davidge, 2015). Thus, antiangiogenic and metabolic factors and other inflammatory leukocyte mediators are thought to provoke the systemic *endotheliopathy*, which is used synonymously here with *endothelial cell activation or dysfunction*. Injury to systemic endothelial cells is seen as a centerpiece of preeclampsia pathogenesis (Burton, 2019; Phipps, 2019).

Cellular dysfunction may result from an extreme activated state of leukocytes in the maternal circulation (Gervasi, 2001). Briefly, cytokines such as tumor necrosis factor α (TNF-α) and the interleukins may contribute to the systemic oxidative stress associated with preeclampsia. This is characterized by generation of highly toxic oxygen radicals. These injure systemic vascular endothelial cells, lower nitric oxide production by these cells, and interfere with prostaglandin balance. Other sequelae include production of the lipid-laden macrophage foam cells seen in placental atherosis; activation of systemic microvascular coagulation, which is manifested by thrombocytopenia; and greater systemic capillary permeability, which is reflected by edema and proteinuria.

Intact endothelium has anticoagulant properties. Also, systemic endothelial cells, by releasing nitric oxide, blunt the response of vascular smooth muscle to agonists. Injured or activated endothelial cells may produce less nitric oxide and may secrete substances that promote coagulation and vasopressor sensitivity. Further evidence of endothelial activation includes changes in glomerular capillary endothelial morphology, greater capillary permeability, and elevated blood concentrations of substances associated with endothelial activations. Likely, multiple factors in the plasma of preeclamptic women combine to exert these vasoactive effects (Myers, 2007; Walsh, 2009).

Vasospasm and Hypertension

Vasospasm has long been associated with preeclampsia. Systemic endothelial activation causes vasospasm, which elevates resistance to produce hypertension. Concurrently, systemic endothelial cell injury promotes interstitial leakage, and platelets and fibrinogen are deposited in the subendothelial space. Endothelial junctional proteins are also disrupted, and the subendothelial region of resistance arteries undergoes ultrastructural change (Suzuki, 2003; Wang, 2002). The much larger venous circuit is similarly involved.

With diminished blood flow because of maldistribution from vasospasm and interstitial leakage, ischemia of the surrounding tissues can cause necrosis, hemorrhage, and other end-organ disturbances. One important clinical correlate to these changes is the markedly attenuated blood volume seen in women with severe preeclampsia (Zeeman, 2009).

Increased Pressor Responses

As discussed in Chapter 4 (p. 53), pregnant women normally develop refractoriness to infused vasopressors (Abdul-Karim, 1961). Women with early preeclampsia, however, have enhanced vascular reactivity to infused norepinephrine and angiotensin II (Raab, 1956; Talledo, 1968). Moreover, increased sensitivity to angiotensin II clearly precedes the onset of gestational hypertension (Gant, 1974). Paradoxically, women who develop preterm preeclampsia have lower circulating levels of angiotensin II (Chase, 2017).

Numerous *prostaglandins* are thought to be central to preeclampsia syndrome pathophysiology. Specifically, the blunted pressor response seen in normal pregnancy is at least partially due to diminished vascular responsiveness mediated by endothelial prostaglandin synthesis. For example, compared with normal pregnancy, endothelial prostacyclin (PGI_2) production is lower in preeclampsia. This action appears to be mediated by

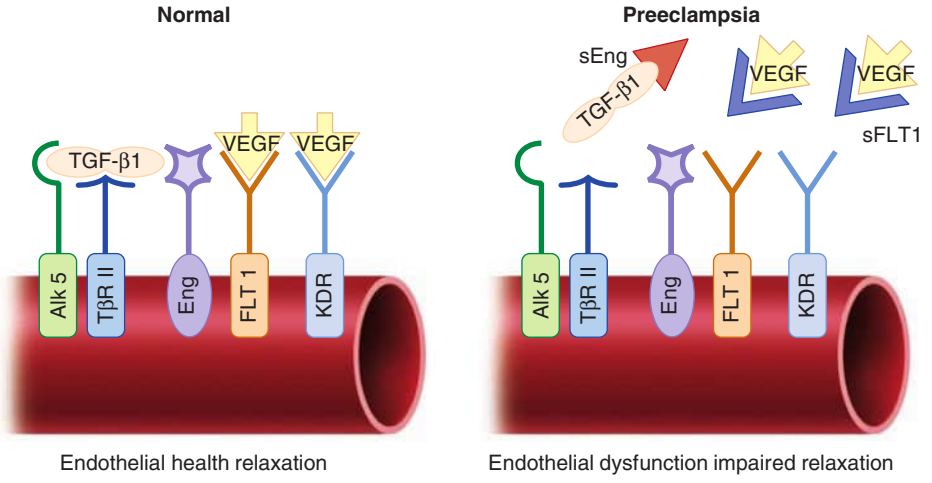

FIGURE 40-4 Schematic of receptor blocking action of soluble fms-like tyrosine kinase 1 (sFlt-1) and soluble endoglin (sENG).

phospholipase A_2 (Davidge, 2015). At the same time, thromboxane A_2 secretion by platelets is increased, and the prostacyclin: thromboxane A_2 ratio declines. The net result favors greater sensitivity to infused angiotensin II and vasoconstriction (Spitz, 1988). These changes appear as early as 22 weeks in gravidas who later develop preeclampsia (Chavarria, 2003).

Nitric oxide is a potent vasodilator and is synthesized from l-arginine by endothelial cells. Inhibition of nitric oxide synthesis raises mean arterial pressure, lowers heart rate, and reverses the pregnancy-induced refractoriness to vasopressors. Nitric oxide likely is the compound that maintains the normal low-pressure vasodilated state characteristic of normal fetoplacental perfusion (Myatt, 1992). Nitric oxide mediates the effects of placental growth factor (PlGF) and vascular endothelial growth factor (VEGF) in vitro (Zhang, 2017). The effects of nitric oxide production in preeclampsia are unclear. It appears that the syndrome is associated with decreased endothelial nitric oxide synthase expression and thus lower nitric oxide activity (Davidge, 2015).

Endothelins are 21-amino-acid peptides and potent vasoconstrictors. Endothelin l (ET-1) is the primary isoform produced by human endothelium (Karumanchi, 2016a). Plasma ET-1 levels are elevated in normotensive pregnant women. Women with preeclampsia have even higher levels, and these peptides may mediate renal injury (Phipps, 2019). Woman with preeclampsia develop functional autoantibodies to the endothelin and angiotensin II receptors (Buttrup, 2018). Interestingly, treatment of preeclamptic women with magnesium sulfate lowers ET-1 concentrations (Sagsoz, 2003). In animal studies, sildenafil reduces ET-1 concentrations (Gillis, 2016).

Angiogenic and Antiangiogenic Factors

Placental vasculogenesis is evident by 21 days after conception. The list of pro- and antiangiogenic substances involved in placental vascular development is extensive, and the VEGF and angiopoietin families are the most studied. Angiogenic imbalance describes excessive amounts of antiangiogenic factors, which are thought to be stimulated by worsening hypoxia at the uteroplacental interface. Trophoblast of women destined to develop preeclampsia overproduce at least two antiangiogenic peptides that enter the maternal circulation (Karumanchi, 2016b).

First, *soluble fms-like tyrosine kinase 1 (sF1t-1)* is a soluble variant of the membrane-bound receptor for VEGF. As depicted in Figure 40-4, elevated maternal sFlt-1 levels inactivate and reduce circulating PlGF and VEGF concentrations, leading to endothelial dysfunction (Phipps, 2019). As shown in data from Myatt and coworkers (2013), sFlt-1 levels begin to rise in maternal serum months before preeclampsia is evident (Fig. 40-5). These high levels in the second trimester are associated with a much higher risk for preeclampsia development (Haggerty, 2012; March, 2015). This elevation from normal levels appears even sooner with early-onset disease (Vatten, 2012). These factors are also

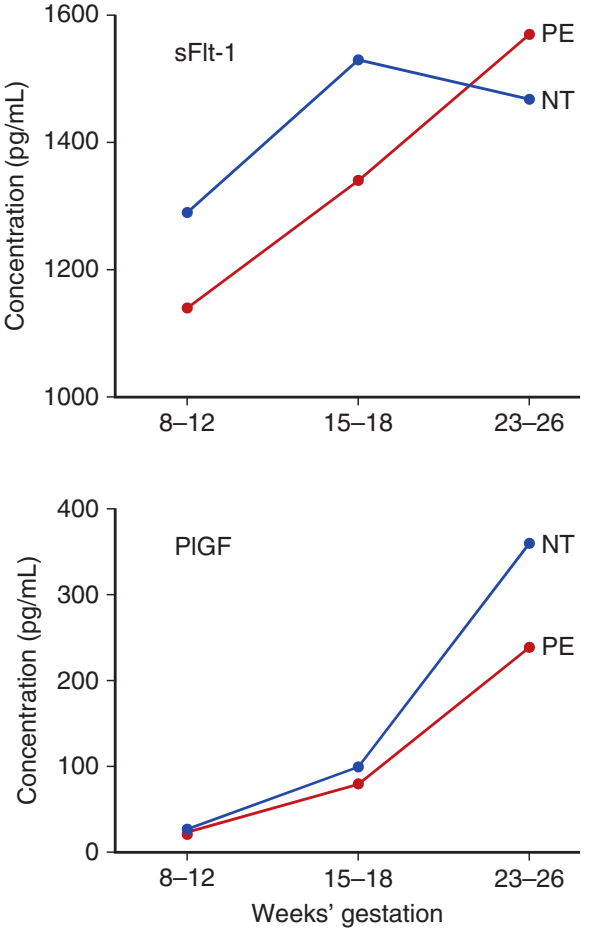

FIGURE 40-5 Angiogenic and antiangiogenic factors in normotensive (NT) and preeclamptic (PE) women across pregnancy. Both pairs of factors are significantly divergent by 23 to 26 weeks' gestation. sFlt-1 = soluble fms-like tyrosine kinase 1; PlGF = placental growth factor.

operative in pregnancies complicated by fetal-growth restriction (Herraiz, 2012).

A second antiangiogenic peptide, *soluble endoglin (sEng)*, inhibits various transforming growth factor beta (TGF-β) isoforms from binding to endothelial receptors (see Fig. 40-4). Endoglin is one of these receptors. Decreased binding to endoglin diminishes endothelial nitric oxide-dependent vasodilation. Serum levels of sEng also begin to rise months before clinical preeclampsia develops (Haggerty, 2012).

Simultaneously elevated levels of sFlt-1 and sEng are associated with more severe forms of preeclampsia (Phipps, 2019). In one systematic review, third-trimester increases in sFlt-1 levels and lower PlGF concentrations were found to correlate with preeclampsia development after 25 weeks' gestation (Widmer, 2007). From another study, doubling of sFlt-1 and sEng expression increased the preeclampsia risk by 39 and 74 percent, respectively (Haggerty, 2012). The cause of placental overproduction of antiangiogenic proteins remains an enigma. Concentrations of the soluble forms are not higher in fetal circulation or amnionic fluid of preeclamptic women, and their levels in maternal blood dissipate after delivery (Staff, 2007).

Clinical use of antiangiogenic protein levels to predict and diagnosis preeclampsia is being evaluated (p. 703). Moreover, one preliminary report described therapeutic apheresis to reduce sFlt-1 levels (Thadhani, 2016).

PATHOPHYSIOLOGY

Cardiovascular System

Disturbances in the cardiovascular system are common with preeclampsia syndrome. These are related to: (1) greater cardiac afterload imposed by hypertension; (2) cardiac preload, which is reduced by a pathologically diminished volume expansion during pregnancy and which is increased by administration of intravenous crystalloid or oncotic solutions; and (3) endothelial activation leading to leakage of intravascular fluid into the extracellular space.

Hemodynamic Changes and Cardiac Function

The cardiovascular aberrations of pregnancy-related hypertensive disorders vary. Modifying factors include preeclampsia severity, degree of hypertension, presence of underlying chronic disease, and the point in the clinical spectrum in which these are studied. In some women, these cardiovascular changes may precede hypertension (Easterling, 1990; Khalil, 2012; Melchiorre, 2013). Nevertheless, with the clinical onset of preeclampsia, cardiac output declines, due at least in part to greater peripheral resistance (Ferrazzi, 2018).

Myocardial Function

Serial echocardiographic studies document diastolic dysfunction in up to 45 percent of women with preeclampsia (Guirguis, 2015; Vaught, 2018). With this dysfunction, ventricles do not properly relax and cannot fill appropriately. In some affected women, functional differences persist up to 4 years after delivery (Evans, 2011; Orabona, 2017). Diastolic dysfunction stems from ventricular remodeling, which is a maladaptive response to the increased afterload of preeclampsia and aims to maintain normal contractility. High levels of antiangiogenic proteins may be contributory (Shahul, 2016). In otherwise healthy gravidas, these changes are usually inconsequential. But in those with underlying ventricular dysfunction—for example, concentric ventricular hypertrophy from chronic hypertension—further diastolic dysfunction may cause cardiogenic pulmonary edema (Wardhana, 2018). This is discussed further in Chapters 50 (p. 883) and 52 (p. 916).

Ventricular Function

Despite the relatively high frequency of diastolic dysfunction with preeclampsia, clinical cardiac function in most affected women is appropriate (Hibbard, 2015). In some preeclamptic women, high-sensitivity cardiac troponin levels are slightly elevated (Morton, 2018). With severe preeclampsia, amino-terminal pro–brain natriuretic peptide (NT–pro-BNP) levels are increased (Zachary, 2017).

Women with preeclampsia syndrome usually have slightly hyperdynamic ventricular function (Fig. 40-6). Both these and normotensive pregnant women have a cardiac output that is appropriate for left-sided filling pressures. This pressure can be altered by intravenous fluid volumes. Thus, aggressive hydration results in overtly *hyperdynamic* ventricular function. This is accompanied by elevated pulmonary capillary wedge pressures, and pulmonary edema may develop despite normal ventricular function. This is partly because of an alveolar endothelial-epithelial leak, and it is compounded by decreased oncotic pressure from a low serum albumin concentration. In sum, aggressive fluid administration to otherwise normal women with severe preeclampsia substantially elevates normal left-sided filling

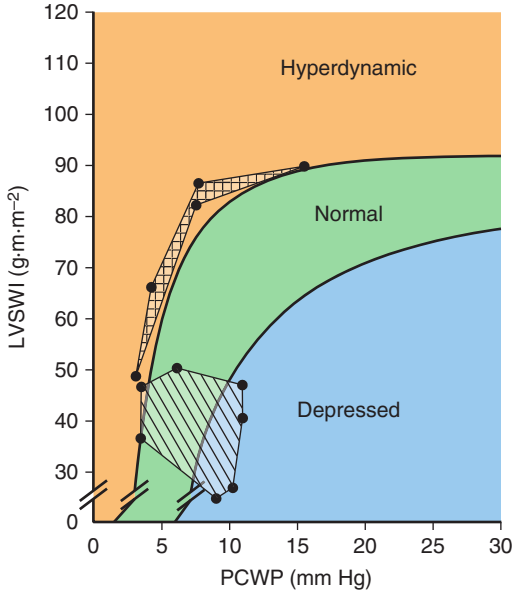

FIGURE 40-6 Ventricular function in normally pregnant women (*striped area*) and in women with eclampsia (*boxed area*) is plotted on a Braunwald ventricular function curve. Normal values are from Clark, 1989, and those for eclampsia are from Hankins, 1984. PCWP = pulmonary capillary wedge pressure; LVSWI = left ventricular stroke work index.

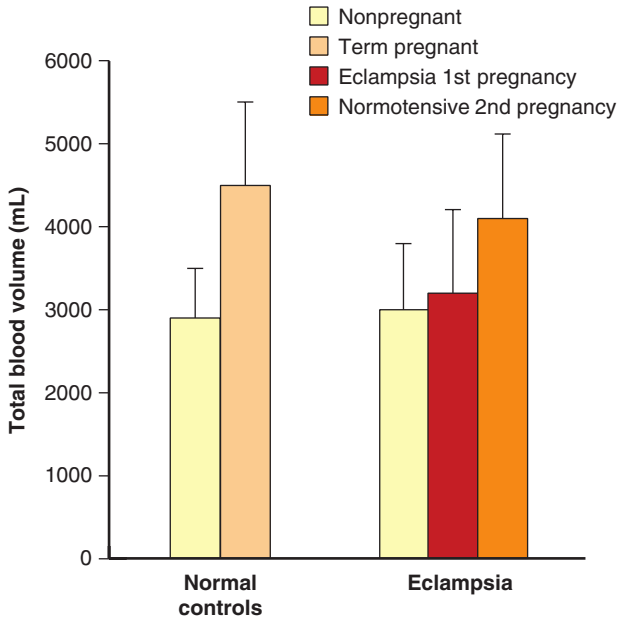

FIGURE 40-7 Total blood volumes in normotensive women compared with those with eclampsia. The vertical extensions are one standard deviation from the mean. In the eclamptic women, note the minimally increased blood volume compared with a subsequent normotensive pregnancy.

pressures and raises a physiologically normal cardiac output to hyperdynamic levels.

Blood Volume

In those with eclampsia, *hemoconcentration* is a hallmark feature (Pritchard, 1984). Data from Zeeman and associates (2009) show that normally expected pregnancy blood volume expansion is severely curtailed (Fig. 40-7). Women of average size have a nonpregnant blood volume of 3000 mL, and during the last several weeks of a normal pregnancy, this averages 4500 mL (Chap. 4, p. 59). With eclampsia, however, much or all of the anticipated 1500 mL excess is lost. Such hemoconcentration results from generalized vasospasm that follows endothelial activation and then from leakage of plasma into the interstitial space. In women with preeclampsia—depending on its severity—hemoconcentration is usually not as marked.

These changes have substantial clinical consequences. Women with severe hemoconcentration are unduly sensitive to blood loss at delivery that otherwise may be considered normal. Vasospasm and endothelial leakage of plasma persist for a variable time after delivery as the endothelium is restored to normal. As this takes place, vasoconstriction reverses, and as the blood volume reexpands, the hematocrit usually falls from dilution. *Importantly, a substantive cause of this fall in hematocrit frequently is the blood loss incurred at delivery.*

Hematological Changes

Thrombocytopenia

The platelet count is routinely measured in women with any form of gestational hypertension. The frequency and intensity of thrombocytopenia vary and are dependent on the severity and duration of preeclampsia (Hellmann, 2007; Hupuczi, 2007). Overt thrombocytopenia—defined by a platelet count <100,000/μL—reflects severe disease (see Table 40-2). In general, the lower the platelet count, the higher the likelihood of maternal and fetal morbidity and mortality. In most cases, delivery is advisable because thrombocytopenia usually worsens.

After delivery, the platelet count may continue to decline for the first day or so. It then usually rises progressively to reach a normal level within 3 to 5 days. As discussed later, in some instances with HELLP syndrome, the platelet count continues to fall after delivery. If this nadir is delayed until 48 to 72 hours, preeclampsia syndrome may be incorrectly attributed to one of the thrombotic microangiopathies (Chap. 59, p. 1060).

Another platelet alteration is platelet activation and increased α-degranulation. This leads to release of β-thromboglobulin and factor 4 and to enhanced platelet clearance (Kenny, 2015). Platelet volume concomitantly increases as young platelets are released (Bellos, 2018). Paradoxically, in most studies, in vitro platelet aggregation is reduced compared with the normal increase that is characteristic of pregnancy. This likely is due to platelet "exhaustion" following in-vivo activation. Although the cause is unknown, immunological processes or simply platelet deposition at sites of endothelial damage may be implicated. Levels of platelet-bound and circulating platelet-bindable immunoglobulins are elevated, which suggests platelet surface alterations. Abnormally low platelet levels do not develop in the fetuses of women with preeclampsia despite severe maternal thrombocytopenia (Kenny, 2015; Pritchard, 1987). Thus, thrombocytopenia in a hypertensive woman is not a fetal indication for cesarean delivery.

Hemolysis

Severe preeclampsia is frequently accompanied by hemolysis, which manifests as elevated serum lactate dehydrogenase levels and reduced haptoglobin levels (Burwick, 2018). Other evidence comes from schizocytosis, spherocytosis, and reticulocytosis in peripheral blood (Cunningham, 1985; Pritchard, 1954, 1976). Red cell distribution width (RDW) reflects variability in the size of circulating red blood cells, and RDW is higher in preeclamptic women (Adam, 2019). These derangements result in part from *microangiopathic hemolysis* caused by endothelial disruption with platelet adherence and fibrin deposition. Cunningham and coworkers (1995) postulated that erythrocyte morphological changes were partially caused by serum lipid alterations. Related, substantively decreased long-chain fatty acid content is found in erythrocytes of women with preeclampsia (Mackay, 2012).

After early reports of hemolysis and thrombocytopenia with severe preeclampsia, descriptions were added of abnormally elevated serum liver transaminase levels that indicated hepatocellular necrosis (Chesley, 1978). Weinstein (1982) referred to this combination of events as the *HELLP syndrome* (p. 699).

Coagulation Changes

Subtle changes consistent with intravascular coagulation commonly are found with preeclampsia and eclampsia (Cunningham, 2015; von Dadelszen, 2018). Some include elevated factor VIII

consumption, increased levels of fibrinopeptides A and B and of D-dimers, and reduced concentrations of the regulatory proteins—antithrombin III and proteins C and S. Coagulation aberrations generally are mild and seldom clinically significant (Kenny, 2015; Pritchard, 1984). Unless placental abruption is comorbid, plasma fibrinogen levels do not differ remarkably from levels found in normal pregnancy (Cunningham, 2015). As preeclampsia worsens, so do abnormal findings with *thromboelastography*, which is described in Chapter 44 (p. 774) (Pisani-Conway, 2013). Despite these changes, routine laboratory assessments of coagulation, such as prothrombin time (PT), activated partial thromboplastin time (aPTT), and plasma fibrinogen level, are not required in the management of pregnancy-associated hypertensive disorders.

Endocrine and Hormonal Alterations

Plasma levels of *renin*, *angiotensin II*, *aldosterone*, *deoxycorticosterone*, and *atrial natriuretic peptide (ANP)* are substantively augmented during normal pregnancy. ANP is released during atrial wall stretching from blood volume expansion, and it responds to cardiac contractility (Chap. 4, p. 65). Serum ANP levels rise in pregnancy, and its secretion is further enhanced in preeclampsia (Gu, 2018). Levels of its precursor—*proatrial natriuretic peptide*—also are elevated in preeclampsia. *Vasopressin* levels are similar in nonpregnant, in normally pregnant, and in preeclamptic women, although its metabolic clearance is elevated in the latter two (Dürr, 1999).

Fluid and Electrolyte Alterations

In women with severe preeclampsia, the volume of *extracellular fluid*, which manifests as edema, is usually much greater than that in normal pregnant women. The mechanism responsible for pathological fluid retention is endothelial injury and subsequent extravasation of intravascular fluid. Affected women also have reduced plasma oncotic pressure. This further displaces intravascular fluid into the surrounding interstitium. In women with preeclampsia, electrolyte concentrations do not differ appreciably from those of normal pregnant women.

Following an eclamptic convulsion, the *serum pH* and *bicarbonate concentration* are lowered due to lactic acidosis and compensatory respiratory loss of carbon dioxide. The intensity of acidosis relates to the amount of lactic acid produced—metabolic acidosis—and the rate at which carbon dioxide is exhaled—respiratory acidosis.

Kidney

During normal pregnancy, renal blood flow and glomerular filtration rate (GFR) rise appreciably (Chap. 4, p. 68). With preeclampsia, several reversible physiological changes ensue. Of clinical importance, renal perfusion and GFR are slightly reduced. Most of the decrement in GFR is from increased renal afferent arteriolar resistance that may be elevated up to fivefold (Conrad, 2015; Cornelis, 2011).

Morphological changes are characterized by *glomerular endotheliosis*, which blocks filtration (Phipps, 2019). Diminished filtration causes serum creatinine levels to rise to values seen in nonpregnant individuals, that is, 1 mg/mL, and sometimes higher. Acute kidney injury is discussed subsequently.

Plasma uric acid concentration is typically elevated in preeclampsia. The elevation exceeds that attributable to the reduced GFR and likely is also due to enhanced tubular reabsorption (Chesley, 1945). At the same time, preeclampsia is associated with diminished urinary excretion of calcium, perhaps because of greater tubular reabsorption (Taufield, 1987).

Proteinuria

Detection of proteinuria helps to establish the diagnosis of preeclampsia (see Table 40-1). Abnormal protein excretion is empirically defined by 24-hour urinary excretion exceeding 300 mg; a spot urine protein: creatinine ratio ≥0.3; or persistent protein values of 30 mg/dL (1+ dipstick) in random urine samples. Although worsening or nephrotic-range proteinuria was in the past considered by most to be a sign of severe disease, this does not appear to be the case (American College of Obstetricians and Gynecologists, 2013; Bartal, 2020).

Problematically, the optimal method of establishing abnormal levels of either urine protein or albumin remains to be defined. For a 24-hour quantitative specimen, the consensus threshold value is ≥300 mg/24 h (American College of Obstetricians and Gynecologists, 2013; Bartal, 2020). Using a urinary protein excretion threshold of 165 mg in a 12-hour sample shows equivalent efficacy (Stout, 2015).

Determination of urinary protein: creatinine ratio may supplant the cumbersome 24-hour quantification (Morris, 2012). In one systematic review, random urine protein:creatinine ratios <130 to 150 mg/g, that is, 0.13 to 0.15, indicate a low likelihood of proteinuria exceeding 300 mg/d (Papanna, 2008). Ratios <0.08 or >1.19 have negative and positive predictive values of 86 and 96 percent, respectively (Stout, 2013). However, midrange ratios, for example, 300 mg/g or 0.3, have poor sensitivity and specificity. Any midrange ratio should be repeated, and if persistent, a 24-hour urine collection for measurement of protein excretion should be considered.

With urine dipstick assessment, results depend on urine concentration and are notorious for false-positive and -negative results. A concentrated urine specimen may show a dipstick value of 1+ to 2+ in women who actually excrete <300 mg/d.

Importantly, proteinuria may develop late, and some women may already be delivered or have had an eclamptic convulsion before it appears. At presentation, 10 to 15 percent of women with HELLP syndrome do not have proteinuria (Sibai, 2004). In another report, 17 percent of women with eclampsia did not have proteinuria by the time of seizures (Zwart, 2008).

Anatomical Changes

Sheehan and Lynch (1973) frequently found microscopic changes that were identified at autopsy in the kidneys of eclamptic women. Glomeruli are enlarged by approximately 20 percent, they are "bloodless," and capillary loops variably are dilated and contracted. Endothelial cells are swollen—termed *glomerular capillary endotheliosis* (Spargo, 1959). Such swelling may be severe enough to block or partially block the capillary

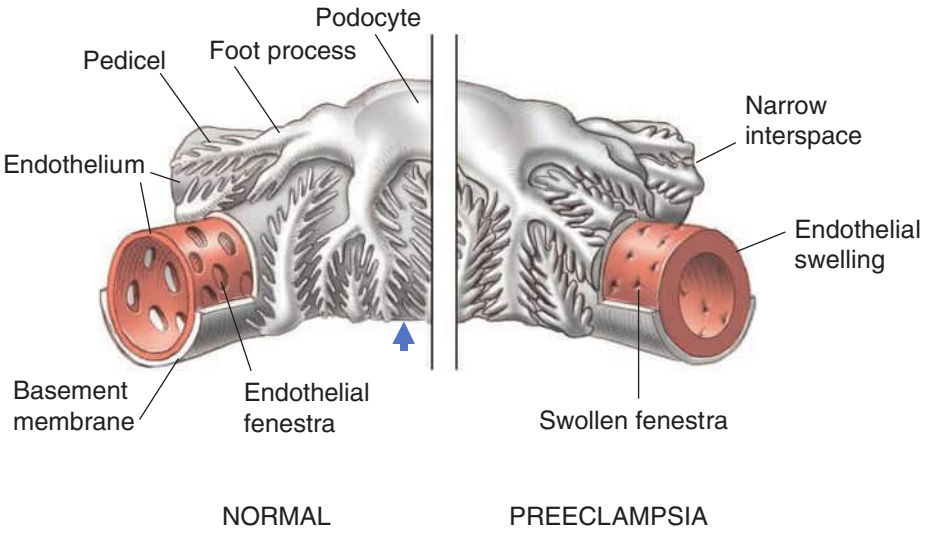

FIGURE 40-8 Schematic showing glomerular capillary endotheliosis. The capillary of the normal glomerulus shown on the left has wide endothelial fenestrations, and the pedicels emanating from the podocytes are widely spaced (*arrow*). The illustration on the right is of a glomerulus with changes induced by the preeclampsia syndrome. The endothelial cells are swollen and their fenestrae narrowed, as are the pedicels that now abut each other.

lumens (Fig. 40-8). Last, homogeneous subendothelial deposits of proteins and fibrin-like material are seen (Hecht, 2017).

Endothelial swelling may result from angiogenic protein "withdrawal." This is caused by the complexing of free angiogenic proteins with a compatible circulating antiangiogenic protein receptor (see Fig. 40-4). The angiogenic proteins are crucial for podocyte health, and their inactivation leads to podocyte dysfunction and endothelial swelling (Conrad, 2015; Phipps, 2019). Eclampsia is characterized by greater excretion of these epithelial podocytes (White, 2014).

Acute Kidney Injury

In one study, preeclampsia syndrome caused acute kidney injury (AKI) in 5 percent of patients and in 14 percent of those with HELLP syndrome (Novotny, 2020). With severe preeclampsia, Rodriguez and colleagues (2021) reported AKI in 15 percent of women in a study from Parkland Hospital. In most, AKI was stage 1. In another study of 72 women with preeclampsia and renal failure, half had HELLP syndrome, and a third had placental abruption (Drakeley, 2002). In a review of 183 women with HELLP syndrome, 5 percent had AKI (Haddad, 2000). Of those with renal injury, half had placental abruption, and most had postpartum hemorrhage. Abnormal renal values usually begin to normalize 10 days or later after delivery (Cornelis, 2011; Spaan, 2012). Although mild degrees of AKI are encountered, clinically apparent acute tubular necrosis is almost invariably induced by comorbid hemorrhage and subsequent hypovolemia and hypotension (Chap. 43, p. 753).

To evaluate AKI etiology clinically, urine electrolytes may be obtained. Results with preeclampsia reflect an *intrarenal* cause. In most with preeclampsia, the urine sodium concentration is elevated. Instead, changes that indicate a *prerenal* mechanism include increase urine osmolality, elevated urine: plasma creatinine ratio, and low fractional excretion of sodium.

In response to oliguria, sodium-containing crystalloid temporarily improves urine output. However, rapid infusions may cause clinically apparent pulmonary edema (p. 695). Intensive intravenous fluid therapy is not indicated as "treatment" for women with preeclampsia and oliguria, unless urine output is diminished from hemorrhage or fluid loss from vomiting or fever. In nonpregnant individuals, intravenous saline infusions have demonstrated a negative impact on renal function. However, at Parkland Hospital, transition from Ringer lactate to normal saline did not significantly impair renal function in women with preeclampsia (Yule, 2020).

Liver

Hepatic changes are common in women with severe preeclampsia syndrome. Several gross and microscopic anatomical derangements lead to elevated serum hepatic transaminase levels. This *transaminitis* indicates hepatocellular injury and is a marker for severe preeclampsia. Values are seldom more than 500 U/L, but levels exceeding 2000 U/L have been reported (Chap. 58, p. 1031). In general, serum concentrations inversely follow platelet levels, and they both usually return to normal levels within 3 days after delivery.

Anatomical Changes

Regions of periportal hemorrhage in the liver periphery typify the hepatic lesions of eclampsia (Hecht, 2017; Sheehan, 1973). Extensive involvement such as shown in Figure 40-9 is

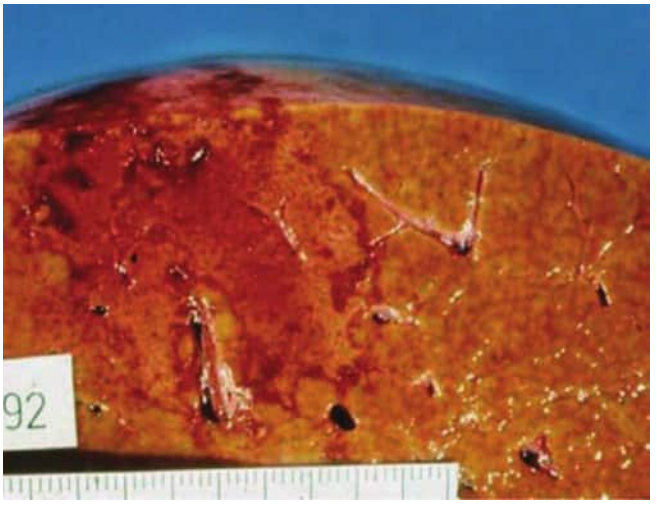

FIGURE 40-9 Hepatic section from a woman with HELLP syndrome who died of aspiration pneumonia. There are areas of ischemia and infarction, and histopathological examination showed periportal hemorrhages.

unusual. Sheehan and Lynch (1973) described that some degree of hepatic infarction accompanied hemorrhage in almost half of women who died with eclampsia. These findings corresponded with reports during the 1960s that described elevated serum hepatic transaminase levels. Pritchard and associates (1954) described hemolysis and thrombocytopenia with eclampsia. This constellation of hemolysis, hepatocellular necrosis, and thrombocytopenia was later termed HELLP syndrome. Similarities with hepatic sinusoidal obstruction are reviewed by von Salmuth and coworkers (2020).

Liver involvement with preeclampsia may clinically display several manifestations. First, pain is considered a sign of severe disease. It typically manifests as moderate to severe right upper quadrant or midepigastric pain and tenderness. These women usually have elevated serum aspartate transaminase (AST) or alanine transaminase (ALT) levels. In some cases, however, the amount of hepatic tissue involved with infarction may be surprisingly extensive yet still clinically insignificant. To study this, we performed magnetic resonance (MR) imaging in 16 women with HELLP syndrome (Nelson, 2018). All but two had evidence of acute liver injury, and the volume of involvement correlated with serum AST levels. Frank infarction is unusual, and in our experiences, it may be worsened or precipitated by hypotension from obstetrical hemorrhage. It occasionally causes hepatic failure—also called *shock liver* (Morgan, 2019; Yoshihara, 2016).

Hepatic Hematoma

In another presentation, periportal hemorrhage and infarction may extend to develop a hepatic hematoma. This in turn can extend to form a subcapsular hematoma that may rupture. Computed tomography (CT) scanning or MR imaging greatly aids diagnosis (Fig. 40-10). Unruptured hematomas are probably more common than clinically suspected and are more likely to be found with HELLP syndrome (Nelson, 2018). Although once considered a surgical condition, current management of a hepatic hematoma is usually observation unless bleeding is ongoing. In some cases, however, prompt surgical intervention or angiographic embolization may be lifesaving (Chandrasekaran, 2020). In one review of 180 cases of hepatic hematoma or rupture, 94 percent of affected gravidas had HELLP syndrome, and in 90 percent of the total, the capsule had ruptured (Vigil-De Gracia, 2012). The maternal mortality rate was 22 percent, and the perinatal mortality rate was 31 percent. Another review of 73 cases found similar outcomes (Gupta, 2021). In rare cases, liver transplantation is necessary (Escobar Vidarte, 2019).

FIGURE 40-10 Abdominal CT imaging performed postpartum in a woman with severe HELLP syndrome and right-upper quadrant pain. A large subcapsular hematoma (*asterisk*) is seen confluent with intrahepatic infarction and hematoma (*arrowhead*). Numerous flame-shaped hemorrhages are seen at the hematoma interface (*arrows*).

Acute fatty liver of pregnancy is sometimes confused with preeclampsia (Byrne, 2020; Nelson, 2013). It too has an onset in late pregnancy, and often hypertension, elevated serum transaminase and creatinine levels, and thrombocytopenia are comorbid. In distinction, the hallmark of acute fatty liver is marked liver dysfunction. Liver function overall is usually normal in HELLP syndrome. Table 58-1 (p. 1031) highlights these clinical differences.

No convincing data link *pancreatic involvement* with preeclampsia syndrome. In 407 women with severe preeclampsia, the incidence was 1 percent (Sang, 2019). That said, the occasional case of concurrent hemorrhagic pancreatitis is likely unrelated (Lynch, 2015). In our experiences from Parkland Hospital, lipase and amylase levels are seldom elevated in women with preeclampsia (Nelson, 2018).

HELLP Syndrome

This acronym stands for hemolysis, elevated liver enzyme levels, and low platelet count. No strict definition of the syndrome is universally accepted, and thus its reported incidence varies.

In women with preeclampsia, those with HELLP syndrome typically have worse outcomes than those without it (Martin, 2012, 2013). In the previously noted study of 183 women with HELLP syndrome, 40 percent had adverse outcomes, and two mothers died (Haddad, 2000). Complications included eclampsia in 6 percent, placental abruption—10 percent, AKI—5 percent, and pulmonary edema—10 percent. Stroke, hepatic hematoma, coagulopathy, acute respiratory distress syndrome, and sepsis were other complications. In one review of 693 women with HELLP syndrome, 10 percent had concurrent eclampsia (Keiser, 2011). Obstetrical outcomes also may suffer. In one study comparing women with HELLP against those with preeclampsia, rates of eclampsia were greater with HELLP—15 versus 4 percent; preterm birth—93 versus 78 percent; and perinatal mortality—9 versus 4 percent, respectively (Sep, 2009). Because of these marked clinical differences, some postulate that HELLP syndrome has a distinct pathogenesis (Reimer, 2013; Vaught, 2016).

■ Central Nervous System

Headaches and visual symptoms are common with severe preeclampsia, and associated convulsions define eclampsia. The earliest anatomical descriptions of brain involvement came from autopsy specimens, but CT and MR imaging and Doppler studies have added important insights.

Neuroanatomical Lesions

From early anatomical descriptions, brain pathology accounted for only approximately a third of fatal cases, such as the one shown in Figure 40-11. In fact, most deaths were from pulmonary edema, and brain lesions were coincidental. Thus, although gross intracerebral hemorrhage was seen in up to 60 percent of eclamptic women, it was fatal in only half of these (Richards, 1988). With data from Sheehan and Lynch (1973) shown in Figure 40-12, cortical and subcortical petechial hemorrhages are other principal lesions found at autopsy in women with eclampsia. The classic microscopic vascular lesions consist of fibrinoid necrosis of the arterial wall and perivascular microinfarcts and hemorrhages. Other lesions include nonhemorrhagic areas of "softening" throughout the brain, hemorrhages in the white matter, and subcortical edema (Hecht, 2017; Willard, 2018). Hemorrhage in the basal ganglia or pons, often with rupture into the ventricles, may develop.

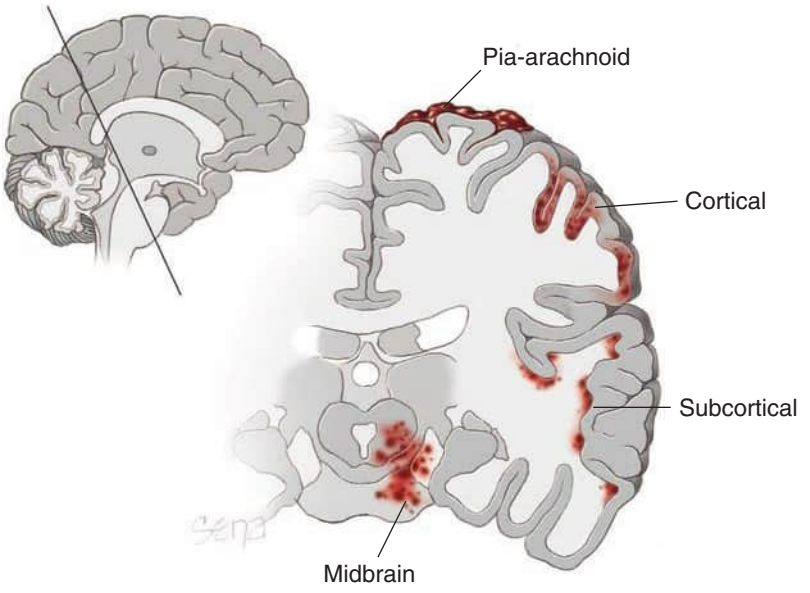

FIGURE 40-12 Composite illustration showing location of cerebral hemorrhages and petechiae in women with eclampsia. Insert shows the level of the brain from which the main image was constructed.

Cerebrovascular Pathophysiology

Clinical, pathological, and neuroimaging findings have led to two general theories to explain cerebral abnormalities with eclampsia. Endothelial cell dysfunction likely plays a key role in both. The first theory suggests that in response to acute and severe hypertension, cerebrovascular overregulation leads to vasospasm and eventual tissue infarction (Trommer, 1988). Little objective evidence supports this mechanism.

The second theory is that sudden elevations in systemic blood pressure exceed the normal cerebrovascular autoregulatory capacity (Schwartz, 2000). Regions of forced vasodilation and vasoconstriction develop, especially in arterial boundary zones. At the capillary level, disruption of end-capillary pressure causes increased hydrostatic pressure, hyperperfusion, and extravasation of plasma and red cells through endothelial tight-junction openings. This leads to *vasogenic edema*.

Most likely, the true mechanism combines these two. Thus, a preeclampsia-associated interendothelial cell leak develops at blood pressure levels much lower than those that usually cause vasogenic edema, and this is coupled with a loss of upper-limit autoregulation (Fugate, 2015; Zeeman, 2009). As shown in Figure 40-13, these abnormalities manifest as the *posterior reversible encephalopathy syndrome (PRES).* Lesions principally involve the occipital and parietal cortices, but other areas are often involved, although less extensively (Edlow, 2013; Zeeman, 2004a).

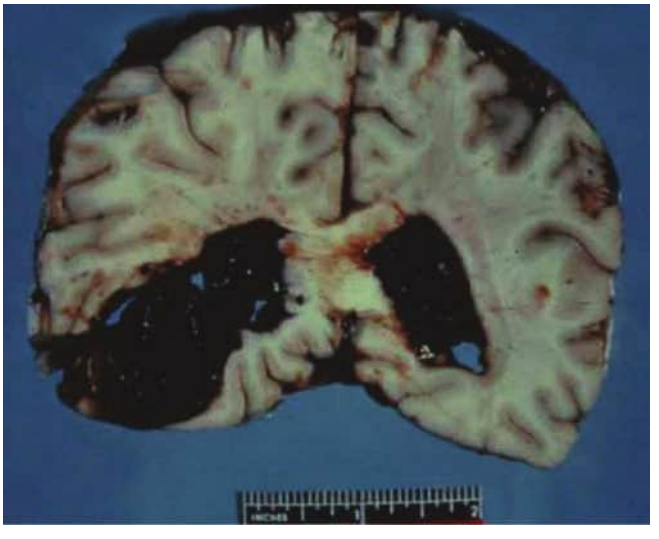

FIGURE 40-11 This autopsy brain slice shows a fatal hypertensive hemorrhage in a primigravida with eclampsia.

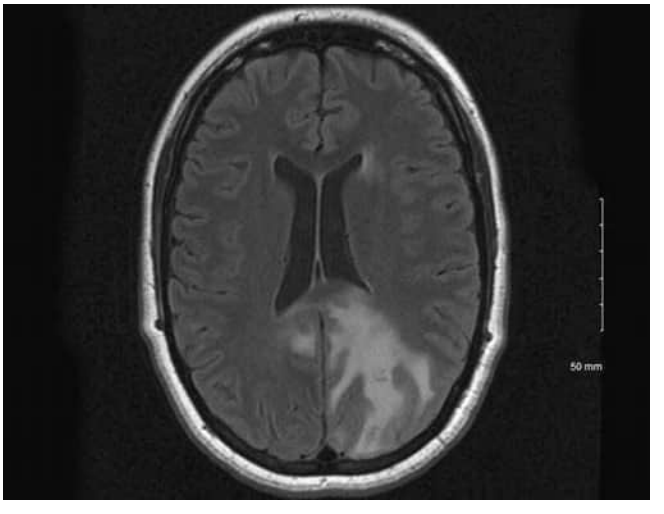

FIGURE 40-13 Cranial magnetic resonance imaging in a nullipara with eclampsia. This T2-FLAIR image shows an occipital lesion consistent with posterior reversible encephalopathy syndrome (PRES). FLAIR = fluid-attenuated inversion recovery.

Cerebral Blood Flow

Autoregulation is the mechanism by which cerebral blood flow remains relatively constant despite alterations in cerebral perfusion pressure. In nonpregnant individuals, this mechanism protects the brain from hyperperfusion when mean arterial pressures increase up to 160 mm Hg. These pressures are far greater than those seen in most women with eclampsia. Thus, to explain eclamptic seizures, it was theorized that autoregulation must be altered by pregnancy. Some investigators have shown impaired autoregulation in women with preeclampsia (Bergman, 2021b; Janzarik, 2014). When studied 2 to 3 years postpartum, women who had preeclampsia had returned to normal autoregulation (Janzarik, 2018).

Zeeman and associates (2003) showed that cerebral blood flow during the first two trimesters of normal pregnancy is similar to nonpregnant values. But during the last trimester, flow significantly drops by 20 percent. They found greater cerebral blood flow in this trimester in women with severe preeclampsia compared with flow in normotensive pregnant women (Lee, 2019; Zeeman, 2004b). Taken together, these findings suggest that eclampsia occurs when cerebral hyperperfusion forces capillary fluid interstitially because of endothelial damage. This leak leads to perivascular edema. Some data suggest that the blood-brain barrier is not impaired, but in-vitro studies may indicate increased permeability (Bergman, 2021a; Burwick, 2018).

Neurological Manifestations

Several neurological manifestations typify the preeclampsia syndrome. Each signifies severe involvement and requires immediate attention.

First, *headache and scotomata* are thought to arise from cerebrovascular hyperperfusion that has a predilection for the occipital lobes. In women preceding an eclamptic convulsion, up to 75 percent have headaches, and 20 to 30 percent have visual changes (Sibai, 2005; Zwart, 2008). The headaches vary in severity and persistence. In our experiences, they are unique in that they do not usually respond to traditional analgesia but frequently improve after magnesium sulfate infusion.

Convulsions are diagnostic for eclampsia. These are caused by abnormal excessive or synchronous neural activity in the brain. Evidence suggests that extended seizures can cause significant brain injury and later brain dysfunction.

Blindness and *generalized cerebral edema* are discussed in subsequent sections. Last, women with eclampsia have been shown to have some cognitive decline when studied 5 to 10 years following the involved pregnancy (Bergman, 2021c). This is discussed further in Chapter 41 (p. 727).

Neuroimaging Studies

With CT imaging, localized hypodense lesions are frequently seen with eclampsia at the gray- and white-matter junction and primarily in the parietooccipital lobes. Frontal and inferior temporal lobes, the basal ganglia, and thalamus are other sites (Brown, 1988). These hypodense areas correspond to petechial hemorrhages and local edema. Edema of the occipital lobes or diffuse cerebral edema may cause blindness, lethargy, and confusion (Cunningham, 2000). Widespread edema can appear as marked compression or even obliteration of the cerebral ventricles. Such women may develop signs of impending life-threatening transtentorial herniation.

Several MR imaging acquisitions are used to study women with eclampsia (Singh, 2021). Common findings are hyperintense T2 lesions in the subcortical and cortical regions of the parietal and occipital lobes, which reflect PRES (see Fig. 40-13). The basal ganglia, brainstem, and cerebellum are other involved sites (Brewer, 2013; Zeeman, 2004a). PRES lesions are almost universal in women with eclampsia, and their incidence in women with severe preeclampsia approximates 20 percent (Hosapatna Basavarajappa, 2020; Mayama, 2016). Although usually reversible, a fourth of these hyperintense lesions with eclampsia have restricted diffusion that signify cerebral infarctions. These have persistent MR imaging findings (Loureiro, 2003; Zeeman, 2004a).

Visual Changes and Blindness

Retinal artery and venular calibers are decreased in women with preeclampsia (Soma-Pillay, 2018). These changes, along with visual cortex involvement, can cause scotomata, blurred vision, or diplopia, which is common with severe preeclampsia and eclampsia. These symptoms usually improve with magnesium sulfate therapy, or lowered blood pressure, or both.

Blindness is rare with preeclampsia alone, but it complicates up to 15 percent of women with eclampsia (Cunningham, 1995). It can develop a week or more following delivery. Blindness is usually reversible and may arise from three potential areas. These are the occipital lobe's visual cortex, the lateral geniculate nuclei, and the retina.

Occipital blindness is also called *amaurosis*. With MR imaging, affected women usually have evidence of extensive occipital lobe vasogenic edema. Of 15 women cared for at Parkland Hospital, occipital blindness lasted from 4 hours to 8 days, but it resolved completely in all cases (Cunningham, 1995). Rarely, extensive cerebral infarctions may result in total or partial visual defects.

In the retina, ischemia, infarction, or serous detachment may occur (Handor, 2014). Retinal infarction, termed *Purtscher retinopathy*, is rare (Fig. 40-14). *Serous retinal detachment* is usually unilateral and seldom causes total visual loss. Asymptomatic serous retinal detachment is relatively common with preeclampsia (Gupta, 2019). In most cases of eclampsia-associated blindness, visual acuity subsequently improves (Mandura, 2021). If blindness is caused by retinal artery occlusion, vision may be permanently impaired (Roos, 2012).

Cerebral Edema

Manifestations that suggest widespread cerebral edema are worrisome. During 13 years at Parkland Hospital, 10 of 175 women with eclampsia were diagnosed with symptomatic cerebral edema (Cunningham, 2000). Symptoms ranged from lethargy, confusion, and blurred vision to obtundation and coma. In most cases, symptoms waxed and waned. Of these 10, three became comatose and had imaging findings of transtentorial herniation. One woman died.

Mental status changes generally correlated with the degree of involvement seen with CT and MR imaging studies. *These women are very susceptible to sudden and severe blood pressure*

FIGURE 40-14 Purtscher retinopathy caused by choroidal ischemia and infarction in preeclampsia syndrome. Ophthalmoscopy shows scattered yellowish, opaque lesions of the retina (*arrows*). (Reproduced with permission from Lam, DS, Chan W: Images in clinical medicine. Choroidal ischemia in preeclampsia. N Engl J Med 344(10):739, 2001).

elevations, which can acutely worsen the already widespread vasogenic edema. Thus, careful blood pressure control is essential.

■ Uteroplacental Perfusion

Compromised uteroplacental perfusion is almost certainly a major contributor to the increased perinatal morbidity and mortality rates associated with preeclampsia syndrome (Harmon, 2015). Contributing defects in endovascular trophoblastic invasion were discussed earlier (p. 692). Thus, measurement of uterine, intervillous, and placental blood flow would likely be informative. Attempts to assess these in humans have been hampered. Barriers include the placenta's inaccessibility, the complexity of its venous effluent, and the need for invasive techniques or radioisotopes.

As a surrogate, sonographic measurement of uterine artery blood flow velocity can estimate resistance to uteroplacental blood flow. Vascular resistance is estimated by comparing arterial systolic and diastolic velocity waveforms (Chap. 14, p. 262). By the completion of placentation, impedance to uterine artery blood flow is markedly decreased, but with abnormal placentation, abnormally high resistance persists (Everett, 2012; Napolitano, 2012). In earlier studies, peak systolic:diastolic velocity ratios from uterine and umbilical arteries in preeclamptic pregnancies were measured. In some cases, but not all, resistance was higher (Ferrazzi, 2018; Trudinger, 1990).

Another Doppler waveform, termed uterine artery "notching," has been linked with increased risks for preeclampsia or fetal-growth restriction (Groom, 2009). However, in one MFMU Network study, notching had a low predictive value except for early-onset, severe disease (Myatt, 2012a).

Resistance in *uterine spiral arteries* also has been measured. In one study, mean resistance values were greater in all women with preeclampsia compared with those in normotensive controls (Matijevic, 1999). Another study used MR imaging and other techniques to assess placental perfusion ex vivo in the myometrial arteries removed from women with preeclampsia or fetal-growth restriction (Ong, 2003). In both conditions, myometrial arteries exhibited similar vascular responses.

Despite these findings, evidence for compromised uteroplacental circulation is found in only a few women who later develop preeclampsia. Indeed, when preeclampsia develops during the third trimester, only a third of women with severe disease have abnormal uterine artery velocimetry (Li, 2005). In a study of 50 women with HELLP syndrome, only a third had abnormal uterine artery waveforms (Bush, 2001). In general, the extent of abnormal waveforms correlates with severity of fetal involvement (Ghidini, 2008; Groom, 2009).

These sonographic findings have value for prediction of fetal-growth restriction but not preeclampsia (American College of Obstetricians and Gynecologists, 2019b; Demers, 2019). Several other flow velocity waveforms have been investigated for preeclampsia prediction. However, none is suitable for clinical use (De Kat, 2019; Townsend, 2018).

Fetal-growth Restriction

Discussed in detail in Chapter 47, this potential consequence of preeclampsia can serve as one severity indicator (see Table 40-2). Namely, poor growth is usually confined to fetuses of women destined to develop severe preeclampsia (Mateus, 2019). Perry and colleagues (2020) reported that pregnancies complicated by fetal-growth restriction more likely had maternal hemodynamic indices similar to preeclampsia. Measures showed higher mean arterial pressure, greater systemic vascular resistance, lower cardiac output, and elevated uterine artery pulsatility index. Fetuses born to preeclamptic mothers have cardiac remodeling similar to growth-restricted fetuses (Youseff, 2020).

PREDICTION

Some biological markers implicated in the genesis of the preeclampsia syndrome have been measured to help predict its development. Although most have been evaluated in the first half of pregnancy, some have been tested as predictors of severity in the third trimester. Still others have been used to forecast recurrent preeclampsia. Overall, these efforts have resulted in testing strategies with poor sensitivity and poor positive predictive values for preeclampsia (Conde-Agudelo, 2015; De Kat, 2019). *Currently, no screening tests for preeclampsia are predictably reliable, valid, and economical.*

Because combinations of tests and risk factors might be superior to single predictors, some have developed multivariable screening algorithms (Boutin, 2021; Brunelli, 2020; Copel, 2020; Serra, 2020; Snell, 2020). One first-trimester screening protocol using serum sFlt-1 levels has been proposed (Pihl, 2020). Other examples are midpregnancy algorithms (Black, 2020; Peguero, 2021; Stepan, 2020). None has been adequately verified sufficiently for widespread clinical use (Capriglione, 2020).

■ Vascular Resistance Testing and Placental Perfusion

Most tests in this category are cumbersome, time consuming, and inaccurate. To evaluate blood pressure changes, three tests

assess the blood pressure rise in response to a stimulus. In one, women at 28 to 32 weeks' gestation rest in the left lateral decubitus position and then roll to lie supine. With this *roll-over test*, rising blood pressure in response to the maneuver signifies a positive test. The *isometric exercise* test employs the same principle by squeezing a handball. The *angiotensin II infusion test* provides incrementally higher doses intravenously, and the hypertensive response is quantified. Sensitivities of all three tests range from 55 to 70 percent, and specificities approximated 85 percent (Conde-Agudelo, 2015).

Uterine artery Doppler velocimetry is posited to reflect faulty trophoblastic invasion of the spiral arteries. The poor predictive value of this for preeclampsia was described in the Uteroplacental Perfusion section (p. 702).

Fetal-Placental Unit Endocrine Function

Several serum analytes have been proposed to help predict preeclampsia. Newer ones are continually added. In general, none of these tests is clinically beneficial for hypertension prediction.

Renal Function Tests

Hyperuricemia results from reduced uric acid clearance caused by diminished glomerular filtration, increased tubular reabsorption, and decreased secretion. In one study, the sensitivity of serum uric acid levels to detect preeclampsia ranged from 0 to 55 percent, and specificity was 77 to 95 percent (Cnossen, 2006). These are seldom used to diagnose preeclampsia (Chescheir, 2019).

Isolated gestational proteinuria is a risk factor for preeclampsia (Jayaballa, 2015; Morgan, 2016). But, as a predictive test for preeclampsia, microalbuminuria has sensitivities ranging from 7 to 90 percent and specificities spanning 29 to 97 percent (Conde-Agudelo, 2015).

Endothelial Dysfunction and Oxidative Stress

Endothelial activation and inflammation are major participants in preeclampsia pathophysiology. Levels of some implicated compounds are elevated in the blood of affected women and have been assessed as predictors.

Fibronectins are high-molecular-weight glycoproteins released from endothelial cells and extracellular matrix following endothelial injury. In one systematic review, however, neither cellular nor total fibronectin levels were clinically useful to predict preeclampsia (Leeflang, 2007).

Thrombocytopenia and *platelet dysfunction* are integral features of preeclampsia. Platelet activation causes their augmented destruction and lower blood concentrations. Platelet volume is increased because of platelet immaturity, and platelet volume has been described to be an early predictor of preeclampsia (Bellos, 2019; Mayer-Pickel, 2021). Although markers of coagulation activation described earlier (p. 696) are elevated, they substantively overlap with levels in normotensive pregnant women (von Dadelszen, 2018).

Of *oxidative stress markers*, higher levels of lipid peroxides coupled with decreased antioxidant activity can be seen with preeclampsia. Other markers are *iron*, *transferrin*, *and ferritin*; *resistin*; *hyperhomocysteinemia*; *blood lipids*; and antioxidants such as *ascorbic acid* and *vitamin E* (Christiansen, 2015; Conde-Agudelo, 2015; Mackay, 2012; Mignini, 2005). However, none has sufficient predictive value.

Angiogenic and Antiangiogenic Factor Imbalance

An imbalance in angiogenic and antiangiogenic factors is convincingly linked to preeclampsia pathogenesis (p. 694). Serum levels of VEGF and PlGF begin to drop before clinical preeclampsia develops. At the same time, levels of some antiangiogenic factors, such as sFlt-1 and sEng, begin to rise. Factor levels and ratios differ significantly between women with preeclampsia and those who are normotensive. These show especially good predictive performance with early-onset preeclampsia (Burton, 2019; Cerdeira, 2019; Phipps, 2019; Stepan, 2020).

These tests also can serve as diagnostic adjuncts (Duhig, 2019; Zeisler, 2016). First, they may aid differentiating between preeclampsia and mimics that include chronic hypertension, chronic kidney disease, systemic lupus erythematosus, and immunological thrombocytopenia. These tests can also help differentiate mild and severe disease. These plus other multiple markers will likely have a future role in first-trimester preeclampsia screening (Sovio, 2019).

Other Markers

Cell-free DNA (cfDNA) of placental origin can be detected in maternal plasma (Chap. 16, p. 327). It is hypothesized that cfDNA is released in preeclampsia by accelerated apoptosis of cytotrophoblasts. However, one MFMU Network study found no correlation between total cfDNA levels and preeclampsia prediction (Silver, 2017).

Other investigated markers include glycosylated hemoglobin A1c, serum cystatin-c, and first-trimester estimated placental volume (Bellos, 2019; Cavero-Redondo, 2018; Kim, 2021). Proteomic, metabolomic, and transcriptomic technologies can be employed to study serum and urinary proteins and cellular metabolites. Preliminary studies indicate their potential predictive value (Bahado-Singh, 2013; Ma, 2014).

PREVENTION

Various strategies used to prevent or modify preeclampsia severity have been evaluated. Some are listed in Table 40-4. With the possible exception of aspirin, none is convincingly and reproducibly effective.

Dietary and Lifestyle Modifications

A *low-salt* diet was one of the earliest researched preventions but is not supported by data (De Snoo, 1937). Of studies, one randomized trial showed that a sodium-restricted diet was ineffective in preventing preeclampsia (Knuist, 1998).

Regular exercise during pregnancy is linked to a lower risk of developing preeclampsia (Barakat, 2016; Morris, 2017). In one

TABLE 40-4. Some Methods to Prevent Preeclampsia That Have Been Evaluated in Randomized Trials

Dietary manipulation: low-salt diet, calcium or fish oil supplementation
Exercise: physical activity, stretching
Cardiovascular drugs: diuretics, antihypertensive drugs
Antioxidants: ascorbic acid (vitamin C), α-tocopherol (vitamin E), vitamin D
Antithrombotic drugs: low-dose aspirin, aspirin/dipyridamole, aspirin + heparin, aspirin + ketanserin

Modified from Jim, 2017; Staff, 2015.

systematic review, a similar trend toward risk reduction with exercise was noted (Kasawara, 2012). Only a few studies have been randomized.

Somewhat related, one retrospective cohort study of 677 nonhypertensive women were hospitalized for bed rest because of threatened preterm delivery (Abenhaim, 2008). When outcomes of these women were compared with those of the general obstetrical population, bed rest was associated with a significantly reduced risk of developing preeclampsia (relative risk 0.27). From two small randomized trials, prophylactic bed rest for 4 to 6 hours daily at home was successful in significantly lowering the preeclampsia incidence in women with normal blood pressures (Meher, 2006). Currently, the Society for Maternal-Fetal Medicine (2020) does not recommend reduced activity for women with hypertensive disorders or for prevention of preeclampsia.

Calcium supplementation has been studied, but in one trial of more than 4500 low-risk nulliparas, supplementation failed to decrease the risk for preeclampsia or pregnancy-associated hypertension (Levine, 1997). Similar findings were reported from another trial (Hofmeyer, 2019). In aggregate, most trials show that unless women are calcium deficient, supplementation offers no benefits (Palacios, 2019; Sanchez-Ramos, 2017).

Subclinical hypothyroidism is associated with increased preeclampsia risk. This insufficiency has been postulated to stem from iodine deficiency, but a recent metaanalysis found no association between iodine sufficiency and preeclampsia (Businge, 2021). *Folic acid* was evaluated in a randomized trial (Wen, 2018). Nearly 2500 high-risk women were given a 4-mg folic acid dose daily or placebo. The incidence of preeclampsia in both groups approximated 14 percent.

Cardioprotective fatty acids found in some fish likely prevent inflammation-mediated atherogenesis. Thus, it was posited that they might also prevent preeclampsia. However, randomized trials conducted thus far show no such benefits from fish oil supplementation (Zhou, 2012). In one longitudinal cohort study, a seafood diet, compared with a western one, provided a protective effect against preeclampsia (Ikem, 2019).

Antihypertensive Drugs

Because of the prior purported benefits of sodium restriction for preeclampsia prevention, diuretic therapy became popular with the advent of chlorothiazide in 1957 (Flowers, 1962). In one metaanalysis of nine randomized trials with more than 7000 pregnancies, women given diuretics had a lower incidence of edema and hypertension but not of preeclampsia (Churchill, 2007). Because women with chronic hypertension are at high risk for preeclampsia, several randomized trials have evaluated various antihypertensive drugs to reduce the incidence of superimposed preeclampsia (Chap. 41, p. 713). A critical analysis of these trials by Staff and coworkers (2015) failed to demonstrate benefits for this goal.

Antioxidants

Data imply that an imbalance between oxidant and antioxidant activity plays a role in preeclampsia pathogenesis. Thus, naturally occurring antioxidants—vitamins C, D, and E—might reduce such oxidation. Several randomized studies have assessed antioxidant vitamin supplementation for women at high risk for preeclampsia (Burton, 2019; Villar, 2009). The Combined Antioxidant and Preeclampsia Prediction Studies (CAPPS) by the MFMU Network included almost 10,000 low-risk nulliparas (Roberts, 2010). None of these studies showed reduced preeclampsia rates in women supplemented with vitamins C and E compared with those given placebo.

Statins were proposed to prevent preeclampsia because they stimulate heme oxygenase-1 expression, which inhibits sF1t-1 release. Early animal data suggest that statins may prevent hypertensive disorders of pregnancy (Lewis, 2017). The MFMU Network plans a randomized trial to test pravastatin for prevention, and a pilot study is completed (Costantine, 2016).

Metformin inhibits *hypoxic inducible factor 1α* by lowering mitochondrial electron transport chain activity. It reduces sFlt-1 and sEng activity and thus has potential to prevent preeclampsia (Brownfoot, 2016). In a preliminary study, prediabetic women were given metformin or placebo throughout pregnancy, and metformin-treated women had a lower incidence of severe preeclampsia (Racine, 2021). However, other clinical studies are lacking.

Antithrombotic Agents

Preeclampsia is characterized by vasospasm, endothelial cell dysfunction, inflammation, and activation of platelets and the coagulation–hemostasis system. Other sequelae include placental infarction and spiral artery thrombosis (Nelson, 2014). Thus, antithrombotic agents have been evaluated to prevent preeclampsia. Low-molecular-weight heparin has been studied in randomized trials. In a subsequent metaanalysis using individual data from 963 women, the risk for recurrent preeclampsia, abruption, or fetal-growth restriction was similar in women receiving heparin or placebo (Rodger, 2016).

Low-dose Aspirin

In low doses of 50 to 150 mg daily, *aspirin* effectively inhibits platelet thromboxane A_2 biosynthesis. It has minimal effects on vascular prostacyclin production. Still, several clinical trials have shown limited benefits in preeclampsia prevention. In a randomized trial from the MFMU Network, risks for adverse outcomes were not significantly reduced with aspirin therapy (Caritis, 1998). This study was followed by numerous similar studies and metaanalyses.

In another randomized trial of more than 1600 women at high risk for preterm preeclampsia, oral low-dose aspirin was given daily from 11 to 14 weeks' gestation until 36 weeks to prevent recurrence (Rolnik, 2017). The rate of preterm preeclampsia recurrence was 1.6 percent in the aspirin group compared with 4.3 percent in the placebo arm. In a metaanalysis, Roberge and colleagues (2017) found that aspirin prophylaxis initiated before 16 weeks' gestation was associated with a significant risk reduction—approximately 60 percent—of preeclampsia and fetal-growth restriction. At the same time, however, Meher and associates (2017) performed an individual participant data metaanalysis and reported a much lower—approximately 10 percent—risk reduction. Effects were significant whether therapy was initiated before or after 16 weeks' gestation.

In a subsequent metaanalysis, Roberge and coworkers (2018) found that aspirin prophylaxis given starting ≤16 weeks' gestation reduced the risk of preterm, but not term, preeclampsia. Turner and colleagues (2020) reported that aspirin improved some perinatal outcomes independent of effects on preeclampsia risk. But to the contrary, the review by Chaemsaithong and coworkers (2020) found no benefits even when low-dose aspirin was given before 11 weeks' gestation.

Based on these data, the U.S. Preventive Services Task Force (2021) recommends low-dose aspirin prophylaxis for women at high risk for preeclampsia. The American College of Obstetricians and Gynecologists (2018, 2020) now recommends low-dose aspirin be given between 12 and 28 weeks' gestation to help prevent preeclampsia in high-risk women. Candidates include those with ≥1 of the following: prior preeclampsia, chronic hypertension, overt diabetes, renal disease, autoimmune disorders, and multifetal gestation. Supplementation may be *considered* for those with more than one of these qualities: nulliparous, aged older than 35 years, obese, family history of preeclampsia, vulnerable sociodemographics, and prior low-birthweight or growth-restricted neonate. These results have also raised the question as to whether all pregnant women should be given aspirin (Ayala, 2019).

Low-dose aspirin coupled with heparin mitigates thrombotic sequelae in women with lupus anticoagulant (Chap. 62, p. 1116). Because of a similarly high prevalence of placental thrombotic lesions found with severe preeclampsia, trials have assessed the possible merits of such treatments for women with prior preeclampsia. In two randomized trials, women with a history of early-onset preeclampsia were given aspirin alone or a regimen of enoxaparin plus aspirin (Groom, 2017; Haddad, 2016). Outcomes were similar. Low-molecular-weight heparin, with or without aspirin, may decrease the risk for preeclampsia in high-risk women (de Vries, 2012; Wang, 2020).

CHAPTER 41

Clinical Management of the Preeclampsia Syndrome

Preeclampsia remains one of the leading causes of death and severe maternal morbidity. This chapter discusses many clinical aspects of the preeclampsia syndrome and its management after recognition. Also presented are the long-term consequences that may accrue in affected women. The pathophysiology of preeclampsia was detailed in Chapter 40.

DIAGNOSIS AND EVALUATION

Diagnosis

In routine prenatal care, gravidas are seen more often during the third trimester, and this aids early detection of preeclampsia. However, it cannot always be diagnosed definitively. Increases in systolic and diastolic blood pressure can be either normal physiological changes or signs of developing pathology.

Women without overt hypertension, but in whom the early development of preeclampsia is suspected, are seen more frequently. Heightened surveillance permits recognition of ominous changes in blood pressure, critical laboratory findings, and clinical signs and symptoms. Outpatient surveillance continues unless overt hypertension, proteinuria, headache, visual changes, or epigastric pain supervene. At Parkland Hospital, women with new-onset overt hypertension—either diastolic pressures ≥90 mm Hg or systolic pressures ≥140 mm Hg—are admitted to exclude preeclampsia or to define its severity.

Evaluation

With hospitalization, a systematic evaluation begins:

- Detailed examination, which is coupled with daily scrutiny for headache, visual changes, or epigastric pain
- Daily weight measurement to identify rapid weight gain
- Quantification of proteinuria or a urine protein: creatinine ratio
- Blood pressure readings with an appropriate-size cuff every 4 hours, unless previously elevated, which would mandate more frequent readings
- Measurements of serum creatinine and hepatic transaminase levels and a hemogram that includes a platelet count. The frequency of testing is determined by hypertension severity. Although some recommend assessment of serum uric acid and lactate dehydrogenase levels and coagulation, their value has been questioned (Chescheir, 2019; Conde-Agudelo, 2015)
- Evaluation of fetal size and well-being and amnionic fluid volume
- Reduced physical activity may have benefits, although evidence is not robust.

Still investigational as a clinical tool, measurements of *placental growth factor (PlGF)* and *soluble fms-like tyrosine kinase 1 (sF1t-1)* levels will likely be available to help predict preeclampsia (Barton, 2020; Chappell, 2013; Zeisler, 2016). Chapter 40 (p. 694) describes their role in preeclampsia genesis.

In sum, evaluation goals are early identification of preeclampsia and then management until timely delivery. Complete

abatement of all signs and symptoms is uncommon until after delivery. If severe preeclampsia is diagnosed using the criteria in Table 40-2 (p. 690), further management is subsequently described.

Consideration for Delivery

With gestational hypertension, its morbidity and management vary depending on hypertension severity, presence of preeclampsia, and gestational age of the fetus. The basic management objectives for any pregnancy complicated by preeclampsia are: (1) termination of pregnancy with the least possible trauma to mother and fetus, (2) birth of a healthy newborn that subsequently thrives, and (3) complete restoration of health to the mother. In many with preeclampsia, especially those at or near term, all three objectives are served equally well by induction of labor.

Termination of pregnancy is the only known cure for preeclampsia. Headache, visual changes, or epigastric pain are indicative that convulsions may be imminent, and oliguria is another ominous sign. Severe preeclampsia almost always demands anticonvulsant and antihypertensive therapy, followed by delivery. Treatment for eclampsia is identical. Prime objectives are to forestall convulsions, control blood pressure to prevent intracranial hemorrhage and serious damage to other organs, and deliver a healthy newborn. This is true even when the cervix is unfavorable. Labor induction is carried out, usually with preinduction cervical ripening (Chap. 26, p. 488).

Concerns stemming from an unfavorable cervix, a perceived sense of urgency because of preeclampsia severity, and a need to coordinate neonatal intensive care have led some to advocate for cesarean delivery. In an earlier study from Parkland Hospital, Alexander and colleagues (1999) reviewed 278 singleton liveborn neonates weighing 750 to 1500 g delivered of women with severe preeclampsia. In half of the women, labor was induced, and induction was successful in accomplishing vaginal delivery in a third. Similar data were reported from the Consortium on Safe Labor (Coviello, 2019). In this study, half of 914 women with severe preeclampsia underwent induction, and half of these were delivered vaginally. Others have reported similar observations (Alanis, 2008; Roland, 2017). For these reasons, we attempt labor induction and reserve cesarean delivery for other obstetrical indications.

With preeclampsia without severe features, optimal delivery timing has not been widely studied. A randomized trial of 756 women with mild preeclampsia supported delivery after 37 weeks' gestation (Koopmans, 2009). This practice is also supported by the American College of Obstetricians and Gynecologists (2020a). At Parkland Hospital, we deliver women with preeclampsia without severe features at 38 weeks' gestation.

With a preterm fetus, the tendency is to delay delivery to help reduce the risk of neonatal death or serious morbidity from prematurity. Such a policy certainly is justified in milder cases. Assessments of fetal well-being and placental function are performed, especially when the fetus is immature. To assess these, most recommend frequent performance of nonstress testing or biophysical profiles, which are described in Chapter 20 (p. 392). The American College of Obstetricians and Gynecologists (2021a,b) recommends consideration for antenatal surveillance twice weekly for those with gestational hypertension and nonsevere features and daily testing for those with severe features.

With late-preterm fetuses, that is, those between 34 and 36 weeks' gestation, the decision to deliver is less clear (Barton, 2011; Langenveld, 2011). The Dutch HYPITAT-II study randomly assigned women with nonsevere hypertension between 34 and 37 weeks to immediate delivery or to expectant management (Broekhuijsen, 2015). Immediate delivery reduced the risks for adverse maternal outcomes—1.1 versus 3.1 percent. However, it increased the risk for neonatal respiratory distress syndrome— 5.7 versus 1.7 percent.

In a more recent study, 901 women at 34 to <37 weeks' gestation with nonsevere preeclampsia were randomly assigned to early delivery or expectant management (Chappell, 2019). A third of each group self-stratified into intervals of 34, 35, and 36 weeks' gestation. For women in the immediate delivery group, rates of the primary maternal outcomes, which were features of severe preeclampsia, were significantly lower than in the expectant group. Conversely, rates of adverse perinatal outcomes, which were perinatal deaths or neonatal unit admission, were significantly greater in the immediate delivery group. Similar findings were reported by other (Bernardes, 2019; Chatzakis, 2021). Last, the PEACOCK study found that angiogenic biomarkers did not help determine the need for delivery in late-preterm preeclampsia (Duhig, 2021). At Parkland Hospital, we favor an active management approach given the maternal risks of expectant management. However, if preeclampsia is nonsevere, we routinely induce after 38 completed weeks.

Inpatient or Outpatient Care

For women with mild to moderate stable hypertension, whether or not preeclampsia has been confirmed, monitoring is continued. During surveillance, reduced physical activity throughout much of the day, at least intuitively, seems reasonable. Complete bed rest was not recommended in the prior consensus work of the American College of Obstetricians and Gynecologists' Task Force on Hypertension in Pregnancy (2013). Also, the Society for Maternal-Fetal Medicine (2020b) suggests that activity restriction not be prescribed for women with hypertensive disorders. Complete bed rest is pragmatically unachievable because of the severe restrictions it places on otherwise well women. It likely also predisposes to thromboembolism (Knight, 2007; McCarty-Singleton, 2014).

To reduce activity, several studies have addressed the benefits of inpatient care and outpatient management. The concept of prolonged hospitalization for women with hypertension arose during the 1970s. At Parkland Hospital, an inpatient antepartum unit was established in 1973 by Dr. Peggy Whalley to provide care for such women. Initial results from this unit were reported by Hauth (1976) and Gilstrap (1978) and their coworkers. Most hospitalized women have a beneficial response characterized by amelioration or improvement of hypertension. *These women are not "cured," and nearly 90 percent have recurrent hypertension before or during labor.* By 2020, more than 10,000 nulliparas with mild to moderate, early-onset hypertension during pregnancy had

TABLE 41-1. Randomized Clinical Trials Comparing Hospitalization Versus Routine Care for Women with Mild Gestational Hypertension or Preeclampsia

	Maternal Characteristics—Admission					Maternal Characteristics—Delivery				Perinatal Outcomes

been managed successfully in this unit. This relatively simple unit requires modest nursing care, no drugs other than iron and folate supplements, and few essential laboratory tests. Provider costs—not charges—for this care are minimal compared with the cost of neonatal intensive care for a preterm neonate. Importantly, thromboembolic disease has been rare in these women.

Many clinicians believe that further hospitalization is not warranted if hypertension abates within a few days, and this has emboldened third-party payers to deny inpatient reimbursement. Consequently, many women with mild to moderate hypertension are managed at home. For women in vulnerable sociodemographic home situations, this strategy may not be feasible. In other groups, outpatient management may continue as long as preeclampsia syndrome does not worsen and fetal jeopardy is not suspected. Decreased activity is recommended, and women are encouraged to report symptoms. Home blood pressure and urine protein monitoring or frequent evaluations by a visiting nurse may be beneficial.

To assess this approach, 1182 nulliparas with mild gestational hypertension—20 percent had proteinuria—were managed with home care (Barton, 2002). Their mean gestational ages were 32 to 33 weeks at enrollment and 36 to 37 weeks at delivery. Severe preeclampsia developed in approximately 20 percent, two women had eclampsia, and 3 percent developed hemolysis, elevated liver enzyme levels, and low platelet count (HELLP) syndrome. Perinatal outcomes were generally good. In approximately 20 percent, fetal growth was restricted, and the perinatal mortality rate was 4.2 deaths in 1000 births.

Table 41-1 presents two studies that compare continued hospitalization and outpatient care. In the first trial, after hospital evaluation, 218 women with mild gestational nonproteinuric hypertension were randomly assigned to continued hospitalization versus home care (Crowther, 1992). The mean hospitalization duration was 22.2 days for women with inpatient management compared with only 6.5 days in the home care group. Severe hypertension and preterm delivery before 34 and before 37 weeks' gestation were significantly increased twofold in the outpatient group. Despite this, maternal and newborn outcomes were otherwise similar.

Another approach, popular in Europe, is day care. In the second trial (Table 41-1), 374 women with gestational hypertension were randomized to either day care or inpatient care (Turnbull, 2004). Almost 95 percent had mild to moderate hypertension and 86 women had ≥1+ proteinuria. There were no perinatal deaths, and none of the women developed eclampsia or HELLP syndrome. Costs for either scheme were not significantly different, and general satisfaction favored day care.

In sum, either inpatient or close outpatient management is appropriate for a woman with mild de novo hypertension, including those with nonsevere preeclampsia. Keys to success are close surveillance and patients with home support and access to care.

Antihypertensive Therapy for Mild to Moderate Hypertension

Antihypertensive drugs have been evaluated to prolong pregnancy or modify perinatal outcomes in pregnancies complicated by various hypertensive disorders. Treatment for women with *chronic hypertension* complicating pregnancy is discussed in Chapter 53 (p. 949). Drug treatment for early mild preeclampsia has been disappointing (Table 41-2). Sibai and associates (1987a) reported that women given labetalol had significantly lower mean blood pressures than those given a placebo. However, mean pregnancy prolongation, gestational age at delivery, and birthweights did not differ between groups. The cesarean delivery rate and the number of newborns admitted to special-care nurseries also were similar. *The frequency of growth-restricted neonates was doubled in women given labetalol compared with placebo—19 versus 9 percent.*

The three other studies listed in Table 41-2 compare labetalol or a calcium-channel blocker drugs against placebo. Except for fewer episodes of severe hypertension, none of these studies showed any benefits from antihypertensive treatment (Magee, 2015). One review of 49 randomized trials of antihypertensive therapy for mild to moderate gestational hypertension compared with either no treatment or placebo reached similar conclusions (Abalos, 2014).

Expectant Management of Preterm Severe Preeclampsia

Up through the early 1990s, women with severe preeclampsia were usually immediately delivered. Subsequently, however, another approach for women with preterm severe preeclampsia was studied. The aim of "expectant" management was to improve neonatal outcome without compromising maternal safety. This approach always includes careful daily—and usually more frequent—inpatient monitoring of the mother and her fetus.

Theoretically, antihypertensive therapy has potential application when severe preeclampsia develops before intact neonatal survival is expected. Such management has been controversial and is potentially dangerous (Churchill, 2018). In one of the first studies, Sibai and the Memphis group (1985) attempted to prolong pregnancy because of fetal immaturity in 60 women with severe preeclampsia between 18 and 27 weeks. *The results were disastrous.* The perinatal mortality rate was 87 percent. Although no mothers died, 13 suffered placental abruption, 10 had eclampsia, three developed renal failure, two had hypertensive encephalopathy, one had an intracerebral hemorrhage, and another had a ruptured hepatic hematoma.

Because of their early study, the Memphis group redefined criteria and performed a randomized trial of aggressive versus expectant management for 95 women who had severe preeclampsia but with more advanced gestations of 28 to 32 weeks (Sibai, 1994). *Women with HELLP syndrome were excluded from this trial.* Aggressive management included glucocorticoid administration for fetal lung maturation followed by delivery in 48 hours. Expectantly managed women were observed at bed rest and given either labetalol or nifedipine orally for severe hypertension. In this study, pregnancy was prolonged for a mean of 15.4 days in the expectant management group. An overall improvement in neonatal outcomes also was reported.

In women expectantly managed at 23 to 34 weeks' gestation, serious complications have included placental abruption, HELLP syndrome, pulmonary edema, renal failure, and eclampsia (Table 41-3). Moreover, perinatal mortality rates averaged 90 per 1000 births. Fetal-growth restriction was common, and in studies from The Netherlands, it was an astounding 94 percent (Ganzevoort, 2005a,b). Perinatal mortality rates were disproportionately high in these growth-restricted neonates (Haddad, 2007; Shear, 2005).

Following these experiences, expectant management became more commonly practiced, with the caveat that women with HELLP syndrome or growth-restricted fetuses were usually excluded. More recently, a prospective comparative study reported that expectant management of women with "stable" HELLP syndrome at <34 weeks may benefit mother and fetus (Cavaignac-Vitalis, 2019). The MEXPRE Latin Study was a multicenter trial that randomly assigned 267 women with severe preeclampsia at 28 to 32 weeks' gestation to prompt delivery or to expectant management (Vigil-De Gracia, 2013). The perinatal mortality rate approximated 90 per 1000 in each group, and the composite neonatal morbidity outcome was not improved with expectant management. Conversely, fetal-growth restriction—22 versus 9 percent—and placental abruption—7.6 versus 1.5 percent—were significantly higher in the group managed expectantly.

Churchill and colleagues (2018) performed a Cochrane Database review of six randomized trials of interventionist versus

expectant care for severe preeclampsia between 24 and 34 weeks. Their review had findings similar to those in Table 41-3 and suggested that expectant management was beneficial to perinatal outcome. However, data were insufficient to establish conclusions on maternal health.

Expectant Management of Midtrimester Preeclampsia

Several small studies have focused on expectant management of severe preeclampsia syndrome before 28 weeks' gestation. In one review of eight such studies, maternal complications were common among nearly 200 women with severe preeclampsia with an onset <26 completed weeks (Bombrys, 2009). Because no neonates survived when delivered before 23 weeks, most experts recommend pregnancy termination in these cases. For women with slightly more advanced pregnancies, however, the decision is less clear. For example, at 23 weeks' gestation, the perinatal survival rate was 18 percent, but long-term perinatal morbidity is yet unknown. For women with pregnancies at 24 to 26 weeks, perinatal survival approaches 60 percent, and it averages almost 90 percent for those at 26 weeks.

As shown in Table 41-4, maternal complications—especially HELLP syndrome—were commonplace and one mother died. Perinatal mortality exceeded 50 percent. At this time, no comparative studies attest to perinatal benefits of such expectant treatment versus early delivery in the face of serious maternal complications, which approach rates of 50 percent.

Corticosteroids for Lung Maturation

To enhance fetal lung maturation, glucocorticoids have been administered to women with severe hypertension who are remote from term. Treatment does not seem to worsen maternal hypertension, and a lower incidence of respiratory distress and

improved fetal survival rates have been cited. That said, only one randomized trial has evaluated corticosteroids given to hypertensive women for fetal lung maturation. This trial included 218 women who had severe preeclampsia between 26 and 34 weeks' gestation and who were randomly assigned to betamethasone or placebo administration (Amorim, 1999). Rates of neonatal complications that included respiratory distress, intraventricular hemorrhage, and death were reduced significantly when betamethasone was given compared with placebo. *On the heavily weighted negative side, there were two maternal deaths and 18 stillbirths.* We add these findings to buttress our unenthusiastic acceptance of attempts to prolong gestation in many of these women (Alexander, 2015; Bloom, 2003).

Corticosteroids to Ameliorate HELLP Syndrome

Several observational studies have indicated that corticosteroid therapy would ameliorate facets of the HELLP syndrome (Añez-Aguayo, 2018; Martin, 2016). Subsequently, at least three randomized trials aimed to evaluate the benefits of glucocorticoids given to improve the laboratory abnormalities associated with HELLP syndrome. Fonseca and associates (2005) randomly assigned 132 women with HELLP syndrome to either dexamethasone or placebo administration. Outcomes assessed included hospitalization length, recovery time of abnormal laboratory test results, resolution of clinical parameters, and complications that included acute renal failure, pulmonary edema, eclampsia, and death. None of these was significantly different between the two groups. In another study, 105 postpartum women with HELLP syndrome were assigned to dexamethasone or placebo treatment. Katz and colleagues (2008) found no advantage to dexamethasone (Fig. 41-1). In the third study, preeclamptic women were given either placebo or methylprednisolone if their platelet count was between 50,000 and 150,000/μL (Pourrat, 2016). Again, no benefits were gained from corticosteroid therapy. A Bolivian study did show benefits from corticosteroid therapy, however, it was not randomized (Añez-Aguayo, 2018). Because of these findings, the 2013 Task Force does not recommend corticosteroid treatment to improve thrombocytopenia with HELLP syndrome.

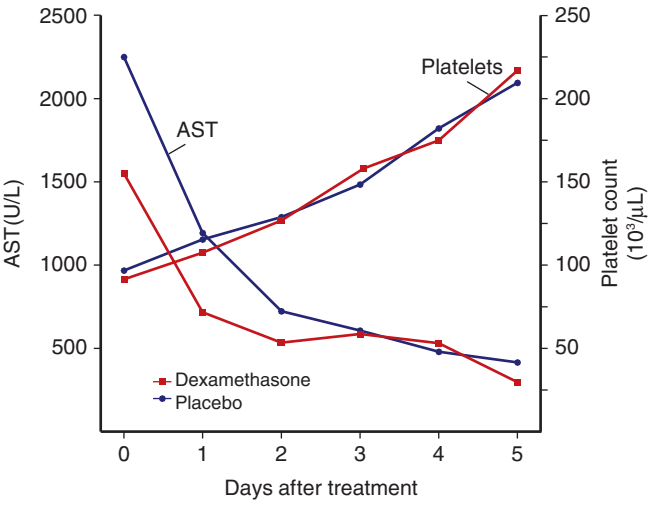

FIGURE 41-1 Recovery times for platelet counts and serum aspartate transaminase (AST) levels in women with HELLP syndrome assigned to receive treatment with dexamethasone or placebo.

Expectant Management Recommendations

Taken in toto, these studies do not show overwhelming benefits of expectant management of severe preeclampsia in women with gestations from 24 to 32 weeks compared with maternal risks. Despite these caveats, the Society for Maternal-Fetal Medicine (2011) has determined that such management is a reasonable alternative in selected women with severe preeclampsia before 34 weeks (Fig. 41-2). The Task Force

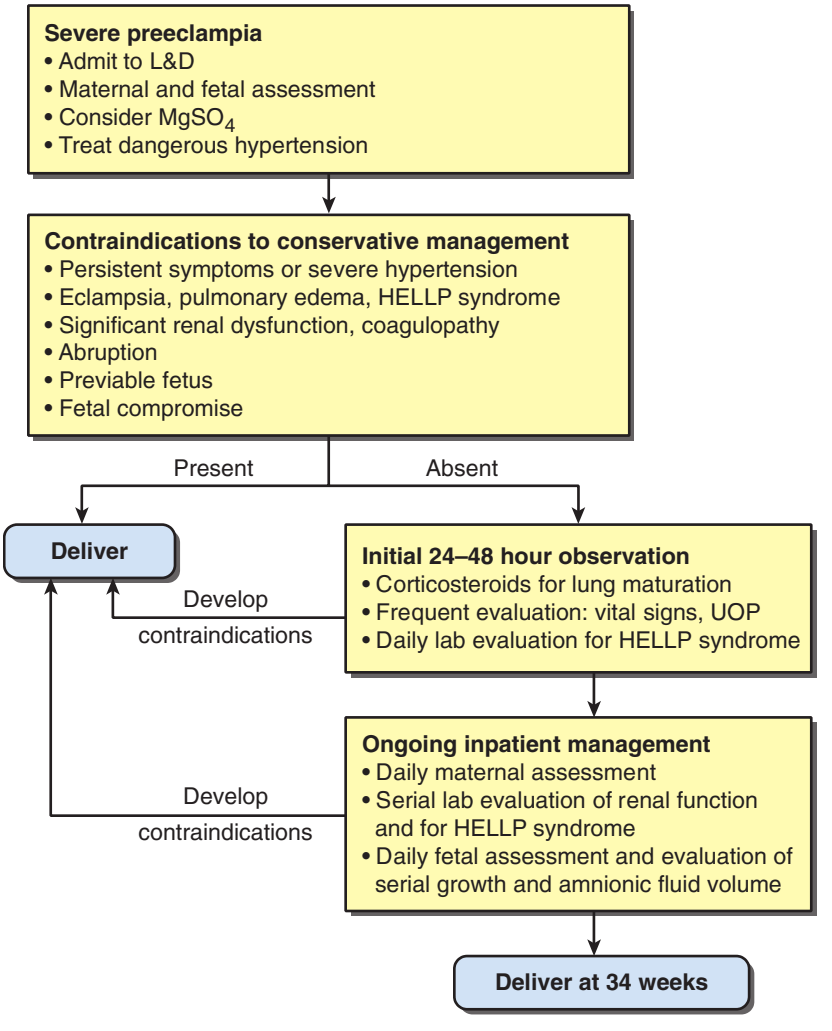

FIGURE 41-2 Clinical management algorithm for severe preeclampsia at <34 weeks. HELLP = hemolysis, elevated liver enzyme levels, low platelet count; L & D = labor and delivery; $MgSO_4$= magnesium sulfate; UOP = urine output.

TABLE 41-5. Indications for Delivery in Women <34 Weeks' Gestation Managed Expectantly

Prompt Delivery After Maternal Stabilization and After Single-dose Corticosteroid Therapy for Lung Maturation:[a]
Uncontrolled severe hypertension
Persistent headaches, refractory to treatment
Persistent epigastric pain
Eclampsia
HELLP syndrome
Pulmonary edema
Placental abruption
Disseminated intravascular coagulation
Stroke
Myocardial infarction
Nonreassuring fetal status
Fetal demise
Delay Delivery 48 hr If Possible to Allow Corticosteroid Therapy for Lung Maturation:
Preterm ruptured membranes or labor
Fetal-growth restriction
Oligohydramnios
Reversed end-diastolic Doppler flow in umbilical artery
Worsening renal dysfunction

[a]Inital dose only, do not delay delivery.
HELLP = hemolysis, elevated liver enzyme levels, low platelet count.
From American College of Obstetricians and Gynecologists, 2020b; Society for Maternal-Fetal Medicine, 2011.

(2013) supports this recommendation. As shown in Table 41-5, such management calls for inpatient maternal and fetal surveillance with delivery prompted by evidence for worsening severe preeclampsia or maternal or fetal compromise. Although attempts are made for vaginal delivery in most cases, the likelihood of cesarean delivery rises with decreasing gestational age.

Our view is more conservative. Undoubtedly, the overriding reason to terminate pregnancies with severe preeclampsia is maternal safety. Indeed, it seems obvious that a delay to prolong gestation in women with severe preeclampsia may have serious maternal consequences. These observations are even more pertinent when considered with the absence of convincing evidence that perinatal outcomes are markedly improved by the average prolongation of pregnancy by approximately 1 week. If undertaken, the caveats that mandate delivery shown in Table 41-5 should be strictly heeded.

Experimental Therapies

In preliminary studies, therapies have been used to lower serum levels of antiangiogenic factors in hopes to mitigate their adverse actions. Some of these include *therapeutic apheresis* to lower sFlt-1 levels (Thadhani, 2016; Winkler, 2018). Another novel therapy uses RNA molecules to silence placental sFlt-1 (Turanov, 2018). The *proton-pump inhibitor* esomeprazole was studied in women with early-onset preeclampsia (Cluver, 2018). *Sildenafil citrate*, a phosphodiesterase inhibitor, has been provided to promote vasodilation (Trapani, 2016; Vigil-De Gracia, 2016). Other studies compared *recombinant antithrombin infusion* with placebo (Paidas, 2020). In general, none of these therapies has shown promise.

SEVERE PREECLAMPSIA AND ECLAMPSIA

Classification of preeclampsia with severe features is summarized in Table 40-2 (p. 690). Briefly, features include systolic blood pressure ≥160 mm Hg or diastolic pressure ≥110 mm Hg; liver derangement with transaminitis; thrombocytopenia; renal insufficiency; pulmonary edema; new-onset headache; or visual changes. Eclampsia is defined by new-onset tonic-clonic, focal, or multifocal seizures in the absence of other causes.

Eclampsia

The development of eclampsia appreciably raises the risk to mother and fetus (Fishel-Bartal, 2020). In an earlier report, Mattar and Sibai (2000) described outcomes in 399 consecutive women with eclampsia from 1977 through 1998. Major maternal complications included placental abruption—10 percent, neurological deficits—7 percent, aspiration pneumonia—7 percent, pulmonary edema—5 percent, cardiopulmonary arrest—4 percent, and acute kidney injury (AKI)—4 percent. Moreover, 1 percent of these women died. Several subsequent reports similarly described excessive maternal morbidity and mortality rates with eclampsia that also included HELLP syndrome, pulmonary embolism, and stroke (Andersgaard, 2006; Knight, 2007).

Almost without exception—but at times unnoticed—preeclampsia precedes convulsions. Eclampsia is most common in the last trimester and becomes increasingly frequent as term approaches. Postpartum, the incidence of eclampsia has declined during the past decade. Improved access to prenatal care, earlier detection of antepartum preeclampsia, and prophylactic use of magnesium sulfate are explanations (Chames, 2002). Other diagnoses should be considered in women with convulsions more than 48 hours postpartum or in women with focal neurological deficits, prolonged coma, or atypical eclampsia.

Clinical Findings with Eclampsia

Eclamptic seizures may be violent, and the woman must be protected, especially her airway. So forceful are the muscular movements that the woman may throw herself out of her bed, and if not protected, her tongue is bitten by the violent action of the jaws (Fig. 41-3). This phase, in which the muscles alternately contract and relax, may last approximately a minute.

Gradually, the muscular movements become smaller and less frequent, and finally the woman lies motionless.

After a seizure, the woman is postictal, but in some, a coma of variable duration ensues. When the convulsions are infrequent, the woman usually recovers some degree of consciousness after each attack. As the woman arouses, a semiconscious combative state may ensue. In severe cases, coma persists from one convulsion to another, and death may result.

FIGURE 41-3 Hematoma of tongue from laceration during an eclamptic convulsion. Thrombocytopenia may have contributed to the bleeding.

FIGURE 41-4 Severe edema in a young nullipara with antepartum preeclampsia. Fingerprint indentations from clinical assessment can be seen on both shins. Rings at the ankles formed from elastic sock bands. (Reproduced with permission from Dr. Nidhi Shah.)

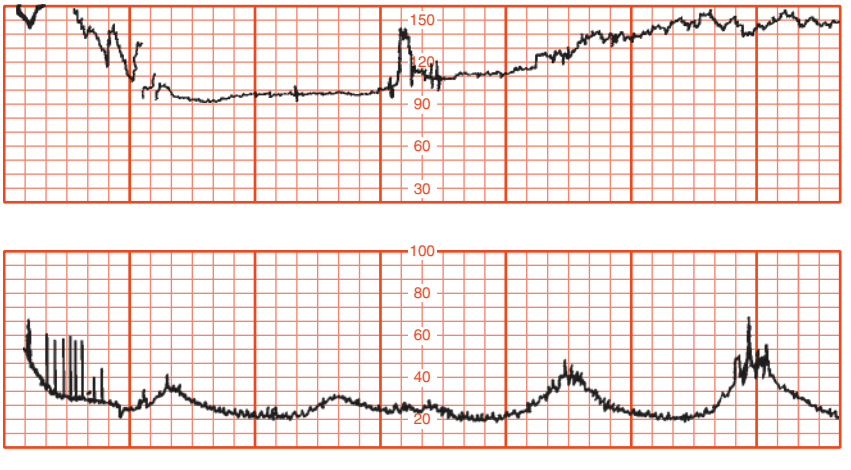

FIGURE 41-5 Fetal heart rate tracing shows fetal bradycardia following an intrapartum eclamptic convulsion. Bradycardia resolved and beat—to—beat variability returned approximately 5 minutes following the seizure.

Rarely, a single convulsion may be followed by coma from which the woman may never emerge. As a rule, however, death does not occur until after frequent convulsions. Last, and also rarely, convulsions continue unabated—*status epilepticus*—and require deep sedation and even general anesthesia to obviate anoxic encephalopathy.

The respiratory rate after an eclamptic convulsion usually rises and may reach 50 or more per minute in response to hypercarbia, lactic acidemia, and transient hypoxia. Cyanosis may be observed in severe cases. High fever is a grave sign as it likely emanates from cerebrovascular hemorrhage.

Proteinuria is usually present, and a fourth of women with severe preeclampsia have some degree of AKI (Rodriguez, 2021). Urine output may be diminished appreciably, and occasionally anuria develops. Hemoglobinuria may be seen, but hemoglobinemia is rare. Edema may be pronounced (Fig. 41-4).

With severe preeclampsia, urinary output rises after delivery and is usually an early sign of improvement. With renal dysfunction, serum creatinine levels are serially monitored. Proteinuria and edema ordinarily disappear within a week postpartum. In most cases, blood pressure returns to normal within a few days to 2 weeks after delivery (Berks, 2009). As subsequently discussed, persisting and severe hypertension likely predicts underlying chronic vascular disease.

In antepartum eclampsia, labor may begin spontaneously shortly after convulsions ensue and may progress rapidly. If the seizures develop during labor, contractions may increase in frequency and intensity, and the duration of labor may be shortened. Because of maternal hypoxemia and lactic acidemia caused by convulsions, fetal bradycardia often follows a seizure (Fig. 41-5). In our experiences, the fetal heart rate usually recovers within 2 to 10 minutes. If it persists more than 10 minutes, another cause of bradycardia, such as placental abruption, should be considered.

Pulmonary edema may follow shortly after eclamptic convulsions or several hours later. This complication is further explored on page 724.

Occasionally, sudden death occurs synchronously with an eclamptic seizure, or it follows shortly thereafter. Most often in these cases, a massive cerebral hemorrhage is the cause (Fig. 40-11, p. 700). Hemiplegia may result from sublethal hemorrhage. Cerebral hemorrhages are more likely in older women with underlying chronic hypertension. For women with a neurological deficit after an eclamptic seizure, consideration is given for emergent cranial computed tomography (CT) scanning. Up to 5 percent of women with eclampsia have altered consciousness, including persistent coma, following a seizure. This may be due to extensive cerebral edema, and associated transtentorial herniation may cause death (Cunningham, 2000). In approximately 10 percent of eclamptic women, some degree of blindness follows a seizure. The causes of impaired vision which usually improves postpartum, are discussed in Chapter 40 (p. 701).

Rarely, eclampsia is followed by psychosis, and the woman becomes violent. This may last for several days to 2 weeks. The prognosis for return to normal function is good, provided mental illness was not preexisting. It is presumed to be similar to postpartum psychosis discussed in Chapter 64 (p. 1148). Antipsychotic medications have been effective in the few cases of posteclampsia psychosis treated at Parkland Hospital.

Generally, eclampsia is more likely to be diagnosed too frequently rather than overlooked. Epilepsy, encephalitis, meningitis, brain tumor, neurocysticercosis, amnionic fluid embolism, postdural puncture cephalalgia, and ruptured cerebral aneurysm during late pregnancy or in the puerperium may simulate eclampsia. Until other such causes are excluded, however, all pregnant women with convulsions should be considered to have eclampsia. As a pragmatic rule, loading with magnesium sulfate should be considered while alternate diagnoses are explored.

MANAGEMENT OF SEVERE PREECLAMPSIA-ECLAMPSIA

Most eclampsia regimens in the United States adhere to a similar philosophy:

- Control or prevent convulsions using an intravenous loading dose of magnesium sulfate. This is followed by maintenance dosing, usually given intravenously
- Provide intermittent antihypertensive medication to lower dangerously high blood pressure
- Avoid diuretics unless pulmonary edema is obvious; limit intravenous fluid administration unless fluid loss is excessive; and avoid hyperosmotic agents
- Deliver the fetus to resolve preeclampsia.

Magnesium Sulfate

This parenterally administered agent is an effective anticonvulsant and avoids producing central nervous system depression. It may be given intravenously by continuous infusion or intramuscularly by intermittent injection (Table 41-6). A third option is intermittent, intravenous, 2-g injections (Easterling, 2018). Dosages for severe preeclampsia mirror those for eclampsia. Because labor and delivery is a more likely time for seizures to develop, women with severe preeclampsia or eclampsia usually are given magnesium sulfate during labor and for 24 hours postpartum. In the United States, magnesium sulfate is almost universally administered intravenously. Of concern, magnesium sulfate solutions, although inexpensive to prepare, are not readily available in all parts of the developing world. Even if solutions are available, the technology to infuse them may not be. Thus, the drug can be administered intramuscularly, and this is as effective as intravenous infusion (Pritchard, 1955, 1975, 1984; Salinger, 2013).

Magnesium sulfate is not given to treat hypertension. Magnesium ion most likely exerts a specific anticonvulsant action on the cerebral cortex. Typically, the mother stops convulsing after the initial 4-g loading dose. By an hour or two, she regains consciousness sufficiently to be oriented to place and time.

The magnesium sulfate dosage regimens presented in Table 41-6 usually result in increased plasma magnesium levels. Data from Brookfield and associates (2016) are illustrated in Figure 41-6. When magnesium sulfate is given to arrest an eclamptic seizure, up to 15 percent of women will have a subsequent convulsion. If so, an additional 2-g dose of magnesium sulfate in a 20-percent solution is slowly administered intravenously. In a small woman, this additional 2-g dose may be used once, but it can be given twice if needed in a larger woman. In

TABLE 41-6. Magnesium Sulfate Dosage Schedule for Severe Preeclampsia and Eclampsia

Continuous Intravenous (IV) Infusion
Give 4- to 6-g loading dose of magnesium sulfate diluted in 100 mL of IV fluid administered over 15–20 min
Begin 2 g/hr in 100 mL of IV maintenance infusion. Some recommend 1 g/hr
Monitor for magnesium toxicity:
Assess deep tendon reflexes periodically
Some measure serum magnesium level at 4–6 hr and adjust infusion to maintain levels between 4 and 7 mEq/L (4.8–8.4 mg/dL)
Measure serum magnesium levels if serum creatinine ≥1.0 mg/dL
Magnesium sulfate is discontinued 24 hr after delivery
Intermittent Intramuscular Injections
Give 4 g of magnesium sulfate ($MgSO_4 7H_2O$ USP) as a 20% solution intravenously at a rate not to exceed 1 g/min
Follow promptly with 10 g of 50% magnesium sulfate solution, one half (5 g) injected deeply in the upper outer quadrant of each buttock through a 3-inch-long 20-gauge needle. (Addition of 1.0 mL of 2% lidocaine minimizes discomfort.) If convulsions persist after 15 min, give up to 2 g more intravenously as a 20% solution at a rate not to exceed 1 g/min. If the woman is large, up to 4 g may be given slowly.
Every 4 hr thereafter, give 5 g of 50% solution of magnesium sulfate injected deeply in the upper outer quadrant of alternate buttocks, but only after ensuring that:
The patellar reflex is present,
Respirations are not depressed, and
Urine output the previous 4 hr exceeded 100 mL
Magnesium sulfate is discontinued 24 hr after delivery

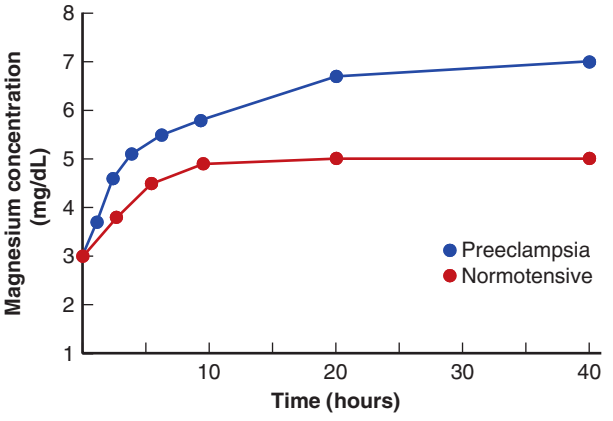

FIGURE 41-6 Serum magnesium concentration in normotensive and preeclamptic women following a 4-g loading dose of magnesium sulfate and 2 g/h infusion.

only 5 of 245 women with eclampsia at Parkland Hospital was it necessary to use alternative supplementary anticonvulsant medication to control seizures (Pritchard, 1984). For these, a small dose of a short-acting benzodiazepine such as midazolam or lorazepam is given intravenously. Their prolonged use is avoided because of an associated higher mortality rate from aspiration pneumonia (Royal College of Obstetricians and Gynaecologists, 2006).

Maintenance magnesium sulfate therapy has traditionally been continued for 24 hours after delivery. For eclampsia that develops postpartum, magnesium sulfate is administered for 24 hours after the onset of convulsions. A few investigators have truncated this therapy duration to 12 hours and reported no seizures (Anjum, 2016; Ehrenberg, 2006; Kashanian, 2016). Outcomes have also been reported when magnesium sulfate therapy was stopped after delivery (Ludmir, 2017; Vigil-De Gracia, 2018). These studies are relatively small, and the abbreviated magnesium sulfate regimens need further study before being routinely implemented.

Pharmacology and Toxicology

Parenterally administered magnesium is cleared almost totally by renal excretion, and magnesium clearance rate is approximately a third of glomerular filtration rate (GFR) determined by creatinine clearance. Magnesium intoxication is unusual when the GFR is normal or only slightly reduced. Adequate urine output usually correlates with preserved GFR. That said, magnesium excretion is not urine flow dependent, and urinary volume per unit time does not, per se, predict renal function. *Thus, serum creatinine levels must be measured to confirm a decreased GFR.*

Eclamptic convulsions are almost always prevented or arrested by plasma magnesium levels maintained at 4 to 7 mEq/L, 4.8 to 8.4 mg/dL, or 2.0 to 3.5 mmol/L. However, one review of magnesium pharmacokinetics showed that most regimens result in much lower serum magnesium levels (Okusanya, 2016). This was especially true if only 1 g/hr was infused (Yefet, 2017). Importantly, the obesity epidemic has affected these observations (Cunningham, 2016). Tudela and colleagues (2013) described our results from Parkland Hospital with magnesium administration to obese women. More than 60 percent of women who had a body mass index (BMI) >30 kg/m^2 and who were receiving a 2-g/hr dose had subtherapeutic levels at 4 hours. Thus, most obese women would require 3 g/hr to maintain effective plasma levels. That said, most currently do not recommend routine magnesium level measurements (American College of Obstetricians and Gynecologists, 2020a; Royal College of Obstetricians and Gynaecologists, 2006).

Patellar reflexes disappear when the plasma magnesium level reaches 10 mEq/L—approximately 12 mg/dL—presumably because of a curariform action. This sign serves to warn of impending magnesium toxicity. When plasma levels rise above 10 mEq/L, breathing weakens. At 12 mEq/L or higher levels, respiratory paralysis and respiratory arrest follow (Somjen, 1966). *Treating with calcium gluconate or calcium chloride, 1 g intravenously, coupled with magnesium sulfate discontinuation, usually reverses mild to moderate respiratory depression.* One of these agents should be readily available whenever magnesium is being infused. Unfortunately, the effects of intravenously administered calcium may be short-lived if a steady-state toxic magnesium level has been reached. For severe respiratory depression and arrest, prompt tracheal intubation and mechanical ventilation are lifesaving. Direct toxic effects on the myocardium from high levels of magnesium sulfate are uncommon (Morisaki, 2000).

Because magnesium is cleared almost exclusively by renal excretion, our described dosages of magnesium sulfate will become excessive if the GFR is substantially decreased. The initial 4- or 6-g loading dose of magnesium sulfate can be safely administered regardless of renal function. It is important to administer the standard loading dose and not to reduce it. A loading dose achieves the desired therapeutic level, and the infusion maintains the steady-state level. *Thus, only the maintenance infusion rate should be altered for those with a diminished GFR.* Renal function is estimated by measuring plasma creatinine. Whenever plasma creatinine levels are >1.0 mg/mL, serial serum magnesium levels are determined to guide the infusion rate (American College of Obstetricians and Gynecologists, 2020a).

After a 4-g intravenous dose is administered during 15 minutes, mean arterial pressure falls slightly and is accompanied by a 13-percent rise in cardiac index (Cotton, 1986b). Thus, magnesium lowers systemic vascular resistance and mean arterial pressure. At the same time, cardiac output is increased. These findings are coincidental with transient nausea and flushing, and the cardiovascular effects persist for only 15 minutes despite continued magnesium infusion. Magnesium-induced vasodilation is weaker in placental vessels because of diminished calcium-channel activity (Tang, 2018).

Thurnau and coworkers (1987) showed that magnesium therapy led to a small but significant rise in the cerebrospinal fluid's total magnesium concentration. The magnitude was directly proportional to the corresponding serum concentration.

Other Effects

Magnesium has anticonvulsant and neuroprotective effects in animal models. Some proposed mechanisms of action include: (1) reduced presynaptic release of the neurotransmitter glutamate, (2) blockade of glutamatergic *N*-methyl-D-aspartate (NMDA) receptors, (3) potentiation of adenosine action, (4) improved

calcium buffering by mitochondria, and (5) blockage of calcium entry via voltage-gated channels (Arango, 2008; Wang, 2012).

In the uterus, relatively high serum magnesium concentrations depress myometrial contractility. Inhibition of uterine contractility is magnesium dose dependent, and serum levels of at least 8 to 10 mEq/L are needed to inhibit uterine contractions (Watt-Morse, 1995). With the suggested magnesium sulfate regimens for seizure prevention, prolonged myometrial depression has not been observed. A transient decline in activity during and immediately after the initial intravenous loading dose can be seen (Leveno, 1998; Witlin, 1997). Blood loss at delivery is not increased by standard magnesium sulfate treatment (Graham, 2016).

■ Neuroprophylaxis—Prevention of Seizures

Several randomized trials have tested the efficacy of seizure prophylaxis for women with gestational hypertension, with or without proteinuria. In all, magnesium sulfate was superior to the comparator agent to prevent eclampsia. Four of the larger studies are summarized in Table 41-7. In the study from Parkland Hospital, magnesium sulfate therapy was superior to phenytoin to prevent seizures in women with gestational hypertension or preeclampsia (Lucas, 1995). In another study, magnesium sulfate and nimodipine, which is a calcium-channel blocking drug with specific cerebral vasodilator activity, were compared in 1650 women with severe preeclampsia (Belfort, 2003). The rate of eclampsia was more than threefold higher for women allocated to the nimodipine group—2.6 versus 0.8 percent.

The largest comparative study was *Magnesium Sulfate for Prevention of Eclampsia* reported by the Magpie Trial Collaboration Group (2002). More than 10,000 women with severe preeclampsia from 33 countries were randomly allocated to treatment with magnesium sulfate or placebo. Women given magnesium had a 58-percent significantly lower risk of eclampsia than those given placebo. Maternal mortality and placental abruption rates also were decreased. Child behavior at 18 months did not differ between groups (Smyth, 2009).

Who Should Be Given Magnesium Sulfate?

Magnesium will prevent proportionately more seizures in women with correspondingly worse disease. However, severity is difficult to quantify, and thus deciding which woman might benefit most from neuroprophylaxis is sometimes difficult. The American College of Obstetricians and Gynecologists (2020a) recommends that women with either eclampsia or severe preeclampsia should be given magnesium sulfate prophylaxis. Again, criteria that establish "severity" are not universal.

Thus, the conundrum is whether women with "nonsevere" gestational hypertension or preeclampsia should receive magnesium neuroprophylaxis. We found that approximately 1 woman in 100 who has nonsevere preeclampsia but who is not given magnesium sulfate prophylaxis can be expected to have a seizure. A fourth of these women likely will require emergent cesarean delivery and be exposed to the attendant maternal and perinatal morbidity from general anesthesia. From this, the major question regarding management of nonsevere gestational hypertension remains whether it is acceptable to avoid unnecessary treatment of 99 women to risk eclampsia in one. The answer appears to be yes, as suggested by the American College of Obstetricians and Gynecologists (2020a). At Parkland Hospital, our policy is to give magnesium neuroprophylaxis to women with preeclampsia with severe features, and conservatively to those with proteinuria hypertension (Table 40-1, p. 689).

Fetal and Neonatal Effects

Magnesium administered parenterally promptly crosses the placenta to achieve equilibrium in fetal serum and less so in amnionic fluid (Gortzak-Uzan, 2005; Narasimhulu, 2017). Magnesium sulfate has small but significant effects on the fetal heart rate pattern and specifically on beat-to-beat variability

TABLE 41-7. Randomized Comparative Trials of Prophylaxis with Magnesium Sulfate and Placebo or Another Anticonvulsant in Women with Gestational Hypertension

Study/Inclusions	No. with Seizures/Total No. Treated (%)		
	Magnesium Sulfate	Control	Comparison[a]

RR = relative risk.

(Hallak, 1999). One study showed a lower baseline heart rate that was within the normal range; decreased variability; and fewer prolonged decelerations (Duffy, 2012).

Overall, maternal magnesium therapy appears safe for perinates (Drassinower, 2015). One study of more than 1500 exposed preterm neonates found no association between the need for neonatal resuscitation and cord blood magnesium levels (Johnson, 2012). Still, a few neonatal adverse events are associated with its use. In a Parkland Hospital study of 6654 mostly term, exposed newborns, 6 percent had hypotonia (Abbassi-Ghanavati, 2012). In addition, exposed neonates had lower 1- and 5-minute Apgar scores, a higher intubation rate, and more admissions to the special care nursery. Neonatal depression occurs only if hypermagnesemia at delivery is severe.

Observational studies suggest a protective effect of magnesium against the development of cerebral palsy in very-low-birthweight newborns (Crowther, 2017). These beneficial effects may extend to growth-restricted fetuses. Randomized trials have also assessed neuroprotective effects for preterm neonates, and findings are discussed in Chapter 45 (p. 803). One review expanded this possibility to include term newborns, but data were insufficient to draw conclusions (Nguyen, 2013).

Maternal Safety and Efficacy

The multinational Eclampsia Trial Collaborative Group study (1995) involved 1687 women with eclampsia randomly allocated to one of three different anticonvulsant regimens: magnesium sulfate, diazepam, or phenytoin (Table 41-8). In aggregate, magnesium sulfate therapy was associated with a significantly lower incidence of recurrent seizures (9.7 percent) compared with women given phenytoin (28 percent) or diazepam (17 percent). Moreover, the aggregate maternal death rate of 3.2 percent with magnesium sulfate was significantly lower than that of 5.2 percent for the other two regimens.

Severe Hypertension Treatment

Dangerous hypertension can cause cerebrovascular hemorrhage and hypertensive encephalopathy, and it can trigger eclamptic convulsions. Other complications are placental abruption and congestive heart failure induced by elevated hypertensive afterload. Studies highlight the importance of treating systolic hypertension when blood pressures are >160 mm Hg (Judy, 2019; Martin, 2005, 2016).

Because of these serious sequelae, the Working Group for the National High Blood Pressure Education Program (2000) and the American College of Obstetricians and Gynecologists (2020a) recommend treatment to lower systolic pressures to a level ≤160 mm Hg and diastolic pressures to ≤110 mm Hg. Lower diastolic pressures can compromise placental perfusion.

From other observations, it seems likely that at least half of serious hemorrhagic strokes associated with preeclampsia are in women with chronic hypertension (Cunningham, 2005; Zofkie, 2018). Long-standing hypertension results in development of *Charcot–Bouchard aneurysms* in the deep penetrating arteries of the lenticulostriate branch of the middle cerebral arteries. These vessels supply the basal ganglia, putamen, thalamus, adjacent deep white matter, pons, and deep cerebellum. These unique aneurysmal weakenings predispose these small arteries to rupture during sudden hypertensive episodes.

Several drugs are available to rapidly lower dangerously elevated blood pressure in women with pregnancy-associated hypertension. Hydralazine, labetalol, and nifedipine are recommended as first-line agents by the American College of Obstetricians and Gynecologists (2020a). Evidence supports their value to decrease stroke risk (Cleary, 2018).

All three agents have equivalent efficacy. Comparative studies of hydralazine and labetalol show similar results (Mable, 1987; Umans, 2015). Hydralazine causes significantly more maternal tachycardia and palpitations, whereas labetalol more frequently leads to maternal hypotension and bradycardia. Randomized trials that compared nifedipine with labetalol found neither drug definitively superior, but nifedipine lowered blood pressure more quickly (Gainder, 2019; Zulfeen, 2019). Both drugs are associated with a reduced frequency of fetal heart rate accelerations (Cahill, 2013). Last, a study comparing nifedipine and hydralazine showed similar efficacy (Sharma, 2017).

A few other generally available antihypertensive agents have been tested in clinical trials but are not widely used (Umans, 2015). These include verapamil, nitroglycerin, nitroprusside, ketanserin, nicardipine, and nimodipine (Belfort, 2003; Cornette, 2016). Experimental antihypertensive drugs may eventually be useful for preeclampsia treatment (Lam, 2013).

Hydralazine

This antihypertensive agent is administered intravenously or intramuscularly. An initial 5- to 10-mg dose can act as rapidly

TABLE 41-8. Randomized Comparative Trials of Magnesium Sulfate versus Phenytoin and Diazepam to Prevent Recurrent Eclamptic Convulsions

	Magnesium Sulfate	Phenytoin	Diazepam
Recurrent seizures[a]	60/453 (13%)	126/452 (28%)	—

TABLE 41-9. Antihypertensive Agents for Urgent Control of Severe Hypertension

Drug	Dose	Side Effects
Hydralazine	5 mg IV or IM followed by 10-mg doses at 15–20 min intervals for up to 3 doses ***or*** Constant infusion 0.5–10 mg/hr	Tachycardia, headaches, hypotension
Labetalol	10 mg IV followed by 20 mg IV in 20 min, then 40 mg IV, then 80 mg IV ***or*** Constant infusion 1–2 mg/min	Asthma precipitation, bradycardia, hypotension
Nifedipine	10 mg orally followed by 20 mg doses at 20 min × 2	Tachycardia, headaches

IM = intramuscular; IV = intravenous

as 10 minutes. If needed, this is followed by 10-mg doses at 15- to 20-minute intervals until a satisfactory response is achieved (Table 41-9). Although we will administer a third dose, the American College of Obstetricians and Gynecologists (2020a) recommends labetalol therapy if severe hypertension persists after the second dose. Another regimen continuously infuses hydralazine at a rate of 0.5 to 10 mg/hr.

For higher blood pressures, the tendency to give a larger initial dose of hydralazine should be avoided. The response to 5- to 10-mg doses cannot be predicted by hypertension severity. Thus, our protocol is to always administer 5 mg as the initial dose. An adverse response to exceeding this initial dose is shown in Figure 41-7. This woman had chronic hypertension complicated by severe superimposed preeclampsia, and hydralazine was injected more frequently than recommended. Her blood pressure in less than 1 hour dropped from 270/150 mm Hg to 110/80 mm Hg. Fetal heart rate decelerations characteristic of uteroplacental insufficiency became evident. Decelerations persisted until her blood pressure was raised with rapid crystalloid infusion. In some cases, this fetal response to diminished uterine perfusion may be confused with placental abruption and may result in unnecessary and potentially dangerous emergency cesarean delivery.

Labetalol

This effective intravenous antihypertensive agent is an α- and nonselective β-blocker. Some prefer its use to hydralazine because of fewer side effects. Importantly, labetalol is usually not given to asthmatic women.

At Parkland Hospital, we give 10 mg intravenously initially. If blood pressure has not declined to suitable levels in 10 minutes, 20 mg is given. The next 10-minute incremental dose is 40 mg and is followed by another 40 mg if needed. If a salutary response is not achieved, an 80-mg dose is provided (see Table 41-9). The American College of Obstetricians and Gynecologists (2020a) recommends starting with a 10- to 20-mg intravenous bolus. If not effective, this is followed by 20 to 80 mg every 10 to 30 minutes. If hypertension persists, hydralazine is then given.

Nifedipine

This calcium-channel blocking agent is given initially as a 10- to 20-mg oral dose of immediate release medication. If necessary after 20 minutes, a 10- to 20-mg oral dose is repeated. With an unsatisfactory response, labetalol is provided. *Nifedipine given sublingually is no longer recommended.* This route is associated with dangerously rapid and extensive effects.

Diuretics

Potent loop diuretics can further compromise placental perfusion. Immediate effects include redistribution of intravascular volume, which most often is already reduced in severe preeclampsia (p. 724). Thus, before delivery, diuretics are not used to lower blood pressure (Zeeman, 2009; Zondervan, 1988). Furosemide or similar drugs are used before delivery

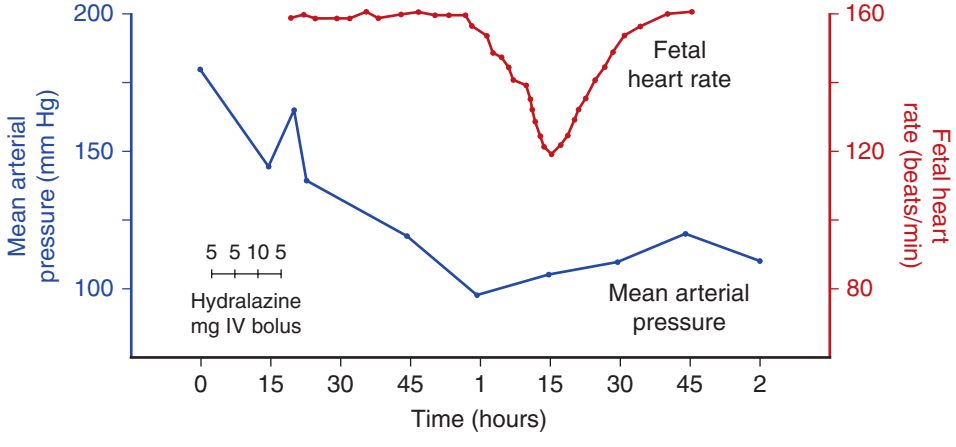

FIGURE 41-7 Hydralazine was given at 5-minute intervals instead of 15-minute intervals. The mean arterial pressure dropped from 180 to 90 mm Hg within 1 hour and was associated with fetal bradycardia. Rapid crystalloid infusion raised the mean pressure to 115 mm Hg, and the fetus recovered.

solely to treat pulmonary edema. Discussed on page 725, they may have a role in treatment of postpartum hypertension.

Fluid Therapy

Crystalloid solution is administered routinely at a rate between 60 and 125 mL per hour, unless fluid loss is unusual from vomiting, diarrhea, diaphoresis, or excessive blood loss. Oliguria is common with severe preeclampsia. Coupled with the knowledge that maternal blood volume is likely constricted compared with that of normal pregnancy, it is tempting to administer intravenous fluids more vigorously. However, controlled, conservative fluid administration is preferred for the typical woman with severe preeclampsia. These gravidas already have excessive extracellular fluid that has inappropriately extravasated from the intravascular compartment.

Infusion of large fluid volumes enhances the maldistribution and thereby elevates the risk of pulmonary and cerebral edema (Sciscioner, 2003; Zinaman, 1985). Thus, for preeclamptic women with anuria, small incremental boluses can be given to maintain urine output above 30 mL/hr. Diminished intravascular volume from hemorrhage or fluid loss from vomiting or fever can similarly be replaced by gradual incremental boluses of crystalloid. For labor analgesia with neuraxial analgesia, crystalloid solutions are infused slowly in graded amounts (Chap. 25, p. 479).

Pulmonary Edema

Women with severe preeclampsia who develop pulmonary edema most often do so postpartum (Cunningham, 1986, 2012). With pulmonary edema in the eclamptic woman, aspiration of gastric contents, which may be the result of convulsions, anesthesia, or oversedation, should be excluded. Otherwise, in women with severe preeclampsia, three common causes of pulmonary edema are pulmonary capillary permeability edema, cardiogenic edema, or their combination.

First, in women with preeclampsia, both increased capillary permeability and greater extravascular fluid oncotic pressure are found (Brown, 1989; Øian, 1986). If intravenous fluid replacement is vigorous, pulmonary congestion can follow.

Second, in some women, pulmonary edema may be caused by ventricular failure from increased afterload that results from severe hypertension. Such pulmonary edema from ventricular failure is more common in morbidly obese women and in those with chronic hypertension.

Invasive Hemodynamic Monitoring

Knowledge concerning cardiovascular and hemodynamic pathophysiological alterations associated with severe preeclampsia–eclampsia has accrued from studies done using invasive monitoring and a pulmonary artery catheter (Fig. 40-5, p. 694). Two conditions frequently cited as indications are preeclampsia associated with oliguria or with pulmonary edema (Clark, 2010). Somewhat ironically, it is usually vigorous treatment of the former that results in most cases of the latter. The Task Force (2013) recommends against routine invasive monitoring. This is best reserved for women with severe preeclampsia and with accompanying cardiac disease, renal disease, or both or with refractory hypertension, oliguria, and pulmonary edema. Preliminary data from studies using a *noninvasive cardiac monitoring system* need to be verified before widespread clinical application (Lavie, 2018).

Plasma Volume Expansion

Because the preeclampsia syndrome is associated with hemoconcentration, some have infused various fluids, starch polymers, albumin concentrates, or combinations to expand blood volume. Older studies describe serious complications—especially pulmonary edema—with volume expansion (Benedetti, 1985; Sibai, 1987b).

The Amsterdam randomized study reported by Ganzevoort and coworkers (2005a,b) was a well-designed investigation done to evaluate volume expansion. A total of 216 women with severe preeclampsia were enrolled between 24 and 34 weeks' gestation. The study included women whose preeclampsia was complicated by HELLP syndrome, eclampsia, pulmonary edema, or fetal-growth restriction. In the group randomly assigned to volume expansion, each woman was given 250 mL of 6-percent hydroxyethyl starch infused over 4 hours twice daily. Pregnancy outcomes were compared with a control group, and none of these were significantly different. Importantly, serious maternal morbidity and a substantive perinatal mortality rate accompanied their expectant management.

Analgesia and Anesthesia

During the past 25 years, the use of neuraxial analgesia for women with preeclampsia syndrome has proved ideal. Randomized studies attest to its safety, and these trials are fully described in Chapter 25 (p. 478).

Initial problems with neuraxial analgesia included hypotension and diminished uterine perfusion caused by sympathetic blockade in preeclamptic women, who already have attenuated hypervolemia. However, slow induction of epidural analgesia with dilute solutions of anesthetic agents counter the need for rapid infusion of large volumes of crystalloid or colloid to prevent maternal hypotension (Hogg, 1999; Wallace, 1995). Importantly, epidural blockade avoids general anesthesia, in which the stimulation of tracheal intubation may cause sudden severe hypertension. Such blood pressure spikes can cause pulmonary edema, cerebral edema, or intracranial hemorrhage. Last, tracheal intubation may be particularly difficult and thus hazardous in women with airway edema due to preeclampsia (American College of Obstetricians and Gynecologists, 2020b).

Judicious fluid administration is essential in women with severe preeclampsia who receive regional analgesia. Vigorous crystalloid infusion with epidural blockade in women with severe preeclampsia elevates pulmonary capillary wedge pressures (Newsome, 1986). Aggressive volume replacement in preeclamptic women raises their risk for pulmonary edema, especially in the first 72 hours postpartum (Clark, 1985; Cotton, 1986a). Last, most cases of pharyngolaryngeal edema are related to aggressive volume therapy (Heller, 1983). In sum, general anesthesia, epidural analgesia, or combined spinal-epidural analgesia are acceptable for women severe preeclampsia if steps are taken to ensure a careful approach to the selected method. At Parkland Hospital, a gentle bolus is given accompanying epidural placement (Chap. 25, p. 479).

■ Blood Loss at Delivery

Hemoconcentration or lack of normal pregnancy-induced hypervolemia is an almost predictable feature of severe preeclampsia–eclampsia (Fig. 40-7, p. 696) (Zeeman, 2009). *These women, who consequently lack normal pregnancy hypervolemia, may poorly tolerate even normal blood loss.* Thus, an appreciable fall in blood pressure soon after delivery most often means excessive blood loss and not sudden resolution of vasospasm and endothelial damage. When oliguria follows delivery, the hematocrit should be evaluated frequently to help detect excessive blood loss. If identified, hemorrhage should be treated appropriately by crystalloid and blood transfusion.

■ Persistent Severe Postpartum Hypertension

Postpartum, 8 percent of women develop de novo hypertension (Goel, 2015). At times, controlling severe hypertension may be difficult or intravenous hydralazine or labetalol or oral immediate-release nifedipine are being used repeatedly. In these cases, oral maintenance regimens can be given. Examples include labetalol or another β-blocking agent; nifedipine extended release; amlodipine; or another calcium-channel blocking agent (Sharma, 2017). Women so treated are less likely to require readmission (Stamilio, 2021; Wen, 2019). The Society for Maternal-Fetal Medicine (2020a) has developed a check list for postpartum care of women with hypertensive disorders.

Persistent hypertension is likely aggravated by pathological interstitial fluid that is now returning to the intravascular compartment, by underlying chronic hypertension, or by both (Sibai, 2012; Tan, 2002). Nonsteroidal antiinflammatory drugs do not aggravate postpartum hypertension (Anastasio, 2018; Penfield, 2019). In some women with chronic hypertension and left-ventricular hypertrophy, severe postpartum hypertension can cause pulmonary edema from cardiac failure (Cunningham, 1986, 2019; Sibai, 1987a).

Furosemide

Severe hypertension persists depending on the onset and length of extracellular fluid mobilization and diuresis. Thus, it seems logical that furosemide-augmented diuresis might serve to hasten blood pressure control (Ascarelli, 2005). In one randomized trial of 384 women with hypertensive disorders of pregnancy, a cohort that received furosemide postpartum had significantly lower blood pressures at 7 days—6 versus 14 percent—compared with women who received placebo (Lopes Perdigao, 2021). The need for antihypertensive treatment to be given at discharge in the furosemide group also was significantly reduced. In another randomized study, women with severe postpartum preeclampsia received nifedipine plus furosemide or nifedipine alone. The furosemide regimen significantly lowered the need for additional antihypertensive agents—8 versus 26 percent, respectively (Veena, 2017). Conversely, in one study, *torsemide* had no significant benefits (Viteri, 2018).

We use a simple method to estimate excessive extracellular fluid. The *postpartum weight* is compared with the most recent *prenatal weight*, either from the last clinic visit or from admission for delivery. Typically, soon after delivery, maternal weight should be reduced by at least 10 to 15 pounds depending on newborn and placental weight, amnionic fluid volume, and blood loss. Because of various interventions, especially intravenous crystalloid infusions given with labor epidural analgesia or during operative vaginal or cesarean delivery, women with severe preeclampsia often have an immediate postpartum weight *in excess of their last prenatal weight*. If this weight increase is associated with severe persistent postpartum hypertension, diuresis with intravenous furosemide can be helpful in controlling blood pressure.

Thrombotic Microangiopathy

Occasionally, women have an atypical syndrome in which severe preeclampsia–eclampsia persists despite delivery. Martin and associates (1995) described 18 such women whom they encountered during a 10-year period. They advocate single or multiple plasma exchange for these women. In some cases, 3 L of plasma was exchanged three times before a response was forthcoming. This is a 36- to 45-donor-unit exposure for each patient. Others have described plasma exchange performed in postpartum women with HELLP syndrome (Förster, 2002; Obeidat, 2002). In all of these cases, however, the distinction between HELLP syndrome and thrombotic thrombocytopenic purpura or hemolytic uremic syndrome was not clear (Tsai, 2016). In our experiences with more than 55,000 women with gestational hypertension among nearly 500,000 pregnancies cared for at Parkland Hospital through 2021, we have encountered very few women with persistent postpartum hypertension, thrombocytopenia, and renal dysfunction who were diagnosed as having a thrombotic microangiopathy (Dashe, 1998).

Reversible Cerebral Vasoconstriction Syndrome

This is another cause of persistent hypertension, "thunderclap" headaches, seizures, and central nervous system findings. *Reversible cerebral vasoconstriction syndrome* is characterized by diffuse segmental constriction of cerebral arteries and may be associated with ischemic and hemorrhagic strokes. This syndrome has several inciting causes that include pregnancy and particularly preeclampsia (Ducros, 2012). It is more frequent in women, and long-term sequelae are uncommon. However, in some cases, vasoconstriction may be so severe as to cause cerebral ischemia and infarction (Boitet, 2020). We have encountered only a few women with a stroke cause by this arteriopathy (Zofkie, 2019). The most appropriate management is unclear (Cho, 2019).

LONG-TERM CONSEQUENCES

■ Future Pregnancies

Women with preeclampsia during an index pregnancy are at risk for hypertensive and other disorders in subsequent pregnancies and later in life (Wang, 2021). In some, but not all women, the risk for hypertension is higher in the first 6 months postpartum (Giorgione, 2021; Mulder, 2021). Even in subsequent nonhypertensive pregnancies, women who had preterm preeclampsia have a higher risk for preterm birth and growth-restricted neonates (Connealy, 2014; Palatnik, 2016). Generally, the earlier preeclampsia is diagnosed during the index pregnancy, the greater the likelihood of recurrence. Women with preeclampsia

TABLE 41-10. Some Long-Term Consequences in Women with Preeclampsia Syndrome

Obstetrical
- Hypertensive disorders
- Preterm delivery
- Fetal-growth restriction

Cardiovascular
- Chronic hypertension
- Ischemic heart disease
- Atherosclerosis
- Coronary artery calcification
- Cardiomyopathy
- Thromboembolism
- Peripheral vascular disease

Renal
- Glomerular dysfunction
- Proteinuria

Neurovascular
- Stroke
- Retinal detachment
- Diabetic retinopathy
- Dementia
- Seizure disorder
- Retinopathy

Metabolic
- Type 2 diabetes
- Metabolic syndrome
- Dyslipidemia
- Obesity

TABLE 41-11. Long-Term Cardiovascular Morbidities After Recurrent Preeclampsia Compared with a Single Pregnancy with Preeclampsia and a Subsequent Normal Pregnancy

Morbidity (No. of Studies)	Recurrent (No.)	Single (No.)	Risk Ratio[a]
Hypertension (7)	2186	5589	2.33
IHD (3)	428	977	2.40
Heart failure (2)	160	298	2.88
CVA (2)	196	616	1.69
Cardiovascular event (2)	1278	5909	1.57

[a]All p values <0.0002.
CVA = cerebrovascular accident; IHD = ischemic heart disease.

near term had a recurrence risk of 23 percent, but nulliparas diagnosed with preeclampsia before 30 weeks had a recurrence risk as high as 40 percent (Bramham, 2011; Sibai 1986, 1991).

As perhaps expected, women with HELLP syndrome have a substantive risk for recurrence in subsequent pregnancies. Even if HELLP syndrome does not recur with subsequent pregnancies, again incidences of preterm delivery, fetal-growth restriction, placental abruption, and cesarean delivery are increased (Habli, 2009; Malmström, 2020).

Cardiovascular Morbidity

The preeclampsia syndrome is also a marker for subsequent long-term cardiovascular morbidity (Table 41-10) (Hammad, 2020; Stuart, 2018; Wang, 2021). Thus, women with hypertension identified during pregnancy should be evaluated during the first several months postpartum.

The Working Group of the NHBPEP (2000) concluded that hypertension attributable to pregnancy should resolve within 12 weeks of delivery, and hypertension persisting beyond this time is considered chronic (Chap. 53, p. 944). The Magpie Trial Follow-Up Collaborative Group (2007) reported that 20 percent of 3375 preeclamptic women seen at a median of 26 months postpartum had hypertension. From one metanaalysis, a 28-percent incidence of hypertension was found within 2 years of deliveries complicated by preeclampsia (Giorgione, 2021). From a Danish registry and after a mean of almost 15 years, the incidence of chronic hypertension was fivefold higher in those who had gestational hypertension, fourfold greater after mild preeclampsia, and sixfold higher after severe preeclampsia compared with women without hypertension in pregnancy (Lykke, 2009).

Any hypertension during pregnancy is a risk marker for cardiovascular morbidity in later life (Wang, 2021). As shown in data from Brouwers and coworkers (2018), the risk is greater in women with recurrent preeclampsia (Table 41-11). In a study from Iceland, the prevalence of ischemic heart disease—24 versus 15 percent, and of stroke—9.5 versus 6.5 percent, were increased in women who had gestational hypertension compared with normotensive controls (Arnadottir, 2005). In a Swedish population study of more than 400,000 women, those with recurrent preeclampsia had systolic dysfunction and a greater incidence of ischemic heart disease (Valensise, 2016). Diastolic dysfunction also is more common (Bokslag, 2018). Preeclampsia is also a risk for coronary artery calcification and idiopathic cardiomyopathy (Gammill, 2018; White, 2016).

Women who have preeclampsia and who develop chronic hypertension later in life have an increased ventricular mass index before they become hypertensive (Ghossein-Doha, 2013). Last, in at least some women with prior preeclampsia, hypertensive cardiovascular pathologies appear to have begun near the time of *their own* births. A similar phenomenon is associated with preterm birth and with fetal-growth disorders.

Other cofactors or comorbidities are related to acquisition of these long-term adverse outcomes (Gastrich, 2012; Harskamp, 2007; Hermes, 2012; Spaan, 2012). These include the metabolic syndrome, diabetes, obesity, dyslipidemia, and atherosclerosis (Catzov, 2021; Cho, 2019; Kajantie, 2017). Women with pregnancy-associated hypertension are at increased risk for type 2 diabetes (Stuart, 2018). Preeclampsia predisposes for later diabetic retinopathy and retinal detachment (Auger, 2017; Beharier, 2016).

Renal Sequelae

Preeclampsia is a marker for subsequent renal disease. Almost 15 percent of women with prior preeclampsia have renal dysfunction (Lopes van Balen, 2017). This may be related to AKI associated with preeclampsia (Novotny, 2020; Rodriquez, 2021). In a Danish study with more than a million women, the chronic renal disease rate was sixfold greater in those who had preeclampsia (Kristensen, 2019). These data need to be considered in light of the findings that 15 to 20 percent of women with preeclampsia who undergo renal biopsy have evidence of chronic renal disease (Chesley, 1978). In another long-term study, women with prior preeclampsia were significantly more likely to be chronically hypertensive—55 versus 7 percent—compared with control women. They also had higher peripheral vascular and renovascular resistance and decreased renal blood flow. These data do not permit conclusions as to cause versus effect (Spaan, 2009).

Central Nervous System Sequelae

Eclamptic seizures were once believed to have no significant long-term CNS sequelae. However, this likely is not the case (Bergman, 2021c; Theilen, 2016). Recall that almost all eclamptic women have multifocal areas of perivascular edema, and approximately a fourth also have areas of cerebral infarction (Zeeman, 2004).

In several long-term studies in women with severe preeclampsia and eclampsia, white-matter lesions in the brain that followed eclamptic convulsions persist (Aukes, 2009, 2012). Specifically, with magnetic resonance (MR) imaging, 40 percent of women with prior eclampsia had more numerous and larger aggregate white-matter lesions compared with 17 percent of normotensive control women. These white-matter lesions were also found in women with preeclampsia without convulsions (Aukes, 2012). Others found temporal lobe white-matter changes and reduced cortical volume in women with prior preeclampsia (Siepmann, 2017).

In some, but not all studies, women with prior eclampsia had subjectively impaired cognitive functioning and increased risk for dementia (Basit, 2018; Elharram, 2018). They also had a modest increase in the frequency of seizure disorders (Nerenberg, 2017). In another study, women with prior eclampsia had lower vision-related quality of life compared with control women (Wiegman, 2012).

CHAPTER 42

Causes of Obstetrical Hemorrhage

In addition to hypertension and infection, obstetrical hemorrhage remains among the infamous triad of maternal death causes. Of more than 7000 pregnancy-related maternal deaths in the United States from 2006 to 2015, hemorrhage was a direct cause in 11 percent (Creanga, 2015, 2017; Petersen, 2019). Hemorrhage is also the single most important cause of maternal death worldwide (Goffman, 2016; Oladapo, 2016). Notably, perhaps a third of severe cases of hemorrhage are likely preventable (Lepine, 2020).

These statistics have prompted several organizations to develop programs to prevent hemorrhage-related maternal morbidity. In the United States, one example is the Alliance for Innovation on Maternal Health (AIM) (2015), with its intent to standardize recognition, response, and reporting of obstetrical hemorrhage. The Joint Commission (2019) has also implemented standards under the Provision of Care, Treatment, and Services chapter for obstetrical hemorrhage—the R3 Report. Our following three chapters align with these.

GENERAL CONSIDERATIONS

Mechanisms of Normal Hemostasis

Near term, an incredible amount of blood—at least 600 mL/min—flows through the spiral arteries and into the intervillous space (Pates, 2010). Averaging 120 in number, the spiral arteries lack a muscular layer because of their remodeling by trophoblasts and thereby form a low-pressure system. With placental separation, vessels at the implantation site are avulsed. Hemostasis is achieved first by myometrial contraction, which directly compresses the arteries. Compression is followed by clotting and eventually by obliteration of vessel lumens.

If, after delivery, the myometrium contracts vigorously, substantial hemorrhage from the placental implantation site is unlikely. *Importantly, an intact coagulation system is not necessary for postpartum hemostasis unless there are lacerations in the uterus, birth canal, or perineum.* However, fatal postpartum hemorrhage can result from uterine atony despite normal coagulation.

Definition and Incidence

Historically, postpartum hemorrhage has been defined as blood losses ≥500 mL after the third stage of labor. This is problematic because almost half of all women delivered vaginally shed that amount of blood or more when losses are carefully measured. Moreover, approximately 5 percent of women delivering vaginally lose >1000 mL of blood (Fig. 42-1) (Pritchard, 1962). Almost a third of women undergoing cesarean delivery have blood loss >1000 mL. The American College of Obstetricians and Gynecologists (2019a) now defines postpartum hemorrhage as cumulative blood loss >1000 mL or blood loss accompanied by signs and symptoms of hypovolemia.

In a Maternal-Fetal Network Units study of more than 115,000 deliveries, the incidence of hemorrhage with vaginal

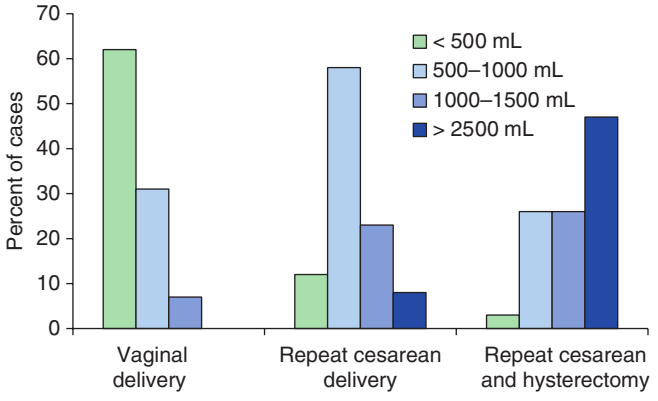

FIGURE 42-1 Measured blood loss with vaginal delivery, repeat cesarean delivery, and repeat cesarean delivery plus hysterectomy.

delivery was 5.3 percent, and it was 10.5 percent for cesarean delivery (Yee, 2019). Importantly, hemorrhage is underreported. From the National Hospital Discharge Summary database, the reported postpartum hemorrhage incidence between 2001 and 2005 was only 2.6 percent (Berg, 2009).

Blood Loss Assessment

At delivery, visual estimation is often used as a *qualitative* measure of blood loss. However, this method is more likely to under estimate the actual blood loss when volumes are high and to over estimate it when volumes are low (Al Kadri, 2011; Natrella, 2018). Thus, estimated blood loss that is considered greater than "average" should alert the provider.

Instead, different methods can be used as *quantitative* measures. First, gravimetric measurement weighs blood-soaked items and subtracts pre-use dry weights. Another evolving tool uses a tablet-device camera and colorimetric analysis to calculate blood loss (Spies, 2020; Venkatesh, 2020). The American College of Obstetricians and Gynecologists (2019b) recognizes the use of quantitative methods to help identify severe hemorrhage.

Intrapartum, quantitative measurement is more accurate than visual estimation, but the effectiveness of these methods on clinical outcomes has not been demonstrated. A Cochrane Review of three trials found no differences between subjective and objective methods when comparing outcomes that included need for transfusion, plasma expanders, or uterotonics (Diaz, 2018).

Postpartum, retrospective estimation also can be informative. The blood volume of a pregnant woman with normal pregnancy-induced hypervolemia usually rises by 50 percent. However, individual increases range from 30 to 60 percent, that is, 1500 to 2000 mL for an average-sized woman (Pritchard, 1965). The equation to calculate blood volume is shown in Table 42-1. It is axiomatic that a normal pregnant woman tolerates, without any decrease in postpartum hematocrit, blood loss at delivery that approaches the volume of blood that was added during pregnancy. Thus, if blood loss is less than the pregnancy-added volume, the hematocrit remains the same acutely and during the first several days postpartum. It then rises as nonpregnant plasma volume levels return during the next week or so. *Whenever the postpartum hematocrit is lower than one obtained on admission for delivery, blood loss can be estimated as the sum of the calculated pregnancy-added volume plus 500 mL for each 3-volume-percent decline of the hematocrit.*

For research and clinical care initiatives, excessive blood loss has been estimated by several methods (Coviello, 2019; Saoud, 2019). Tita and colleagues (2012) used a 6-volume-percent drop in the postpartum hematocrit to define clinically significant blood loss with vaginal delivery. This decline easily signifies a >1000-mL blood loss in the average-sized woman. They documented this amount in a fourth of women.

Another marker used to estimate hemorrhage incidence is the transfusion rate. In the study by Tita just cited, more than 6 percent of women who delivered vaginally underwent blood transfusion. In a study of more than 66,000 women delivered at Parkland Hospital, 2.3 percent overall were given

TABLE 42-1. Calculation of Maternal Total Blood Volume

Nonpregnant blood volume[a]:

$$\frac{[\text{Height (inches)} \times 50] + [\text{Weight (pounds)} \times 25]}{2} = \text{Blood volume (mL)}$$

Pregnancy blood volume:
Average increase is 30 to 60 percent of calculated nonpregnant volume
Increases across gestational age and plateaus at approximately 34 weeks' gestation
Usually larger with low-normal-range hematocrit (~30) and smaller with high-normal-range hematocrit (~40)
Average increase is 40 to 80 percent with multifetal gestation
Average increase is less with preeclampsia – volumes vary inversely with severity

Postpartum blood volume with serious hemorrhage:
Assume acute return to nonpregnant total volume after volume resuscitation
Pregnancy hypervolemia cannot be restored postpartum

[a]Formula arrived at by measuring blood volume and blood loss in more than 100 women using ^{51}Cr-labeled erythrocytes.
Data from Hernandez, 2012; Pritchard, 1962.

blood transfusions for hypovolemia (Hernandez, 2012). Half of these women had undergone cesarean delivery. Importantly, for those transfused, these investigators calculated blood loss to average approximately 3500 mL!

The need for blood transfusion is now followed as a *severe maternal morbidity (SMM)* indicator. The heightened awareness of SMM is outlined in Chapter 1 (p. 5). Transfusions represent more than 80 percent of total SMM rates. The incidence of *massive transfusion* for postpartum hemorrhage has been reported to be from 25 to 65 per 100,000 births (Green, 2016; Ramler, 2019). However, defining healthcare quality using transfusion as an SMM metric is problematic. First, this metric is solely derived from administrative billing codes. Second, transfusion rates may be skewed based on the hospital's case-mix (Bailit, 2013). This can distort values for regional referral centers that care for women at high risk for hemorrhage, such as those with placenta accreta spectrum.

Risk Factors

Hemorrhage can manifest at any time during pregnancy, delivery, or the puerperium. Contributions to maternal death from some of these causes of are shown in Figure 42-2. The Joint Commission (2019) requires accredited delivery services to employ tools that evaluate maternal hemorrhage risk on admission to labor and delivery and postpartum. Several methods are available, and the American College of Obstetricians and Gynecologists' (2019b) scoring tool stratifies risk using several obstetrical factors listed in Table 42-2. Unfortunately, these scoring systems only modestly predict hemorrhage (Chu, 2020). Kawakita and colleagues (2019) examined three commonly referenced tools and found moderate performance in identifying women at risk during cesarean delivery. In contrast, the Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) risk assessment tool was predictive of those at high risk (Colalillo, 2021).

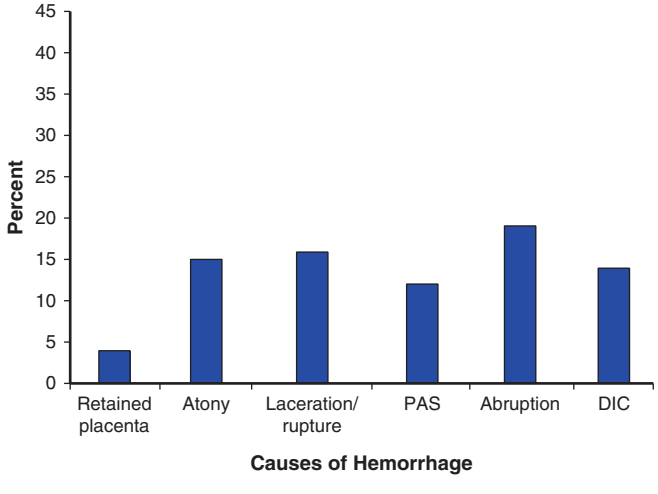

FIGURE 42-2 Contributions to maternal death from various causes of obstetrical hemorrhage. Percentages are approximations because of different classification schemata used. DIC = disseminated intravascular coagulopathy; PAS = placenta accreta spectrum. (Data from Al-Zirqi, 2008; Berg, 2010; Creanga, 2015; Zwart, 2008.)

TABLE 42-2. Obstetrical Hemorrhage: Causes, Predisposing Factors, and Vulnerable Patients

Abnormal Placentation
- Placenta previa
- Placental abruption
- Placenta accreta spectrum
- Ectopic pregnancy
- Hydatidiform mole

Injuries to the Birth Canal
- Episiotomy and lacerations
- Forceps or vacuum delivery
- Cesarean delivery or hysterectomy
- Uterine rupture
  - Previously scarred uterus
  - High parity
  - Tachysystole
  - Obstructed labor
  - Intrauterine manipulation
  - Midforceps rotation
  - Breech extraction

Obstetrical Factors
- Obesity
- Previous postpartum hemorrhage
- Early preterm pregnancy
- Sepsis
- Preeclampsia/eclampsia

Vulnerable Patients
- Chronic renal insufficiency
- Constitutionally small size

Uterine Atony
- Uterine overdistention
  - Large fetus
  - Multiple fetuses
  - Hydramnios
  - Retained clots
- Labor induction
- Anesthesia or analgesia
  - Halogenated agents
  - Regional analgesia with hypotension
- Labor abnormalities
  - Rapid labor
  - Prolonged labor
  - Augmented labor
  - Chorioamnionitis
- Previous uterine atony
- Parity: primiparity, high parity

Coagulation Defects—Intensify Other Causes
- Massive transfusions
- Placental abruption
- Sepsis
- HELLP syndrome
- Acute fatty liver
- Anticoagulant treatment
- Congenital coagulopathies
- Amnionic fluid embolism
- Prolonged retention of dead fetus
- Saline-induced abortion

HELLP = hemolysis, elevated liver enzyme levels, low platelet count.

Timing of Hemorrhage

Obstetrical hemorrhage is traditionally classified as *antepartum*—such as with placenta previa or placental abruption, or as *postpartum*—commonly caused by uterine atony or genital tract lacerations. In individual women, however, these terms are nonspecific, and it is reasonable to specify the cause and gestational age as descriptors.

With antepartum hemorrhage, timing may give a clue to its cause. Many aspects of bleeding during the first half of pregnancy from abortion or ectopic pregnancy are covered in Chapters 11 and 12. Discussions that follow concern pregnancies with a viable-size fetus. *In these cases, rapid assessment should always consider the deleterious fetal effects of maternal hemorrhage.*

During active labor, slight vaginal bleeding is common. This "bloody show" is the consequence of cervical effacement and dilation and concurrent tearing of small vessels. However, with uterine bleeding above the cervix, placental abruption, placenta

previa, and vasa previa must be considered. The first two are presented in Chapter 43 and vasa previa is discussed in Chapter 6 (p. 115). In some women, especially those with a placenta previa, cervical varicosities may bleed (O'Brien, 2013).

Near term in many women, the source of uterine bleeding is not identified, bleeding ceases, and no apparent anatomical cause is found at delivery. In most of these cases, bleeding likely originated from a slight marginal placental separation. *Despite this, any pregnancy with antepartum bleeding remains at higher risk for an adverse outcome even though bleeding has stopped and placenta previa has been excluded sonographically.*

Bleeding after midpregnancy is associated with several adverse outcomes. The Canadian Perinatal Network described 806 women with hemorrhage between 22 and 28 weeks' gestation (Sabourin, 2012). Placental abruption (32 percent), previa (21 percent), and cervical bleeding (6.6 percent) were the most frequent causes identified. In a third, no cause was found. Of all women, 44 percent were delivered before 29 weeks' gestation. In more than 68,000 women in Scotland, the incidence of antepartum hemorrhage after the first trimester was 11 percent (Bhandari, 2014). These women were at significantly higher risk for preterm birth, labor induction, and postpartum hemorrhage.

With postpartum hemorrhage, the source in most cases can and should be determined. Frequent causes are uterine atony with placental site bleeding, genital tract trauma, or both. Postpartum hemorrhage is usually obvious. Important exceptions are unrecognized intrauterine and intravaginal blood accumulation and uterine rupture with intraperitoneal or retroperitoneal bleeding. Another consideration is an expanding vulvar or vaginal hematoma (p. 740). Initial evaluation includes attempts to differentiate uterine atony from genital tract lacerations. For this, risk factors are sought, the lower genital tract is examined, and uterine tone is assessed. Atony is identified by a boggy, soft uterus during bimanual examination and by expression of clots and hemorrhage during uterine massage.

Persistent bleeding despite a firm, well-contracted uterus suggests that hemorrhage most likely is from lacerations. Bright red blood further suggests arterial bleeding. *To confirm that lacerations are a source of bleeding, careful inspection of the vagina, cervix, and uterus is essential.* Examination is easier if regional analgesia is employed. Transfer from a labor and delivery room to an operative suite also may be prudent. If there are no lower genital tract lacerations and the uterus is contracted, yet supracervical bleeding persists, manual exploration of the uterus is done to exclude a uterine tear (Kaplanoglu, 2016). This also is completed routinely after internal podalic version or breech extraction. Some perform this after successful vaginal birth after cesarean, and this is our practice. *Late postpartum hemorrhage* describes bleeding after the first 24 hours. Found in up to 1 percent of women, one risk factor is postpartum hemorrhage at the time of delivery (Fein, 2021). Delayed hemorrhage may be serious and is discussed in Chapter 36 (p. 637).

Appreciation of Estimated Blood Loss

As discussed, visual blood loss estimates are often inaccurate, especially with excessive bleeding. Instead of sudden and massive hemorrhage, postpartum bleeding is frequently steady. If bleeding from atony or laceration persists, it may appear to be only moderate at any given instant but may continue until serious hypovolemia develops. In some cases, after placental separation, blood may not escape vaginally but instead may collect within the uterine cavity, which can become distended by 1000 mL or more of blood. Moreover, postpartum uterine massage will be ineffective if applied to a roll of abdominal fat mistaken for the uterus. All of these factors can lead to an underappreciation of the magnitude of hemorrhage over time.

The effects of hemorrhage depend mainly on the maternal nonpregnant blood volume and the corresponding degree of pregnancy-induced hypervolemia. Small women—even those with appropriate pregnancy-induced hypervolemia—do not tolerate more than seemingly average blood loss. Some gravidas may be particularly susceptible to hemorrhage because their blood volume expansion is less than expected. An example is women with severe preeclampsia or eclampsia, who are more vulnerable to hemorrhage because they frequently do not have a normal blood volume accrual. Specifically, Zeeman and associates (2009) documented a mean increase above nonpregnant volume of only 10 percent in eclamptic women (Chap. 40, p. 693). Another example is the moderate to severe curtailing of pregnancy-induced volume expansion in women with chronic renal insufficiency (Chap. 56, p. 1004). *When excessive hemorrhage is suspected in these high-risk women, crystalloid and blood are promptly administered for suspected hypovolemia.*

A treacherous feature of postpartum hemorrhage is the failure of the pulse and blood pressure to undergo more than moderate alterations until large amounts of blood have been lost. The normotensive woman initially may actually become somewhat hypertensive from catecholamine release in response to hemorrhage. Importantly, women with preeclampsia may become "normotensive" despite remarkable hypovolemia. Accordingly, hypovolemia may not be recognized until very late.

UTERINE ATONY

Third-stage Labor Management

The most frequent cause of obstetrical hemorrhage is failure of the uterus after delivery to contract sufficiently and arrest bleeding from vessels at the placental implantation site (Yee, 2019). That said, some bleeding is inevitable during third-stage labor as the placenta begins to separate. Blood from the implantation site may escape into the vagina immediately—the *Duncan mechanism* of placental separation, or it remains concealed behind the placenta and membranes until the placenta is delivered—the *Schultze mechanism.* Placental descent is signified by a slack umbilical cord. After signs of placental separation, the uterus should be massaged if it is not contracted firmly. *Importantly, separation and delivery of the placenta by cord traction, especially when the uterus is atonic, may cause uterine inversion.*

Following placental delivery, the fundus is always palpated to confirm that the uterus is well contracted. If it is not firm,

vigorous fundal massage usually prevents postpartum hemorrhage from atony (Hofmeyr, 2013). Concurrent administration of a uterotonic agent, discussed in the next sections, is another recommended preventive measure.

Risk Factors

In many women with known risks, uterine atony can at least be anticipated. However, as discussed earlier (p. 733), risk-based scoring systems have limited value. In one study, up to half of women with atony after cesarean delivery had no risk factors (Rouse, 2006). The magnitude of risk for atony imposed by each of the factors shown in Table 42-2 varies considerably between reports. *Primiparity* and *high parity* are two factors (Driessen, 2011). In one study, the incidence of postpartum hemorrhage rose from 0.3 percent in women of low parity to 1.9 percent with parity of four or greater. It was 2.7 percent with parity of seven or greater (Babinszki, 1999). The *overdistended uterus* is prone to hypotonia after delivery, and thus women with a large fetus, multiple fetuses, or hydramnios carry greater risk (Blitz, 2019). *Labor abnormalities* predispose to atony and include hyper- or hypotonic labor. Similarly, *labor induction* or *augmentation* with either prostaglandins or oxytocin is more likely to be followed by atony (Driessen, 2011). The frequency of hemorrhage increases with third-stage labor lasting >20 minutes (Frolova, 2016). Last, the woman who has had a *prior postpartum hemorrhage* is at risk for recurrence.

Evaluation and Management

To improve immediate postpartum care, clinical safety bundles provide a standardized response (Fig. 42-3). In principle, all of these programs suggest notifying unit personnel, activating resources, and standardizing management. With immediate postpartum hemorrhage, careful inspection aims to exclude birth canal laceration. In some cases, bleeding is caused by retained placental fragments, and placental inspection after delivery should be routine. If a defect is seen, the uterus should be manually explored and the fragment removed. Occasionally, retention of a *succenturiate lobe* may cause postpartum hemorrhage (Chap. 6, p. 108). During examination for lacerations and causes of atony, the uterus is massaged and uterotonic agents are administered.

Manual Removal of the Placenta

If heavy bleeding persists after delivery of the newborn but while the placenta remains partially or totally attached, then manual placental removal is indicated (Cummings, 2016; Frolova, 2016). For this, adequate analgesia is mandatory, and aseptic surgical technique is used. As illustrated in Figure 27-8 (p. 508), the fingertips of one hand, with fingers approximated, are insinuated between the uterine wall and placenta. A sweeping forward motion in this plane will peel the placenta off its uterine attachment. After its removal, trailing membranes are carefully teased free from the decidua using ring forceps as needed. Another method to clear membranes is to wipe out the uterine cavity with a gauze-wrapped hand. Bierer forceps guided by ultrasound to remove retained placenta also has been described (Siegel, 2020).

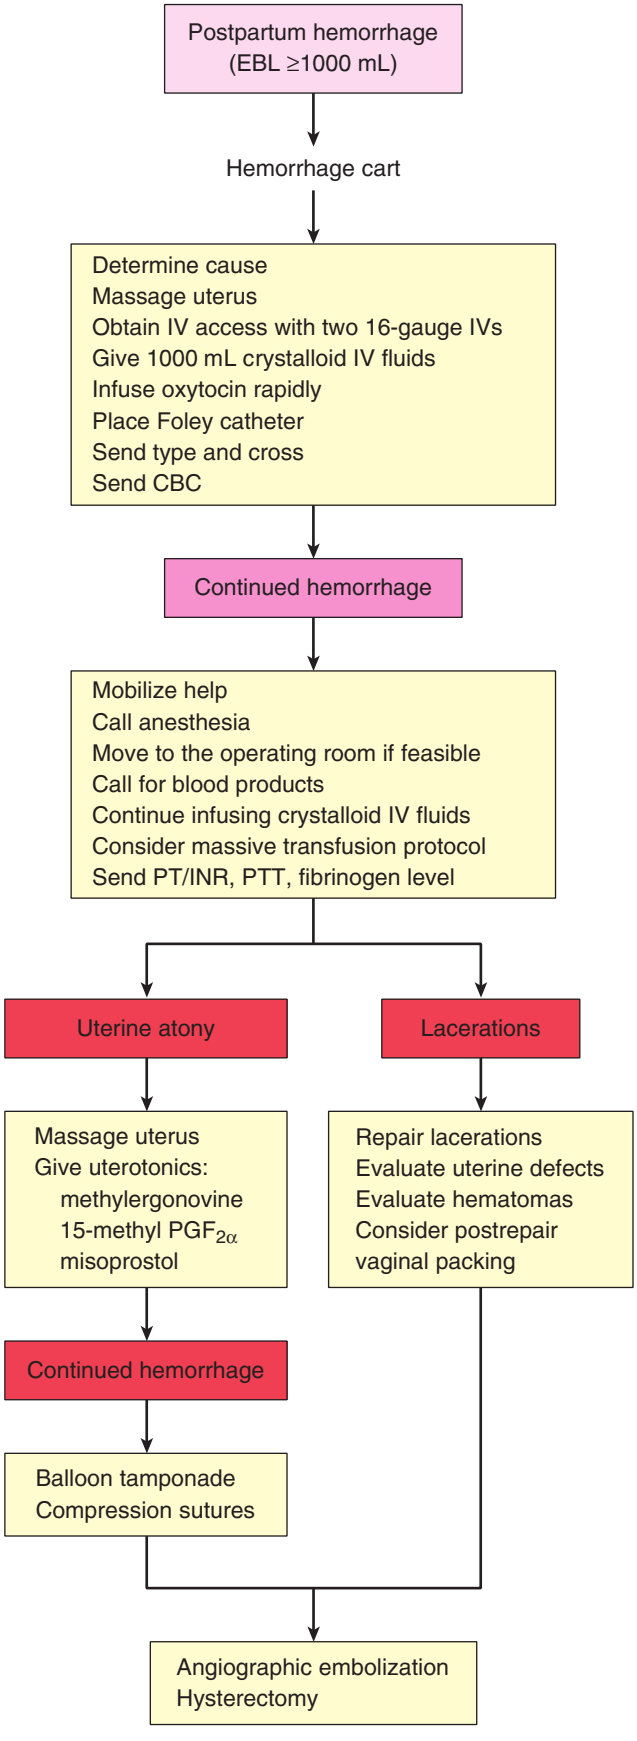

FIGURE 42-3 Parkland Hospital algorithm for management of postpartum hemorrhage. CBC = complete blood count; EBL = estimated blood loss; INR = international normalized ratio; IV = intravenous; PT = prothrombin time; PTT = partial thromboplastin time.

Some administer a single dose of intravenous antibiotics after manual uterine exploration, however, one systematic review of observational studies found no benefits (Chibueze, 2015). The American College of Obstetricians and Gynecologists (2020b) concluded that data neither support nor refute this practice. The World Health Organization (WHO) (2015) recommends ampicillin or cefazolin antimicrobial prophylaxis after manual placenta removal. At Parkland Hospital, we routinely provide a single dose of cefazolin after manual exploration.

Uterotonic Agents

Several compounds can be used to prompt the postpartum uterus to contract. One of these is routinely selected and given to *prevent* postpartum bleeding. Choices for prophylaxis include oxytocin (Pitocin); the ergots, namely ergonovine (Ergotrate) and methylergonovine (Methergine); or misoprostol (Cytotec) (Chap. 27, p. 507). The WHO (2018) recommends oxytocin for first-line use for prophylaxis. For administration, 20 units of oxytocin in 1000 mL of crystalloid solution is effective and given intravenously (IV) at 10 mL/min for a dose of 200 mU/min. Higher concentrations are minimally more efficient (Tita, 2012). A summary of oxytocin administration regimens is found in the Practice Brief of the Association of Women's Health Objective and Neonatal Nurses—AWHONN (2014). In those without IV access, oxytocin may be given intramuscularly (IM). Adnan and colleagues (2018) found the IV route to more effectively prevent severe hemorrhage compared with IM administration. *Oxytocin is never given as an undiluted bolus dose because serious hypotension or cardiac arrhythmias can develop.*

Most agents for prevention of atony are also used to *treat* it. For atony, IV oxytocin is continued or may be initiated if not selected initially. It is considered first-line treatment by the WHO (2012). If bleeding and atony are refractory, an agent from a different group can be added (American College of Obstetricians and Gynecologists, 2019a).

Ergot alkaloids have been used for centuries to treat uterine atony. If atony persists despite oxytocin and other preventive measures, ergot derivatives can be used for second-line treatment. Given parenterally, these drugs rapidly stimulate tetanic uterine contractions and act for approximately 45 minutes (Schimmer, 2011). A common regimen is 0.2 mg of either drug given IM. Methergine can be repeated at 2- to 4-hour intervals as needed. *A caveat is that ergot agents, especially given IV, may cause dangerous hypertension, especially in women with preeclampsia.* Severe hypertension is also seen with concomitant use of protease inhibitors given for human immunodeficiency viral (HIV) infection. These adverse effects notwithstanding, it is speculative whether ergot derivatives offer superior therapeutic effects compared with oxytocin.

Other second-line agents for atony have included the E- and F-series prostaglandins. Carboprost tromethamine (Hemabate) is the 15-methyl derivative of prostaglandin $F_{2\alpha}$. It is approved for uterine atony treatment in a dose of 250 μg (0.25 mg) given IM. This dose can be repeated if necessary, at 15- to 90-minute intervals up to a maximum of eight doses. Observational data indicate an 88-percent success rate (Oleen, 1990).

Carboprost causes side effects in approximately 20 percent of women. These include, in descending order of frequency, diarrhea, hypertension, vomiting, fever, flushing, and tachycardia. Another pharmacological effect is pulmonary airway and vascular constriction. Thus, carboprost should not be used for asthmatic women or those with pulmonary hypertension, including women those with suspected amnionic fluid embolism (p. 745). It has also been reported to cause arterial oxygen desaturation that averaged 10 percent (Hankins, 1988). We have occasionally encountered severe hypertension with carboprost given to women with preeclampsia. Other relative contraindications to carboprost include renal, liver, and cardiac disease (American College of Obstetricians and Gynecologists, 2019a).

Misoprostol is a synthetic prostaglandin E_1 analogue. In a Cochrane review, Mousa and associates (2014) reported no added benefits for misoprostol use for treatment compared with oxytocin or ergonovine. If misoprostol is used to treat atony, the American College of Obstetricians and Gynecologists (2019a) recommends a dose of 600 to 1000 μg rectally, orally, or sublingually.

Dinoprostone (*Cervidil, Prepidil*) is prostaglandin E_2. It may also be used off label for atony treatment and is given as a 20-mg suppository per rectum or per vagina every 2 hours. It typically causes diarrhea, which is problematic for the rectal route, whereas vigorous vaginal bleeding may preclude its use per vagina. Hypotension, which is commonly encountered with hemorrhage, is considered a contraindication by some. For this reason, this agent is not deployed for hemorrhage management at Parkland Hospital. IV prostaglandin E_2—*sulprostone*—is used in Europe, but it is not available in the United States.

Tranexamic Acid

This antifibrinolytic agent has been evaluated to treat postpartum hemorrhage. In the randomized WOMAN trial of gravidas with hemorrhage following vaginal birth or during cesarean delivery, mortality rates from obstetrical hemorrhage were 1.2 percent in those given a 1-g IV tranexamic acid dose plus traditional care for bleeding. This rate was significantly lower than the 1.7-percent death rate in women given traditional care alone (WOMAN Trial Collaborators, 2017). Another study of women with hemorrhage following vaginal birth found that rates of progression to severe PPH, of transfusion, and of peripartum hysterectomy were lower in the TXA group compared with the traditional-care group (Ducloy-Bouthors, 2011). Use of tranexamic acid in hemorrhage is discussed further in Chapter 44 (p. 773).

Bleeding Unresponsive to Uterotonic Agents

If bleeding persists after initial measures for atony, the following management steps are performed immediately and simultaneously:

1. Begin bimanual uterine compression, which is easily done and controls most cases of continuing hemorrhage (Fig. 42-4). This technique is not simply fundal massage. The posterior uterine wall is massaged by one hand on the abdomen, while the other hand is made into a fist and placed into the vagina. This fist kneads the anterior uterine wall through the anterior vaginal wall, and the uterus is compressed between the two hands.
2. Mobilize the emergent-care obstetrical team and call for whole blood or packed red cells.

FIGURE 42-4 Bimanual compression for uterine atony. The uterus is positioned with the fist of one hand in the anterior fornix pushing against the anterior wall, which is held in place by the other hand on the abdomen. The abdominal hand is also used for uterine massage.

3. Request urgent help from the anesthesia team.
4. Secure at least two large-bore IV catheters so that crystalloid with oxytocin can be continued simultaneously with blood products. Insert a Foley catheter for continuous urine output monitoring.
5. Begin volume resuscitation with rapid IV crystalloid infusion (p. 734).
6. With sedation, analgesia, or anesthesia established and now with optimal exposure, once again manually explore the uterine cavity for retained placental fragments and for uterine abnormalities, including lacerations or rupture.
7. Thoroughly inspect the cervix and vagina again for lacerations that may have escaped attention.
8. Administer blood transfusions if the woman is still unstable or if bleeding persists (Chap. 44, p. 771).

At this juncture, after causes other than atony have been excluded and after hypovolemia is reversed, several other measures are considered if bleeding continues (Merriam, 2020). Their use depends on several factors such as parity, desire for sterilization, and experience with each method.

Balloon Tamponade and Surgical Procedures. For this, the tip of a 24F to 30F Foley catheter with a 30-mL balloon is guided into the uterine cavity and filled with 60 to 80 mL of saline. The open tip permits continuous drainage of blood from the uterus. We have experienced balloon rupture when more than 50 mL was instilled into the balloon, thus a 34F Foley with a 60-ml balloon can be used. If bleeding subsides, the catheter is typically removed after 12 to 24 hours. Similar devices for tamponade include Sengstaken-Blakemore, Rusch, and ebb balloons and condom catheters (Antony, 2017; Kondoh, 2019). Antibiotic prophylaxis using cefazolin, 1 gram every 8 hours until removal, has recently been suggested to reduce risk of postpartum endometritis (Martingano, 2020).

FIGURE 42-5 Intrauterine Bakri balloon for postpartum hemorrhage.

Instead, specially constructed intrauterine balloons are available to treat hemorrhage from uterine atony and other causes. A *Bakri Postpartum Balloon* or *BT-Cath* may be inserted and inflated to tamponade the endometrial cavity and stop bleeding (Fig. 42-5). Insertion requires two or three team members. The first performs abdominal sonography during the procedure. The second places the deflated balloon into the uterus and stabilizes it. The third member instills fluid to inflate the balloon, rapidly infusing at least 150 mL followed by further instillation over a few minutes for a total of 300 to 500 mL to arrest hemorrhage. It is reasonable to remove the balloon after approximately 12 hours (Einerson, 2017).

In small studies evaluating uterine balloons for all causes, the success rate approximated 85 percent (Kaya, 2016; Said Ali, 2021; Vintejoux, 2015). From their review, Suarez and associates (2020) used balloon tamponade in 4729 women and reported a similar success rate. At least one case of uterine rupture with a balloon has been reported (Ngyuen, 2018). Combinations of balloon tamponade and uterine compression sutures also have been described (Diemert, 2012; Yoong, 2012).

Failure of uterotonic agents and tamponade requires more invasive methods. These include uterine compression sutures, major pelvic vessel ligation, angiographic embolization, and hysterectomy. These are discussed in detail in Chapters 44 (p. 778). Peripartum hysterectomy is illustrated in Chapter 30 (p. 560).

UTERINE INVERSION

Puerperal inversion of the uterus is one of the classic hemorrhagic disasters encountered in obstetrics. Unless promptly recognized and managed appropriately, associated bleeding often is massive. Risk factors include alone or in combination: (1) placental implantation at the fundus, (2) uterine atony, (3) cord traction applied *before* placental separation, and (4) abnormally adherent placentation seen with placenta accreta spectrum disorders (Chap. 43, p. 759). Other risk factors are a short cord, uterine wall weakening at the implantation site, uterine tumors, and excessive fundal pressure (Wendel, 2018).

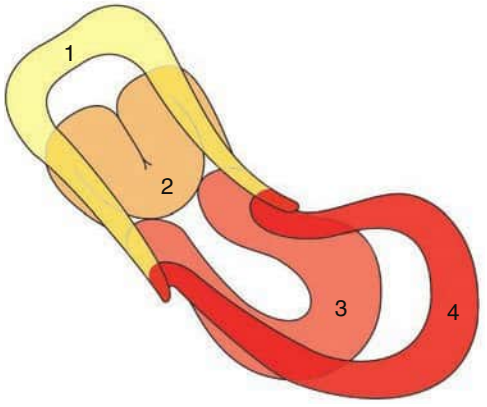

FIGURE 42-6 Progressive degrees of uterine inversion.

Depending on which of these factors are contributory, the incidence and severity of uterine inversion varies and can be progressive (Fig. 42-6). The worst scenario is complete inversion with the uterus protruding from the birth canal (Fig. 42-7).

The incidence of uterine inversion ranges from 1 case in 2000 to 1 in 20,000 vaginal deliveries (Coad, 2017; Witteveen, 2013). Our experiences at Parkland Hospital correspond with the higher 1:2000 incidence. This is despite our policy of discouraging placental delivery by cord traction alone, and before certainty of its separation. It is unknown if *active management of third-stage labor* with cord traction applied ostensibly *after* signs of placental separation raises the likelihood of uterine inversion (Deneux-Tharaux, 2013; Prick, 2013).

Recognition and Management

Immediate recognition of uterine inversion improves the chances of a quick resolution and good outcome. If initially unrecognized, continued hemorrhage likely will prompt closer examination of the birth canal. Although complete inversion is usually evident, the partially inverted uterus can be mistaken for a uterine myoma, and sonography can aid differentiation (Pan, 2015; Smulian, 2013). Many cases are associated with immediate life-threatening hemorrhage, and a fourth require blood replacement (Coad, 2017).

Once any degree of uterine inversion is recognized, several steps must be implemented urgently and simultaneously:

1. Immediate assistance is summoned, including obstetrical and anesthesia personnel.
2. Blood is brought to the delivery suite for potential use.
3. Two large-bore IV infusion systems are secured to begin rapid crystalloid infusion to treat hypovolemia while awaiting arrival of blood products.
4. The woman is evaluated for emergency general anesthesia.
5. If the recently inverted uterus has not contracted and retracted completely and if the placenta has already separated, the uterus may often be replaced simply by pushing up on the inverted fundus with the palm of the hand and fingers in the direction of the long axis of the vagina (Fig. 42-8). Some use two fingers rigidly extended to push the center of the fundus upward. *Care is taken not to apply so much pressure as to perforate the uterus with the fingertips.*
6. If the placenta is still attached, attempts are made to reposition the uterus with the placenta in situ. In theory, the uterus contracts to a lesser degree and placenta-site blood loss is less with an attached placenta. At this time a trial of an intravenously administered tocolytic drug may aid uterine relaxation and repositioning. Of options, a 250-μg subcutaneous dose of terbutaline, a 50- to 100-μg IV dose of nitroglycerin, or a 4-g IV dose of magnesium sulfate are suitable (Catanzarite, 1986; Dufour, 1997). If these fail to provide sufficient relaxation, then a rapid-acting halogenated inhalational

FIGURE 42-7 Maternal death during home delivery caused by exsanguination from uterine inversion, which stemmed from a fundally implanted placenta increta.

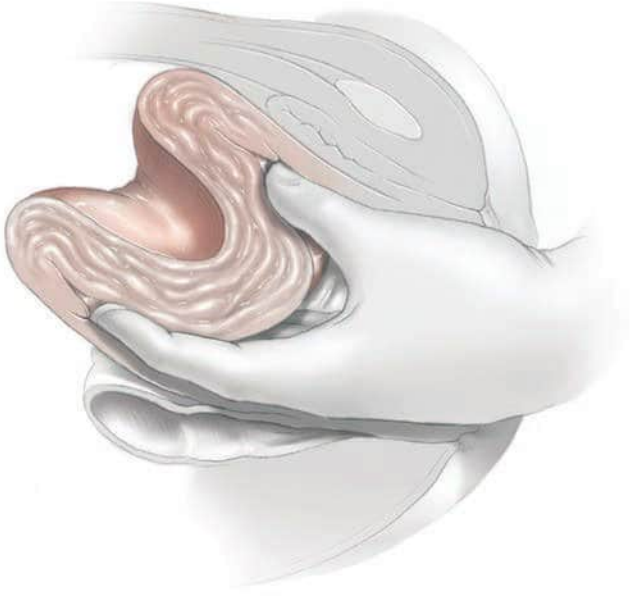

FIGURE 42-8 Incomplete uterine inversion can be repositioned by using the abdominal hand for palpation of the crater-like depression while simultaneously gently pushing the inverted fundus upward.

agent is administered by anesthesia staff. After the uterus is replaced, the placenta is carefully manually removed.

7. If uterine repositioning fails with the placenta attached, it is peeled off, and uterine repositioning is attempted again.
8. Once the uterus is restored to its normal configuration, tocolysis is stopped, oxytocin is then infused, and other uterotonic agents may be given as described for atony (p. 735). Meanwhile, the operator maintains the fundus in its normal anatomical position while applying bimanual compression to control further hemorrhage until the uterus is well contracted (see Fig. 42-4). The operator continues to monitor the uterus transvaginally for evidence of subsequent inversion. A Bakri balloon has been used by some to maintain the repositioned uterus (Haeri, 2015; Ida, 2015).

■ Surgical Intervention

In most cases, the inverted uterus can be restored to its normal position by the just-described techniques. Occasionally, manual replacement fails. One cause is a dense myometrial constriction ring. At this point, laparotomy is imperative. The anatomical configuration found at surgery can be confusing as shown in Figure 42-9. During laparotomy and after tocolysis is given, a combined effort is made to reposition the uterus by concurrently pushing upward from below and pulling upward from above. Application of atraumatic clamps to each round ligament and upward traction may be helpful—the *Huntington procedure*. In some cases, placing a deep traction suture in the inverted fundus or grasping it with tissue forceps may help but can be technically difficult. If a constriction ring still prohibits repositioning, a sagittal surgical cut—*Haultain incision*—is made posteriorly through the muscular ring to release it. The exposed fundus can then be reinverted (Sangwan, 2009).

After uterine replacement, tocolytics are stopped, and oxytocin and other uterotonic agents are given. If the Haultain method is used, the uterine incision is repaired. Risks of separation of this posterior hysterotomy incision during subsequent pregnancy, labor, and delivery are unknown (Wendel, 2018). Further illustration and discussion are found in *Cunningham and Gilstrap's Operative Obstetrics*, 3rd edition (Timofeev, 2017).

In some cases, the uterus will again invert almost immediately after repositioning. With this problem, uterine compression sutures can be used to prevent another inversion (Matsubara, 2009; Mondal, 2012). Occasionally, chronic puerperal uterine inversion may become apparent weeks after delivery.

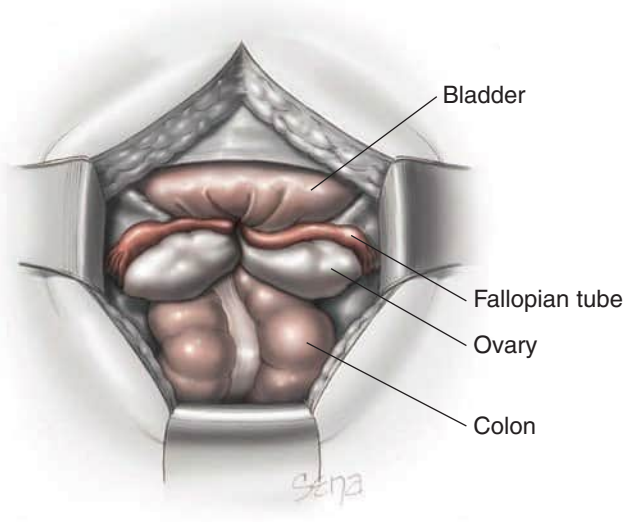

FIGURE 42-9 Surgical anatomy of a completely inverted uterus viewed from above at laparotomy.

BIRTH CANAL INJURIES

■ Vulvovaginal Lacerations

Childbirth is invariably associated with trauma to the uterus and cervix, vagina, and perineum. Injuries range from minor mucosal tears to lacerations that create life-threatening hemorrhage or hematomas. According to the American College of Obstetricians and Gynecologists (2020a), up to 80 percent of women sustain some type of laceration at vaginal birth. These may lie proximally or distally along the lower genital tract.

Small tears of the vaginal wall near the urethra are relatively common. They are often superficial with little to no bleeding but occasionally require fine-gauge absorbable sutures for hemostasis. Those large enough to require extensive repair are typically associated with short-term voiding difficulty, and an indwelling bladder catheter will obviate this.

Deeper perineal lacerations are usually accompanied by varying degrees of injury to the outer third of the vagina. Some extend to involve the anal sphincter or varying depths of the vaginal walls. Repair of these perineal lacerations is detailed in Chapter 27 (p. 510).

Lacerations involving the middle or upper third of the vagina usually are comorbid with injuries of the perineum or cervix. These sometimes are missed unless inspection is thorough. Those that extend upward usually are longitudinal. They may follow spontaneous delivery but frequently result from injuries sustained during operative vaginal delivery. Most involve deeper underlying tissues and thus usually cause significant hemorrhage, which is controlled by suture repair. For this, effective analgesia or anesthesia, clear visualization, capable assistance, and sufficient resuscitation of hypovolemia are mandatory.

Extensive vaginal or cervical tears should prompt a careful search for evidence of retroperitoneal hemorrhage or of peritoneal perforation with hemorrhage. Intrauterine exploration is also considered to exclude uterine tears or rupture (Conrad, 2015). If peritoneal perforation or uterine rupture is strongly suspected, laparotomy is reasonable (Rafi, 2010). As discussed later (p. 742), imaging and potential embolization may be suitable for large retroperitoneal hematomas.

■ Cervical Lacerations

Superficial lacerations of the cervix can be seen on close inspection in more than half of all vaginal deliveries. Most of these measure <0.5 cm and seldom require repair. Deeper lacerations are less frequent, but even these may be unnoticed. Such lacerations are more likely to be associated with vacuum- or

forceps-assisted vaginal delivery (Fong, 2014). Due to ascertainment bias, variable incidences are described. For example, with close inspection, the incidence of cervical lacerations in the Consortium on Safe Labor database was 1 percent in nulliparas and 0.5 percent in multiparas (Landy, 2011). But, the overall incidence in a study of more than 81,000 Israeli women was only 0.16 percent (Melamed, 2009).

Cervical lacerations are not usually problematic unless they cause hemorrhage or extend to the vagina. Rarely, the cervix may be entirely or partially avulsed from the vagina in the anterior, posterior, or lateral fornices, an injury termed *colporrhexis*. Another rare injury is avulsion of the entire vaginal portion of the cervix—*annular* or *circular detachment*. These injuries sometimes follow forceps deliveries performed through an incompletely dilated cervix and with the blades applied against the cervix. In some women, cervical tears reach into the lower uterine segment and involve the uterine artery and its major branches. They occasionally extend into the peritoneal cavity. More severe lacerations usually manifest as external hemorrhage or as a hematoma, however, they may occasionally be unsuspected. In the Israeli study just cited, almost 11 percent of women with a cervical laceration required blood transfusions (Melamed, 2009).

At times, the edematous anterior cervical lip is compressed between the fetal head and maternal symphysis pubis. This usually is of little consequence and resolves spontaneously. Rarely, this causes severe ischemia, and the anterior lip may undergo necrosis and later separate from the rest of the cervix.

As with vulvovaginal lacerations, cervical tears can be more fully appreciated with adequate exposure, which may be best attained with transfer to an operating room. An assistant applies firm downward pressure on the uterus, while the operator exerts gentle traction on the lips of the cervix with ring forceps. A second assistant can provide even better exposure with right-angle vaginal wall retractors or Breisky vaginal retractors. Yankauer or other suction tips also can aid viewing.

In general, cervical lacerations of 1 to 2 cm are not repaired unless they are bleeding. Such tears heal rapidly and ultimately form an irregular, sometimes stellate-appearing, external cervical os (Fig. 36-1, p. 635).

Deep cervical tears usually require surgical repair. When the laceration is limited to the cervix or even when it extends somewhat into the vaginal fornix, satisfactory results are obtained by suturing the cervix after bringing it into view as depicted in Figure 42-10. While cervical lacerations are repaired, any associated vaginal lacerations or an episiotomy may be tamponaded with gauze packs to arrest their bleeding. Because hemorrhage usually comes from the upper angle of the wound, the first suture using 2–0 chromic or polyglactin is placed in tissue above the angle. Subsequently, either interrupted or continuous locking sutures are serially placed outward toward the operator. If the uterus is involved and hemorrhage persists, some of the surgical and angiographic methods described in Chapter 44 (p. 777) may be necessary to obtain hemostasis. Following cervical lacerations, subsequent pregnancy outcomes include excessive recurrent lacerations, cervical incompetence, preterm labor, cesarean delivery, and severe perineal lacerations (Hamou, 2020).

FIGURE 42-10 Repair of cervical laceration with appropriate surgical exposure. Continuous absorbable sutures are placed beginning at the upper angle of the laceration.

Puerperal Hematomas

Pelvic hematomas can have several anatomical manifestations following childbirth. One classification is anatomical and describes vulvar, vulvovaginal, paravaginal, and retroperitoneal hematomas. Vulvar hematomas may involve the vestibular bulb or branches of the pudendal artery, which are the inferior rectal, perineal, and clitoral arteries (Fig. 42-11). Paravaginal hematomas may involve the descending branch of the uterine artery. In some cases, a torn vessel lies above the pelvic fascia, and a *supralevator hematoma* develops. These can extend into the upper portion of the vaginal canal and may almost occlude its lumen. Continued bleeding may dissect retroperitoneally to form a mass palpable above the inguinal ligament. In some cases, it may even dissect up behind the ascending colon to the hepatic flexure (Rafi, 2010).

Risks for puerperal hematomas include vaginal or perineal laceration, episiotomy, or operative vaginal delivery (Iskender, 2016). Any hematoma can also develop following stretch and rupture of a blood vessel without an associated laceration (Alturki, 2018; Lee, 2020). This may be especially true with forceps delivery. Occasionally, they are associated with an underlying coagulopathy (Chap. 44, p. 775).

Diagnosis

Perineal, vulvar, and paravaginal hematomas can develop rapidly and frequently cause excruciating pain (Fig. 42-12). A tense, tender swelling of varying size rapidly develops, encroaches on the vaginal lumen, and causes overlying skin or epithelium to become ecchymotic. A paravaginal hematoma may escape detection initially. However, symptoms of pelvic

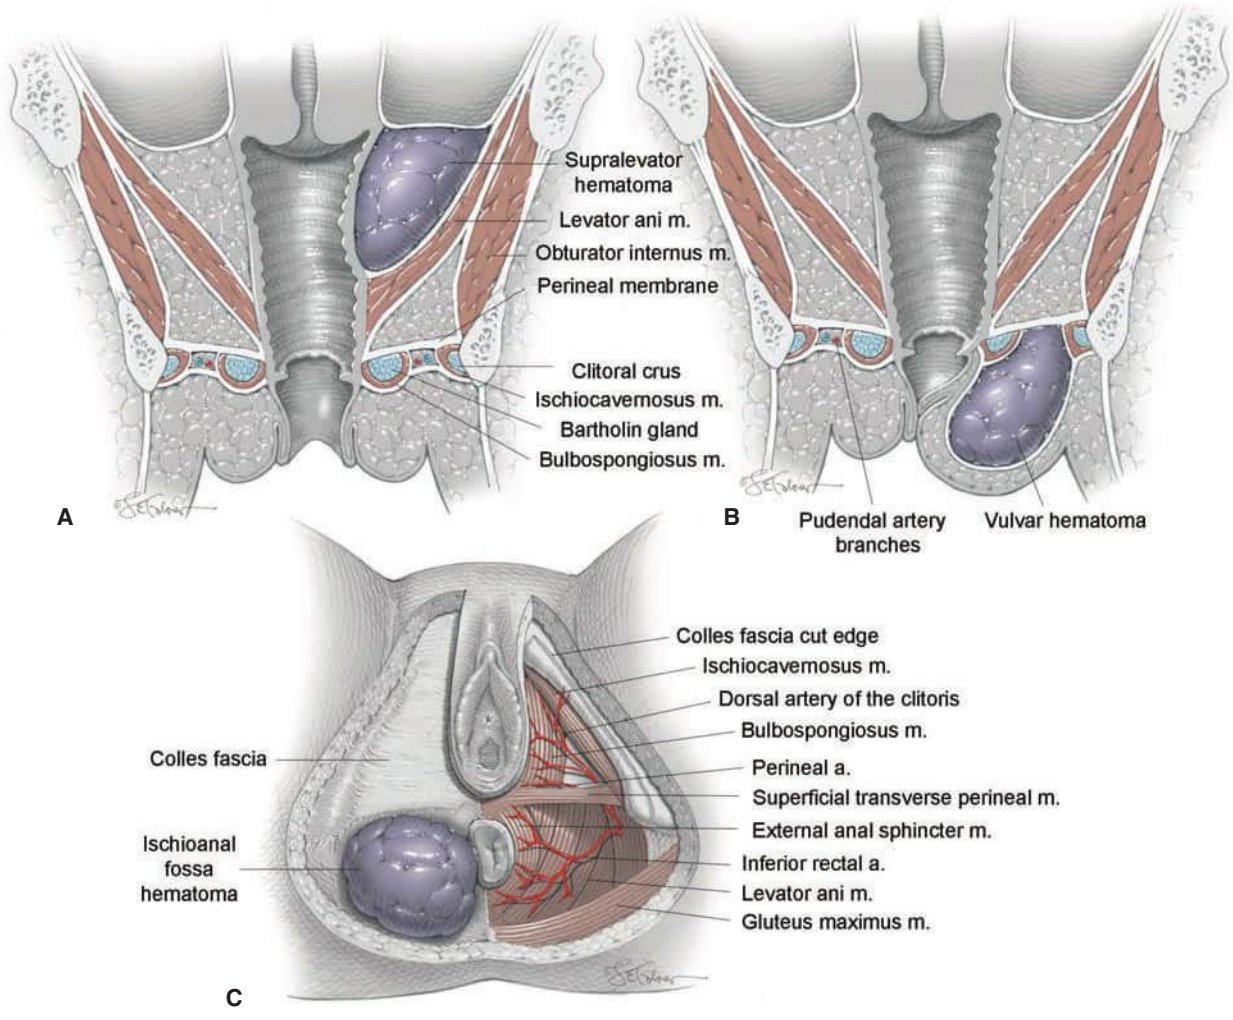

FIGURE 42-11 Schematic drawing showing types of puerperal hematomas. **A.** Coronal view showing a supralevator hematoma. **B.** Coronal view showing a hematoma in the urogenital triangle. **C.** Perineal view showing anal triangle anatomy and an ischioanal fossa hematoma. pressure, pain, or inability to void should prompt evaluation. Others may go undetected until other measures of hypovolemia become evident. With a supralevator extension, the hematoma extends upward in the paravaginal space and between the leaves of the broad ligament. The hematoma may escape detection until it can be felt on abdominal palpation or until hypovolemia develops. Imaging with sonography or computed tomographic scanning may be useful (Cichowski, 2017; Kawamura, 2014).

Management

Small hematomas often remain contained and show minimal expansion. In others, the tissues overlying an expanding hematoma may rupture from pressure necrosis. In some, profuse hemorrhage may follow, but in other cases, the hematoma drains in the form of large clots and old blood. In those that involve the paravaginal space and extend above the levator sling, retroperitoneal bleeding may be massive and occasionally fatal. In rare instances, we encountered hematomas that rebled up to 2 weeks postpartum (Cunningham, 2017).

Vulvovaginal hematomas are managed according to their size, location, duration since delivery, and expansion. If bleeding ceases, then small- to moderate-sized hematomas may be treated expectantly until absorbed. Cool packs and analgesics are supportive care, and an inability to void merits catheter drainage. But, if pain is severe or if the hematoma continues to enlarge, surgical exploration is preferable. *Blood loss with large puerperal hematomas is nearly always considerably more than the clinical estimate.* Hypovolemia is common, and transfusions are frequently required when surgical repair is necessary.

For repair, an incision is made at the point of maximal distention, blood and clots are evacuated, and bleeding points ligated. Often, no distinct bleeding vessels are identified. The cavity may then be obliterated in layers with absorbable sutures. With this, layered tissue closure acts to tamponade low-pressure bleeding. With vaginal hematomas, the vagina is packed with 1 to 2 gauze roll(s) for 12 to 24 hours, and the number of rolls is recorded. Supralevator hematomas are more difficult to treat. Although some can be evacuated by vulvar or vaginal incisions, laparotomy or angiographic embolization are considerations if bleeding continues.

Embolization has become popular for management of some puerperal hematomas. This is especially true for supralevator or retroperitoneal hematomas. Embolization can be used primarily, or more likely secondarily, if surgical attempts at hemostasis have failed or if the hematoma is difficult to access surgically (Distefano, 2013; Lee, 2012; Poujade, 2012). The use of a Bakri balloon for a paracervical hematoma also has been described (Gizzo, 2013; Grönvall, 2014). Last, ultrasound-guided drainage of a recurrent supralevator hematoma has been reported (Mukhopadhyay, 2015).

UTERINE RUPTURE

Predisposing Factors

Uterine rupture is another event that may lead to potentially catastrophic hemorrhage. Rupture may be *primary*, defined as occurring in a previously intact or unscarred uterus. More often, rupture is *secondary* and associated with a preexisting incision, anomaly, or injury of the myometrium (Table 42-3).

The contribution of each of these underlying causes has evolved during the past 50 years. Before 1960, when cesarean delivery was infrequent and women of great parity were numerous, primary uterine rupture predominated. As the incidence of cesarean delivery rose, and especially as a subsequent trial of labor in these women became prevalent through the 1990s, uterine rupture through the cesarean hysterotomy scar became the preeminent cause (Chang, 2020; Gibbins, 2015; Mone, 2016).

Concurrent with the diminished enthusiasm for a trial of labor after cesarean delivery (TOLAC), incidence trends for the two types of rupture have again changed. In a study of 3942 cases of uterine rupture in more than 15 million women, only approximately half were in women with a prior cesarean delivery (Yao, 2017). The International Network of Obstetric Survey Systems (INOSS) identified 864 complete uterine ruptures in more than 2.6 million deliveries (Vanderberghe, 2019). The overall prevalence was 3 cases per 10,000 births. In women without a prior cesarean delivery, the prevalence was 0.6 per 10,000 births, and it was 22 per 10,000 in those with a prior cesarean delivery. This is similar to the recent overall rate of 5 cases per 10,000 births at Parkland Hospital. During this time, there were 40 cases of uterine rupture, and despite a very conservative TOLAC policy, 25 of the 40 events were in women with a prior hysterotomy.

TABLE 42-3. Some Causes of Uterine Rupture

Preexisting Uterine Injury or Anomaly	Uterine Injury or Abnormality Incurred in Current Pregnancy
Surgery involving the myometrium:	**Before delivery:**
Cesarean delivery or hysterotomy	Persistent, intense, spontaneous contractions
Previously repaired uterine rupture	Labor stimulation: oxytocin or prostaglandins
Myomectomy incision through or to the endometrium	Intraamnionic instillation: saline or prostaglandins
Deep cornual resection of interstitial fallopian tube	Perforation by internal uterine pressure catheter
Operative hysteroscopy	External trauma: sharp or blunt
Metroplasty	External version
Sharp or blunt trauma—assaults, vehicular accidents, bullets, knives	Uterine overdistention: hydramnios, multifetal pregnancy
Silent rupture in previous pregnancy	**During delivery:**
Congenital:	Internal version of second twin
Pregnancy in rudimentary uterine horn	Difficult forceps delivery
Defective connective tissue—Marfan or Ehlers-Danlos syndrome	Breech extraction
	Fetal anomaly distending the lower segment
	Vigorous uterine pressure during delivery
	Difficult manual removal of placenta
	Acquired:
	Placental accreta spectrum
	Gestational trophoblastic neoplasia
	Adenomyosis
	Sacculation of entrapped retroverted uterus

The current lower incidence of women of great parity also has lowered the primary-rupture rate. In this regard, advancing maternal age may be a greater risk factor (Hochler, 2020). Another risk is excessive or inappropriate uterine stimulation with oxytocin. This previously frequent cause has mostly disappeared. In an analysis of three trials comparing contemporaneous high- and low-dose oxytocin regimens for labor induction in those with an unscarred uterus, the rate of uterine rupture did not differ between groups (Budden, 2014). The rate of rupture, however, is increased with sequential induction of labor with prostaglandins and oxytocin in those both with and without prior cesarean delivery (Al-Zirqi, 2017).

Other operations that traumatize the myometrium include uterine curettage or perforation, endometrial ablation, myomectomy, operative hysteroscopy, or prior uterine rupture (Frank, 2018; Zhao, 2019). Uterine rupture is also linked with disorders associated with connective tissue weakness (Cauldwell, 2019a,b; Noh, 2013). Another report described rupture in a woman with prior childhood pelvic radiotherapy (Huarte Cignada, 2020).

Blunt abdominal trauma also can rupture a substantially gravid uterus (Miller, 1996). Thus, pregnant women in the later second- and third trimesters who sustain such trauma are ideally monitored for signs of uterine rupture. Specific monitoring protocols are outlined in Chapter 50 (p. 896).

Uncommon causes today are those due to internal podalic version and extraction, difficult forceps delivery, breech extraction, and unusual fetal enlargement such as with hydrocephalus. In one unusual case, fundal rupture followed spontaneous labor in a woman with an abdominal cerclage (Dandapani, 2019). Rupture associated with multifetal pregnancy or uterine anomalies also is rare (Bankada, 2015; Tarney, 2013; Tola, 2014). Although rare, rudimentary uterine horns are especially susceptible and described in Chapter 3 (p. 43). Discussed in Chapter 43 (p. 760), placenta percreta may cause focal myometrial weakness and rupture (Sun, 2016).

Pathogenesis

Rupture of the previously intact uterus during labor most often involves the thinned-out lower uterine segment. When the rent is in the immediate vicinity of the cervix, it frequently extends transversely or obliquely. When the rent forms in the portion of the uterus adjacent to the broad ligament, the tear is usually longitudinal (Fig. 42-13). Although these tears develop primarily in the lower uterine segment, they can extend upward into the active segment or downward through the cervix and into the vagina. In some cases, the bladder also may be lacerated.

If the rupture is of sufficient size, the uterine contents will usually escape into the peritoneal cavity. If the presenting fetal part is firmly engaged, however, then only a portion of the fetus may be extruded from the uterus. Fetal prognosis is largely dependent on the size of the rent, the degree of placental separation, the magnitude of maternal hypovolemia, and the rapidity of diagnosis and response (Al-Zirqi, 2018; Rottenstreich, 2021). In some cases, the overlying peritoneum remains intact, and this usually is accompanied by hemorrhage that extends into the broad ligament to cause a large retroperitoneal hematoma.

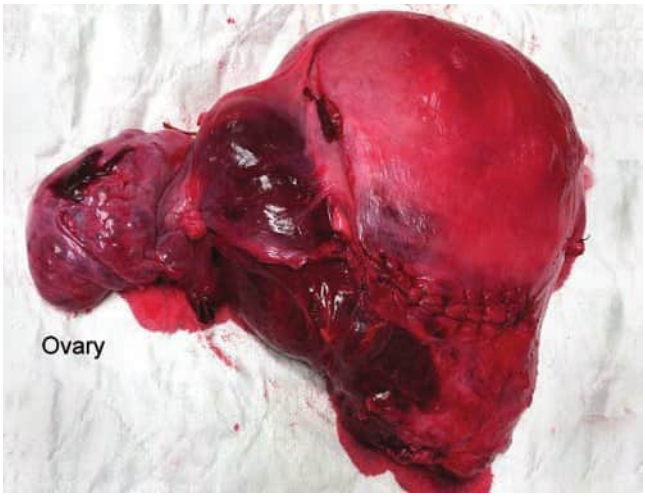

FIGURE 42-13 Peripartum hysterectomy specimen. A right broad ligament hematoma is seen lateral to the closed hysterotomy incision and medial to the ovary. (Reproduced with permission from Dr. Emily H. Adhikari.)

Following vaginal delivery in an unscarred uterus, we and others have occasionally encountered cases of an incomplete tear on the inside of the uterus that extends vertically into the active segment to cause profuse hemorrhage (Conrad, 2015). These tears are usually not visible from below but are found at the time of hysterectomy for intractable bleeding despite a contracted uterus. Hemorrhage with this type of tear can be torrential, and bleeding is usually not slowed until the uterine artery pedicles are clamped bilaterally.

Management and Outcomes

The varied clinical presentations of uterine rupture and its management are discussed in detail in Chapter 31 (p. 579). In the most recent national maternal mortality statistics, uterine rupture accounted for nearly 10 percent of hemorrhage-associated deaths (Creanga, 2015, 2017). Maternal morbidity includes hysterectomy that may be necessary to control hemorrhage. Rates of perinatal mortality and morbidity, which may include severe neurological impairment, also are high (Al-Zirqi, 2018; Rottenstreich, 2021). Table 42-4 lists some perinatal outcomes in 72 women with uterine rupture. Last, maternal obesity comorbid with uterine rupture is associated with increased rates of adverse neonatal outcomes (Yao, 2017). With prior rupture and a subsequent pregnancy, Fox (2020) recommends cesarean delivery prior to labor or at the onset of preterm labor.

AMNIONIC FLUID EMBOLISM

Pathophysiology

This syndrome usually is caused by intravenous embolization of meconium-laden amnionic fluid. It results in rapid cardiorespiratory collapse and profound consumptive coagulopathy. The understanding of the mechanism of injury for amnionic fluid embolism (AFE) has evolved. Early theories proposed that amnionic fluid and debris entered the maternal circulation and obstructed pulmonary artery flow, which led to hypoxia, right

TABLE 42-4. Some Maternal and Perinatal Outcomes in 72 Women with Uterine Rupture

Outcomes	Parkland Hospital[a]	Australia-New Zealand[b]
Number	40	32
Maternal		
Blood loss	2500 mL[c]	2580 mL[d]
Transfusions	55%	63%
Hysterectomy	27%	10%
ICU admission	17%	NS
Perinatal		
Cord artery pH	7.07[c]	NS
Cord pH <7.0	35%	NS
5-min Apgar <7	25%	NS
NNICU	47%	13%
HIE	15%	NS
Death	5%	16%

heart failure, and death. However, during normal delivery, amnionic fluid commonly enters maternal circulation through venous channels at the placental implantation site or small lacerations. Accordingly, squames, fetal cells, and trophoblasts can often be identified in maternal peripheral blood at delivery (Clark, 1986; Lee, 1986). And, at least in experimental animals, infused clear amnionic fluid is generally innocuous, even in large amounts (Adamsons, 1971; Stolte, 1967).

Instead, meconium-laden amnionic fluid is likely a potent cause of symptomatic AFE (Hankins, 1993). Disruption of the maternal-fetal interface allows material from the fetal compartment to enter maternal circulation. This dyad leads to abnormal activation of proinflammatory mediator systems, similar to the systemic inflammatory response syndrome (SIRS), and causes initial, transient pulmonary vasoconstriction and hypertension (Bernstein, 2019). Pulmonary hypertension causes acute right ventricular failure, which is followed by hemodynamic collapse from right ventricular infarction, interventricular septum displacement, and decreased left-sided cardiac output (Pacheco, 2020). This right and then left ventricular dysfunction leads to cardiogenic pulmonary edema and systemic hypotension. Acute respiratory failure with severe hypoxemia from shunting develops. Notably, the resulting multiorgan dysfunction is an interrelated process, with both the cardiac and pulmonary systems affecting each other.

Women who survive beyond these first phases invariably develop the third component of the classic triad—a consumptive coagulopathy. Material from the fetal compartment that contains tissue factor then activates factor VII. This leads to the development of disseminated intravascular coagulation. The rapidity of the coagulopathy is amazing (Fig. 42-14).

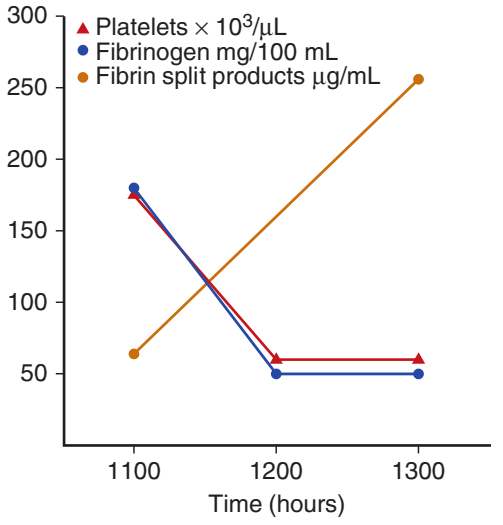

FIGURE 42-14 Fatal amnionic fluid embolism. Results of some coagulation studies show an abrupt drop in plasma fibrinogen levels and platelet count but an extremely elevated serum fibrin split product level.

To those who succumb, postmortem histopathological findings may be obvious. However, detection of squames and keratin may require special stains, and even then, debris may not be seen. In one study, fetal elements were detected in 75 percent of autopsies and in 50 percent of specimens prepared from concentrated buffy coat aspirates taken antepartum from a pulmonary artery catheter (Clark, 1995).

Incidence and Risk Factors

Most reports describe an AFE frequency of 1 to 2 cases per 100,000 births (Clark, 2014; Fitzpatrick, 2019; Knight, 2010). The case-fatality rate in all of these studies ranges from 11 to 43 percent. From another perspective, AFE caused 5 to 15 percent of all pregnancy-related deaths in the United States, Canada, and France (Bonnet, 2018; Kramer, 2012; Petersen, 2019).

Predisposing conditions are rapid labor, meconium-stained amnionic fluid, and tears into uterine and other large pelvic veins that permit an exchange of fluids between the maternal and fetal compartment (Society of Maternal-Fetal Medicine, 2016). Other commonly cited risks include older maternal age; postterm pregnancy; labor induction or augmentation; eclampsia; cesarean, forceps, or vacuum delivery; placental abruption or previa; and hydramnios (Indraccolo, 2018; Knight, 2012; Kramer, 2012). The associations of uterine hypertonus appears to be the *effect* rather than the *cause* because uterine blood flow ceases when intrauterine pressures exceed 35 to 40 mm Hg. Thus, a hypertonic contraction would be the *least* likely circumstance for amnionic fluid and other debris to enter uterine veins (Clark, 1985). For this reason, hypertonus from oxytocin does not seem implicated.

Diagnosis

The classic triad of abrupt hemodynamic and respiratory compromise along with consumptive coagulopathy underpins its diagnosis (Pacheco, 2020). Proposed criteria for AFE diagnosis

TABLE 42-5. Diagnostic Criteria for Amnionic Fluid Embolism

Clinical onset during labor or within 30 minutes of placental delivery
Abrupt onset of cardiorespiratory arrest, or both hypotension and respiratory compromise
Overt disseminated intravascular coagulopathy
No fever ≥38°C

Adapted from Clark, 2016; Pacheco, 2020.

are shown in Table 42-5. In a French study, only 60 percent of women with autopsy-confirmed AFE had all four criteria (Bonnet, 2018). The classic example is dramatic, and a woman in the late stages of labor or immediately postpartum begins gasping for air. Seizures or cardiorespiratory arrest rapidly follow and are accompanied by massive hemorrhage from consumptive coagulopathy (Bernstein, 2019; Tanaka, 2017). Clinical manifestations vary, and we and others have managed several women in whom otherwise uncomplicated vaginal or cesarean delivery was followed by severe acute consumptive coagulopathy without overt cardiorespiratory difficulties. In these women, consumptive coagulopathy appears to be the *forme fruste* of AFE (Kramer, 2012; Porter, 1996).

In such cases, other sources of acute cardiac or respiratory failure should be considered. These include myocardial infarction, pulmonary or air embolism, high spinal blockage, eclampsia, and anaphylactic shock (Bernstein, 2019). In some cases, the temporal relationship of events aids diagnosis. *Unfortunately, no specific diagnostic laboratory test confirms or refutes the diagnosis of AFE, and it remains a clinical diagnosis*. Importantly, women suffering from excessive blood loss and resulting coagulopathy may be misdiagnosed with AFE, when the true culprit is unrecognized or underappreciated hemorrhage (Clark, 2016). In either event, a woman with cardiopulmonary compromise should receive immediate resuscitation (Society for Maternal-Fetal Medicine, 2016).

Management

The initial period of systemic and pulmonary hypertension with AFE is transient. Thus, immediate high-quality cardiopulmonary resuscitation and advanced cardiac life support must be initiated without delay (Pacheco, 2020; Society for Maternal-Fetal Medicine, 2016). These are discussed in detail in Chapter 50 (p. 897). Coagulopathy is managed as described in Chapter 44 (p. 777).

If resuscitation is successful, hemodynamic instability is common in survivors. Both fever and hyperoxia will worsen ischemia-reperfusion injury to the brain. A suitable goal for temperature is 36°C and for mean arterial pressure is 65 mm Hg (Society for Maternal-Fetal Medicine, 2016). Additional supportive care measures such as intubation are usually necessary. During the phase of right ventricular failure, inotropic agents such as dobutamine may improve right heart output, and later systemic hypotension should be treated with vasopressors such as norepinephrine. Excess fluid administration is discouraged because it can worsen dilation of an already engorged right ventricle, which may cause right-sided myocardial infarction and interventricular septum displacement.

Extracorporeal membrane oxygenation (ECMO) has been described in the treatment of AFE (Bernstein, 2019; Webster, 2020). Further discussed in Chapter 50 (p. 886), venovenous ECMO is used for severe hypoxemic respiratory failure, without right or left ventricular failure. Venoarterial ECMO is less readily available and used for impending cardiac arrest and ventricular failure. One recent review of outcomes in 20 women with AFE managed with ECMO reported a maternal mortality rate of only 15 percent. The authors concluded that publication biases may have overestimated the favorable outcomes (Viau-Lapointe, 2019).

Either immediately after cardiopulmonary collapse or during the ensuing phases of injury, a coagulopathy develops in most cases from activation of factor VII and X. This may be exacerbated by ongoing hemorrhage, and a common source is uterine atony. Thus, immediate evaluation of coagulation parameters is indicated with concurrent management of bleeding.

Clinical Outcomes

Most reports describe significant maternal and perinatal mortality with AFE. This is likely influenced by underdiagnosis and reporting biases that favor the most severe cases with the highest mortality rates. From a California database of 1.1 million deliveries, the mortality rate with AFE was 60 percent (Gilbert, 1999). In the INOSS database, maternal mortality rates ranged from 30 to 41 percent (Fitzpatrick, 2019). Death can be rapid, and in one study, 12 of the 34 women died within 30 minutes (Weiwen, 2000). The mortality rate is highest in women who present with cardiac arrest—89 percent (Fitzpatrick, 2019).

Survivors commonly have profound neurological impairment. Clark (1995) observed that only 8 percent of women who lived despite cardiac arrest survived without neurological injury. In a report of 20 cases, the maternal mortality rate was 15 percent, and 40 percent of survivors had neurological disability (Skolnik, 2019). Overall, the prognosis appears to be more associated with disease severity and the attendant cardiac arrest than with any specific treatment modality (Clark, 2014; Fitzpatrick, 2019).

As perhaps expected, perinatal outcomes also are poor and are inversely related to the maternal cardiac arrest-to-delivery interval. Even so, the neonatal survival rate is 70 percent, but unfortunately, up to half of survivors suffer residual neurological impairment. In a Canadian study, 28 percent of neonates were considered to be asphyxiated at birth (Kramer, 2012).

CHAPTER 43

Hemorrhagic Placental Disorders

Hemorrhage following partial or complete separation of the placenta can be torrential. Recall that the amount of blood flowing through the intervillous space at term exceeds 600 mL/min (Pates, 2010). In the second half of pregnancy, three placental disorders contribute substantially to maternal mortality rates. These include placental abruption, placenta previa, and placenta accreta spectrum.

The contributions of hemorrhagic placental disorders to maternal mortality are discussed in Chapter 1 (p. 7) and Chapter 42 (p. 733). The management and clinical experience with these disorders span more than a generation. Placental abruption, for example, has been emphasized in this text for more than 50 years beginning with the work of Dr. Jack Pritchard. Now more common than years past, placenta accreta spectrum is another substantial threat to maternal well-being.

PLACENTAL ABRUPTION

Etiopathogenesis

Separation of the placenta—either partially or totally—from its implantation site before delivery is called *placental abruption* or *abruptio placentae*. From Latin, the latter translates as "rending asunder of the placenta," which denotes a sudden accident, which is characteristic of most cases. In the purest sense, the cumbersome—and thus seldom used—term *premature separation of the normally implanted placenta* is most descriptive because it excludes separation of a placenta previa.

Abruption likely begins with rupture of a decidual spiral artery and hemorrhage into the decidual basalis. The subsequent expanding retroplacental hematoma splits the decidua and leaves a thin layer adherent to the myometrium. The decidual hematoma grows to lift away and compress the adjacent placenta. In some cases that are associated with preeclampsia, impaired trophoblastic invasion with subsequent atherosis is one underlying predisposition (Brosens, 2011). Inflammation or infection also may be contributory (Mhatre, 2016). However, histological findings cannot be used to determine the timing of the abruption (Chen, 2017).

In the early stages of placental abruption, clinical symptoms may be absent. Even with continued bleeding and placental separation, placental abruption can still be either total or partial (Fig. 43-1). With either, bleeding typically insinuates itself between the membranes and uterine wall, ultimately escaping through the cervix to cause *external hemorrhage*. Less often, the blood is retained, leading to *concealed hemorrhage* and delayed diagnosis. The delay translates into greater maternal and fetal hazards. With concealed hemorrhage, the likelihood of consumptive coagulopathy is also increased. This is because increased pressure within the intervillous space, caused by the expanding retroplacental clot, forces more placental thromboplastin into the maternal circulation (Chap. 44, p. 775).

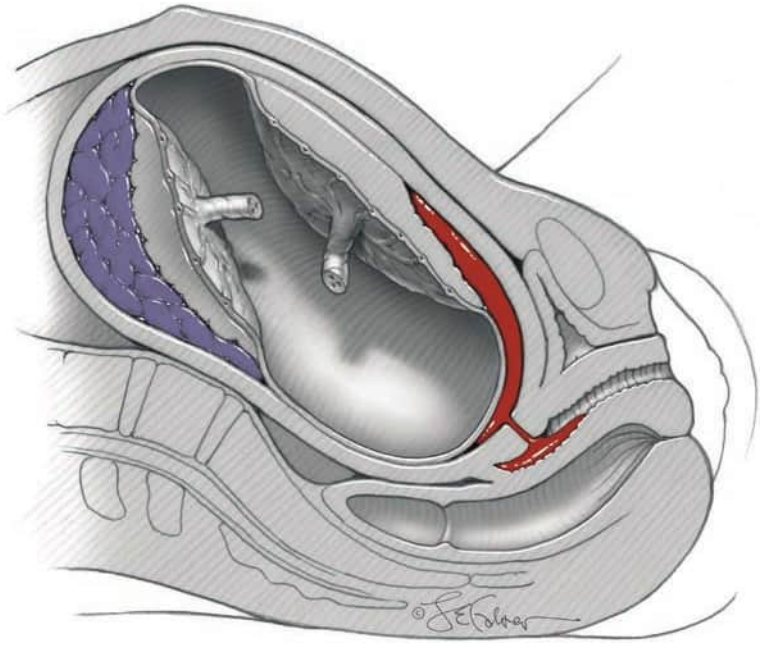

FIGURE 43-1 Schematic of placental abruption. Shown to the left is total placental abruption with concealed hemorrhage. To the right is a partial abruption with blood and clots that dissect between membranes and decidua to reach the internal cervical os and then the vagina.

Traumatic Abruption

External trauma—usually from motor vehicle crashes or aggravated assault—can cause placental separation. The frequency of abruption originating from trauma varies. Importantly, abruption can stem from relatively minor trauma (Huls, 2018). The clinical presentation and consequences of these abruptions differ somewhat from spontaneous cases. For example, associated fetomaternal hemorrhage, while seldom clinically significant with most spontaneous abruptions, is more common with trauma because of concomitant placental tears or "fractures" (Fig. 50-10, p. 895). In eight women with traumatic placental abruption cared for at Parkland Hospital, we found fetal-to-maternal hemorrhage of 80 to 100 mL in three (Stettler, 1992). Importantly, in some cases of trauma, a nonreassuring fetal heart rate tracing may not be accompanied by other evidence of placental separation. A sinusoidal tracing is one example. Following blunt abdominal trauma, uterine contractions are the single most important predictor of placental abruption (Greco, 2019). Traumatic abruption is considered in more detail in Chapter 50 (p. 894).

Most blood in the retroplacental hematoma in a nontraumatic placental abruption is maternal. This is because hemorrhage derives from separation within the maternal decidua, and placental villi are usually initially intact. In 78 women at Parkland Hospital with a nontraumatic placental abruption, fetal-to-maternal hemorrhage was documented in only 20 percent. All of these had <10 mL fetal blood loss (Stettler, 1992). In another series of 68 women with a placental abruption, fetal cells were found in peripheral blood in only 4 percent (Atkinson, 2015).

Placental abruption can create a visible circumscribed depression on the maternal surface of a freshly delivered placenta. These depressions usually measure a few centimeters in diameter and are covered by dark, clotted blood. Because several minutes are required for these anatomical changes to materialize, a very recently separated placenta may appear totally normal at delivery. Our experiences are like those of Benirschke and associates (2012) in that the "age" of the retroplacental clot cannot be determined exactly. In the example shown in Figure 43-2, a large dark clot is well formed. It has depressed the placental bulk and likely is at least several hours old.

Defining placental abruption severity is problematic. We consider placental abruption severe when the fetus dies. However, maternal and fetal complications are frequently serious even with a liveborn fetus. Ananth and coworkers (2016) have defined severe placental abruption as displaying one or more of the following: (1) maternal sequelae that include disseminated intravascular coagulation (DIC), shock, transfusion, hysterectomy, renal failure, or death; (2) fetal complications such as nonreassuring fetal status, growth restriction, or death; or (3) neonatal outcomes that include death, preterm delivery, or growth restriction.

Chronic Abruption

When placental separation is not followed by delivery, the placental abruption is termed chronic. Some of these cases begin early in pregnancy. Dugoff and coworkers (2004) observed an association between some abnormally elevated maternal serum aneuploidy markers and subsequent abruption. Others have correlated first- and second-trimester bleeding with third-trimester placental abruption (Ananth, 2006; Weiss, 2004). In some cases, chronic abruption and oligohydramnios develop and are called the *chronic abruption–oligohydramnios sequence* (CAOS) (Elliott, 1998). Even later in pregnancy, hemorrhage with retroplacental hematoma formation is occasionally arrested completely without delivery. These women may have

FIGURE 43-2 Partial placental abruption with a dark adherent clot.

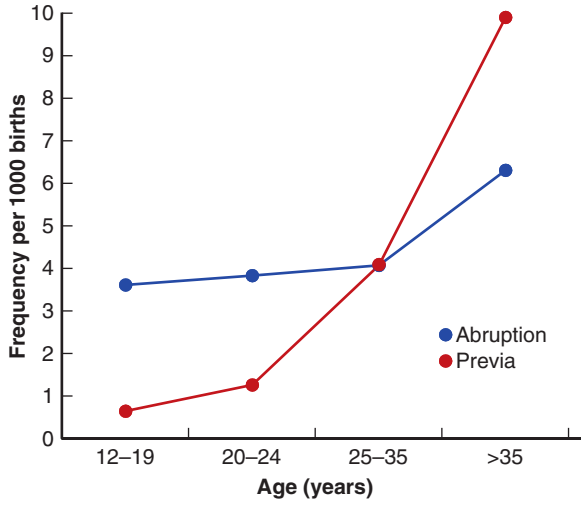

FIGURE 43-3 Frequency of placental abruption and placenta previa by maternal age at Parkland Hospital from 2000 through 2015.

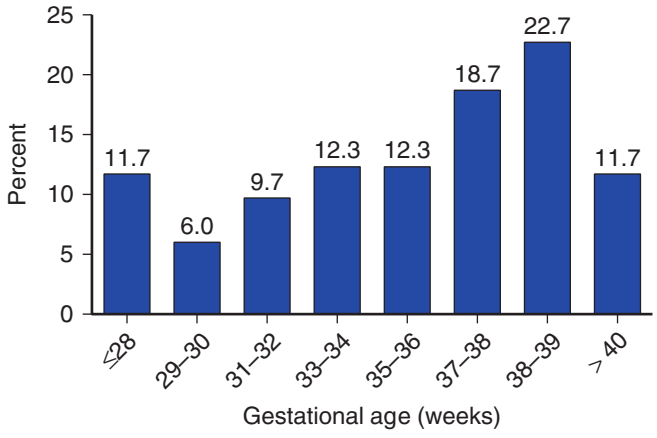

FIGURE 43-4 Frequency of placental abruption by gestational age at Parkland Hospital.

abnormally elevated levels of maternal serum alpha-fetoprotein (MSAFP) or placenta-specific RNAs as markers of the event (Miura, 2017; Ngai, 2012).

Frequency

The reported incidence of placental abruption varies because of differing criteria used for diagnosis. Its frequency averages 0.5 percent or 1 case in 200 deliveries. From one database of more than 125 million births from 1979 through 2010, the incidence of placental abruption was nearly 1 percent (Hill, 2020). In more than 250,000 deliveries at Parkland Hospital from 2000 through 2015, the incidence of placental abruption averaged 1 case in 290 births (Fig. 43-3).

The frequency of placental abruption has risen in this country, and most of this increase is in black women (Ananth, 2005, 2016). This disproportion may be explained in part by the conservative management of early-onset preeclampsia in some institutions (Chap. 41, p. 714). At Parkland Hospital, however, the frequency of severe placental abruption has declined. Specifically, with placental abruption so extensive as to kill the fetus, the incidence was 0.24 percent or 1 case in 420 births from 1956 through 1967 (Pritchard, 1967). Through 2020, this same frequency dropped to 0.05 percent or 1 case in 2060 births. This likely reflects a concurrent decline in the number of high-parity women giving birth and rise in the availability of prenatal care and emergency transportation.

Perinatal Morbidity and Mortality

Overall, perinatal outcomes are influenced by gestational age, and the frequency of placental abruption rises across the third trimester. As seen in Figure 43-4, more than half of the placental abruptions at Parkland Hospital developed at gestational ages ≥37 weeks' gestation. Perinatal mortality and morbidity, however, are more common with earlier abruptions and with concomitant preeclampsia (Furukawa, 2015; Han, 2019). Of other related factors, major fetal congenital anomalies have greater association with placental abruption (Riihimäki, 2013).

Although the rates of fetal death have declined, the contribution of abruption as a cause of stillbirth remains prominent because other causes also have decreased. For example, since the early 1990s, 10 to 12 percent of all third-trimester stillbirths at Parkland Hospital have been the consequence of placental abruption. In a review of more than 15 million singleton births between 1995 and 1998 in the United States, the perinatal mortality rate associated with placental abruption was 119 death per 1000 births. This was higher than the rate of 8 deaths per 1000 births in the general obstetrical population (Salihu, 2005).

Neonatal deaths also are common following placental abruption. At Parkland Hospital, 15 percent of liveborn neonates die. Perinatal morbidity also is common in this group (Downes, 2017). Moreover, associated childhood mortality mainly stems from birth-related asphyxia and prematurity (Riihimäki, 2018). In one series, 20 percent of 43 liveborn neonates had severe fetal acidemia following placental abruption, and 20 percent of survivors developed cerebral palsy (Matsuda, 2013). In another study of 84 liveborns, 29 (35 percent) had an umbilical artery pH <7.00 (Onishi, 2019). Ananth and coworkers (2017) attribute some of the adverse neurodevelopmental outcomes to preterm delivery.

Predisposing Factors

Demographic Factors

Several predisposing factors raise the placental abruption risk (Table 43-1). *Advancing maternal age* is one risk, although data regarding women of great parity are conflicting (see Fig. 43-3) (Okby, 2017). Race or ethnicity also appears important (Eubanks, 2021). In an earlier study, in almost 366,000 deliveries at Parkland Hospital, abruption severe enough to kill the fetus was most common in black and white women—1 case in 200 births; less so in Asian women—1 in 300; and least common in Latinas—1 in 350 (Pritchard, 1991). A *familial association* was found from one Norwegian population-based registry (Rasmussen, 2009). In this study, if a woman had a severe abruption, the risk for her sister was doubled. Candidate genes involved in mitochondrial biogenesis and oxidative phosphorylation pathways, which confer risk for placental abruption, have been described (Workalemahu, 2018).

TABLE 43-1. Risk Factors for Placental Abruption

Risk Factor	Relative Risk
Prior abruption	10–188
Increased age and parity	1.3–2.3
Preeclampsia	2.1–4.0
Chronic hypertension	1.8–3.0
Chorioamnionitis	3.0
Preterm ruptured membranes	2.4–4.9
Multifetal gestation	2–8
Low birthweight	14.0
Hydramnios	1.9
Cigarette smoking	1.4–1.9
Single umbilical artery	3.4
Cocaine use	—
Uterine leiomyoma	2.6
Subchorionic hematoma	5.7

Data from Aviram, 2015; Downes, 2017; Gutvirtz, 2016; Khazaei, 2019; Kortekaas, 2020; Morgan, 2016; Ruiter, 2015; Tuuli, 2011.

Pregnancy-associated Hypertension

Some form of hypertension is the most frequent condition associated with placental abruption. This includes gestational hypertension, preeclampsia, chronic hypertension, or a combination. The hemolysis, elevated liver enzyme levels, low platelet count (HELLP) syndrome carries an increased risk for placental abruption. Moreover, expectant management of preeclampsia in significantly preterm pregnancies was complicated by placental abruption in 4 percent (Shoopala, 2019). In a report by Pritchard and colleagues (1991) that described 408 women with placental abruption and fetal demise, hypertension was apparent in half once hypovolemia was corrected. Half of these latter women—a fourth of all 408—had chronic hypertension. Examined another way, one Maternal-Fetal Medicine Units (MFMU) Network study found that 1.5 percent of pregnant women with chronic hypertension suffered placental abruption (Sibai, 1998). At Parkland Hospital, the placental abruption frequency in women with treated chronic hypertension and significant proteinuria was almost 1 percent. This incidence compared with the 0.3-percent incidence in women with treated hypertension without substantial proteinuria (Morgan, 2016).

Chronic hypertension with superimposed preeclampsia or with fetal-growth restriction confers an even greater risk (Lueth, 2020). Even so, the severity of hypertension does not necessarily correlate with abruption incidence (Morgan, 2016; Zetterstrom, 2005). However, women with preeclampsia that experience placental abruption have worse maternal, fetal, and neonatal outcomes compared with women experiencing abruption alone (Han, 2019). The long-term effects of these associations are apparent from the significantly elevated cardiovascular mortality risk in women with prior abruption, with or without chronic hypertension (DeRoo, 2016; Pariente, 2013). Observations from the Magpie Trial Collaborative Group suggest that women with preeclampsia, with or without chronic hypertension, given magnesium sulfate may have a reduced risk for abruption (Altman, 2002). Last, Roberge and colleagues (2018), performed a metaanalysis and reported that a 100-mg daily aspirin may decrease the incidence of placental abruption.

Preterm Prelabor Ruptured Membranes

The placental abruption risk substantially rises when placental membranes rupture before term. (Hackney, 2016). Of 756 women with ruptured membranes between 20 and 36 weeks' gestation, 5 percent developed an abruption (Major, 1995). The frequency was 17 percent with previable prelabor ruptured membranes (Kibel, 2016). The risk for abruption with preterm membrane rupture is further elevated with comorbid infection (Ananth, 2004). In one cohort study of pregnancies ≥34 weeks' gestation, the placental abruption rate was eightfold higher if hydramnios was comorbid (Aviram, 2015). From a metaanalysis of 10 studies that included term and preterm gestational ages, hydramnios was associated with a twofold greater rate of placental abruption (Khazaei, 2019). Abrupt uterine decompression during membrane rupture may be an inciting factor.

Prior Abruption

Many of the predisposing factors in women with a history of an abruption are chronic conditions, and in these cases, placental abruption has a high recurrence rate. Women with abruption and fetal death have a recurrence rate of 12 percent, and half of these abruptions caused another fetal death (Pritchard, 1970). Furuhashi and colleagues (2002) reported a 22-percent recurrence rate, and half recurred at a gestational age 1 to 3 weeks earlier than the first abruption. In one longitudinal Dutch study, Ruiter and coworkers (2015) cited a recurrence risk of 5.8 percent. In a population-based study of 767,000 pregnancies, the authors found a sevenfold higher risk for recurrence of a "mild" abruption and twelvefold risk for a "severe" abruption (Rasmussen, 2009). For women who had two severe abruptions, the risk for a third was increased 50-fold.

Management of a pregnancy subsequent to an abruption is difficult because another separation may suddenly occur, even remote from term. In many of these recurrences, evaluation of fetal well-being is almost always reassuring beforehand. Thus, antepartum fetal testing is usually not predictive. Because term abruptions tend to be recurrent, Ruiter and coworkers (2015) recommend labor induction at 37 weeks' gestation. It seems reasonable to induce labor at 38 completed weeks if other complications do not develop beforehand.

Other Associations
