Williams OBSTETRICS

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

DR. F. GARY CUNNINGHAM

Editor of *Williams Obstetrics*
18th through 26th Editions

In the early 1970s, as I was finishing my residency at Charity Hospital of New Orleans, the 14th edition of *Williams Obstetrics* was published. The residents in our program were totally enamored with the textbook because it was a clinical manual derived from the editors' personal experiences and from contemporary, evidence-based literature.

During my last year, my chairman, Dr. Abe Mickal, invited me to attend a national meeting where I first met four obstetricians who would have an immeasurable impact on my life—Drs. Jack Pritchard, Paul MacDonald, Norman Gant, and Peggy Whalley. Following that, I was invited to Dallas to spend time at the University of Texas Southwestern and Parkland Hospital. As I followed Dr. Pritchard through Labor & Delivery and his clinical research laboratory, I became hooked on "Parkland Obstetrics" and later that year began a fellowship that was the nascent subspecialty of Maternal–Fetal Medicine. It also began a lifelong friendship with Jack Pritchard that I will always treasure.

Beginning with the 15th edition of *Williams Obstetrics*, the author-editors were Drs. Pritchard, MacDonald, and Gant. After publication of the 17th edition, these mentors asked me to assume the senior editor role. I was immediately struck by the awesome responsibility of shepherding the book that many people called "the bible of obstetrics."

Over the years, and now as we publish this 26th edition, I reflect on the evolution of obstetrics, and hence the complexity of sustaining a textbook designed to cover the breadth of obstetrics. As essential fields such as sonography, genetics, and fetal medicine were developed, we enlisted the help of extremely talented leaders in their respective fields to ensure that the book adequately presented these innovations. As for my role in this and other editions, I can only promise the readers that the quality of the book has been foremost in my mind and led me to spend literally tens of thousands of hours to help prepare the past nine editions. To this end, the editors have always strived to put the best product forward because of the tremendous responsibility that we shoulder regarding the care of women and their unborn children. The textbook has been one of the great passions in my life, and I will miss the challenge.

DEDICATION

KENNETH LEVENO, MD
1941–2020

Dr. Kenneth Leveno was a vocal and stalwart defender of evidence-based obstetrics. Sadly, he passed away in May 2020. Ken joined the Department of Obstetrics & Gynecology at the University of Texas Southwestern after completing a Maternal–Fetal Medicine fellowship in 1978. In 1984, he was appointed Chief of Obstetrics at Parkland Memorial Hospital—a role in which he served for the next 20 years. During that time and afterwards, he worked tirelessly to achieve a level of excellence in obstetrical care for indigent women of Dallas County. His inspiring leadership and innovations raised the quality of care at the community obstetrics clinics, the high-risk prenatal clinics at Parkland, and the inpatient units, which include the Obstetrical Triage Unit, Labor & Delivery, postpartum wards, and the High-Risk Pregnancy Unit. Early on, he also designed a computerized database to measure quality indicators and provide an underpinning for clinical research. Indeed, his contributions to these programs were reverently referred to by us as *Parkland Obstetrics.*

Ken Leveno's leadership extended well beyond the hospital that he loved. He was a leader in American obstetrics by his defining of clinical research. Through his hundreds of peer-reviewed publications, his clinical opinions, and his willingness to engage in national debates, he helped shape obstetrical practices worldwide. In 1993, Ken began serving as an editor for *Williams Obstetrics*—a task that he regarded as a privilege and a responsibility. He co-authored the 19th through the current 26th editions. Last and importantly, he mentored the careers of many Maternal–Fetal Medicine fellows and young faculty who have gone on to achieve national reputations in the care of women. Ken will be greatly missed.

PREFACE

Over its 26 editions, *Williams Obstetrics* has aimed to serve practicing obstetricians and midwives in the bedside care of their patients. With its detailed explanations of disease pathophysiology and treatment fundamentals, it provides a bedrock text for residents who are training in Obstetrics or in Family Medicine specialties. Fellows in Maternal–Fetal Medicine will benefit from its additional discussions of complicated pathology and management. Last, *Williams Obstetrics* can aid specialists who act as consultants for gravidas with non-pregnancy-related disorders. Specifically, each chapter in Section 12 focuses on a specific organ system, the normal physiological changes and frequent disorders of that system in pregnancy, and suitable treatment options.

For this 26th edition, we continue to present the detailed staples of basic obstetrics such as maternal anatomy and physiology, preconceptional and prenatal care, labor, delivery, and the puerperium. These accompany detailed discussions of obstetrical complications exemplified by preterm labor, hemorrhage, hypertension, and many more. To emphasize the "M" in Maternal–Fetal Medicine, we continue to instruct on the many medical and surgical disorders that can complicate pregnancy. And, our second patient—the fetus—has accrued especial attention with an entire section devoted to diagnosis and treatment of fetal disorders. For all of these, we once again emphasize the science-based practice of clinical obstetrics. Expert clinical pearls add depth to these discussions and are written for busy practitioners—those "in the trenches." To integrate all our content, the reader of one chapter may be referred to a different chapter that contains complementary content. This offers a more global understanding of a given topic.

To accomplish our teaching goals, the text has been updated with more than 3000 new literature citations through 2021. Many of the nearly 900 figures are new, and these graphs, sonograms, magnetic resonance images, photographs, photomicrographs, and data graphs are all in vivid color. Much of the original artwork was rendered by our own medical illustrators.

As before, we continue to incorporate contemporaneous guidelines from professional and academic organizations such as the American College of Obstetricians and Gynecologists, the Society for Maternal–Fetal Medicine, the Centers for Disease Control and Prevention, the National Institutes of Health, and other authoritative sources. Many of these data are distilled into nearly 100 tables, in which information has been arranged in an easy read-and-use format. In addition, several diagnostic and management algorithms are available to quickly guide practitioners. Although we strive to cite numerous sources and provide multiple evidence-based options for such management schemes, we also include our own clinical experiences drawn from the large obstetrical service at Parkland Hospital. We are convinced that these are disciplined examples of evidence-based obstetrics but quickly acknowledge that they do not constitute the sole method of management.

ACKNOWLEDGMENTS

In the creation and production of this textbook, we were fortunate to have the assistance and support of countless talented professionals both within and outside the Department of Obstetrics and Gynecology. To begin, we acknowledge that an undertaking of this magnitude would not be possible without the unwavering support provided by our recent Chairman Dr. Steven Bloom and Vice-Chairman Dr. Barry Schwarz, whose financial and academic endorsement has been essential. Dr. Bloom has served as an editor for the 22nd through 25th editions but now has assumed the important role of Associate Dean of Clinical Sciences at the University of Texas Southwestern Medical Center.

In constructing such an expansive academic compilation, the expertise of many colleagues was needed to add vital, evidence-based content. It was indeed fortuitous for us to have access to a trove of collaborators from our medical center. From our own Department of Obstetrics and Gynecology, Dr. Shivani Patel was essential to the production of our book and is an invaluable addition to our team. We benefitted from her obstetrical expertise, writing talent, and ability to translate difficult concepts into teaching pearls. Faculty with specific expertise included Dr. Claudia Werner, who lent valuable insight into the management of cervical dysplasia. Our nationally known pelvic anatomist, Dr. Marlene Corton, prepared graphic masterpieces for the anatomy chapter with artist Lew Calver. We also are grateful to the numerous faculty and residents who added seminal clinical photographs to our text.

In addition to these contributors, we relied heavily on our colleagues in the Division of Maternal–Fetal Medicine. These professionals, in addition to providing expert consultation, graciously assisted us by covering clinical duties when writing and editing were especially time consuming. These include Drs. Scott Roberts, Oscar Andujo, Vanessa Rogers, Charles Brown, Julie Lo, Robyn Horsager, Patricia Santiago-Muñoz, Mark Peters, Elaine Duryea, Jamie Morgan, Morris Bryant, Shena Dillon, Anne Ambia, Robert Martin, Robert Stewart, Stephan Shivvers, Ashley Zink, Sarah Happe, and Christina Herrera.

We also emphasize that production of *Williams Obstetrics* would not be feasible without the help of our Maternal–Fetal Medicine fellows and our residents in Obstetrics and Gynecology. Their insatiable curiosity serves to energize us to find new and effective ways to convey age-old truths, new data, and cutting-edge concepts. Their logical and critical questions lead us to weaknesses in the text, and thereby always help us to improve our work. In addition, we sincerely thank them for their vigilance in capturing photographs of spectacular examples of both obstetrical pathology and normal findings.

This edition is heavily populated with seminal examples of sonographic findings. We are grateful for the efforts of Mary Gibbs, RDMS; Rafael Levy, RDMS; Michael Davidson, RDMS; and the many talented sonographers at Parkland Hospital.

Thanks to generous funding from the McGraw-Hill Companies, this 26th edition now contains more than 200 color illustrations. Most of these were crafted by several skilled medical illustrators who include Ms. Marie Sena, Ms. Erin Frederickson, and Ms. SangEun Cha. All of these talented artists trained here at UT Southwestern under the instruction of Mr. Lewis Calver. Additional artistic support came from Mr. Joseph Varghese, Ms. Shreya Tiwari, Dr. Sudhi Singh, and Mr. Manoj Kumar Choudhry. Their work at Thomson Digital provided the full-color graphs and line art used to enhance this edition. Their team tirelessly coordinated efforts between author and artist and graciously accommodated our numerous changes and tweaks.

Production of the 5000-page manuscript would not have been possible without a dedicated team. Once again, we are deeply indebted to Ms. Dawn Wilson and Ms. Melinda Epstein for their untiring efforts with manuscript production. Ms. Regina Williams also provided excellent, cheerful, conscientious manuscript assistance. Mr. Charles Richards offered knowledgeable and responsive information technology support. For these and many more that go unnamed, we could not have done our job without their expertise.

It again has been a privilege to work with the dedicated professionals from McGraw-Hill Education. We have had the pleasure to work with Executive Editor Mr. Jason Malley in production of our textbook and are grateful for his support of *Williams Obstetrics*. Senior Project Development Editor Ms. Christie Naglieri has again brought her considerable knowledge to this edition of our book. Her dedication to creating the best textbook supported our efforts, and we appreciate her productive, gracious style. We thank Ms. Leah Carton, who provided professional, timely, and ever-sunny aid. Mr. Richard Ruzycka served as production supervisor for this edition of the textbook, and our book benefits from his years of experience.

Our text took its final shape under the watchful care of our compositors at Aptara, Inc. We thank Ms. Indu Jawwad for her talents in graciously and masterfully coordinating and overseeing composition. Her dedicated attention to detail and organization were vital to completion of our project. She has created many editions with us, and we consider her an essential team member. At Aptara, Mr. Mahender Singh carried out the crucial task of quality control. He also assisted, along with Mr. Rajesh Chander, Mr. Kamlesh Bhatt, and Mr. Anil Varghese, in creating beautiful chapter layouts to highlight our content aesthetically and informatively. This edition's chapters were also posted and available online for use prior to print publication. We thank Mr. Braj Bhushan and Mr. Ashish Kumar Sharma for preparing this content so brilliantly. Special thanks go to Mr. Greg Feldman. As copyeditor, Greg added

precision and clarity to our efforts. His endurance and pleasant professionalism through many challenging chapters has made our text better.

Last, we acknowledge our significant debt to the women who have entrusted themselves and their unborn children to us for obstetrical care. The clinical expertise and many images provided in this text would not have been possible without their collaborative spirit to help us advance obstetrical knowledge. We also offer enthusiastic and heartfelt appreciation to our families and friends. Without their patience, generosity, love, and encouragement, this task would have been impossible.

SECTION 1

OVERVIEW

CHAPTER 1

Overview of Obstetrics

The science and clinical practice of obstetrics focuses on human reproduction. The specialty promotes the health and well-being of the pregnant woman and her fetus through quality perinatal care. Such care entails recognition and treatment of complications, supervision of labor and delivery, initial care of the newborn, and management of the puerperium. Postpartum care promotes health and provides family planning options.

Evidence-based medicine dominates the modern practice of obstetrics. As described by Williams in this textbook's first edition, we too strive to present the scientific evidence for current obstetrical care. Still, high-quality data do not support most recommendations (Brock, 2021). Thus, much of our practice stems from expert-based opinions and historical experiences (Society for Maternal-Fetal Medicine, 2021). To help bridge knowledge gaps, we also rely on authoritative sources such as the American College of Obstetricians and Gynecologists and the Society for Maternal-Fetal Medicine, as well as agencies such as the Centers for Disease Control and Prevention (CDC) and National Institutes of Health (NIH).

VITAL STATISTICS

The importance of obstetrics is demonstrated by the use of maternal and neonatal outcomes as an index of health and life quality among nations. Intuitively, indices showing poor obstetrical and perinatal outcomes could be assumed to reflect medical care deficiencies for the entire population.

The National Vital Statistics System of the United States collects statistics on births and deaths, including fetal deaths. Legal authority for collection resides individually with the 50 states; two regions—the District of Columbia and New York City; and five territories—American Samoa, Guam, the Northern Mariana Islands, Puerto Rico, and the Virgin Islands. The standard birth certificate includes information on medical and lifestyle risks, labor and delivery factors, and newborn characteristics. Importantly, the current death certificate contains a pregnancy checkbox (Hoyert, 2020).

Definitions

Standard definitions are encouraged by the World Health Organization as well as the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2019a). Uniformity allows data comparison between states or regions and between countries. Still, not all definitions are uniformly applied. For example, uniformity is incomplete among states regarding birthweight and gestational age criteria for reporting fetal deaths (American College of Obstetricians and Gynecologists, 2020a). Not all states follow this recommendation. Specifically, 28 states stipulate that losses beginning at 20 weeks' gestation should be recorded as fetal deaths; eight states report all products of conception as fetal deaths; and still others use a minimum birthweight of 350 g, 400 g, or 500 g to define fetal death. To further the confusion, the National Vital Statistics Reports tabulates fetal deaths from pregnancies that are 20 weeks' gestation or older (Centers for Disease Control and Prevention, 2020a). This is problematic because the 50th percentile for fetal weight at 20 weeks approximates 325 to 350 g—considerably less than the 500-g definition. In fact, a birthweight of 500 g corresponds closely with the 50th percentile for 22 weeks' gestation.

Definitions recommended by the National Center for Health Statistics and the CDC are as follows:

Perinatal period. The interval between the birth of a neonate born after 20 weeks' gestation and the 28 completed days after that birth. When perinatal rates are based on birthweight, rather than gestational age, recommendations define the perinatal period as commencing at the birth of a 500-g neonate.

Birth. The complete expulsion or extraction from the mother of a fetus after 20 weeks' gestation. As described above, in the absence of accurate dating criteria, fetuses weighing <500 g are usually not considered births but rather are termed *abortuses* for purposes of vital statistics.

Birthweight. Neonatal weight determined immediately after delivery or as soon thereafter as feasible. It should be expressed to the nearest gram.

Birth rate. The number of live births per 1000 population.

Fertility rate. The number of live births per 1000 females aged 15 through 44 years.

Live birth. The term used to record a birth whenever the newborn at or sometime after birth breathes spontaneously or shows any other sign of life such as a heartbeat or definite spontaneous movement of voluntary muscles. Heartbeats are distinguished from transient cardiac contractions, and respirations are differentiated from fleeting respiratory efforts or gasps.

Stillbirth or fetal death. The absence of signs of life at birth.

Early neonatal death. Death of a liveborn neonate during the first 7 days after birth.

Late neonatal death. Death after 7 days but before 29 days.

Stillbirth rate or fetal death rate. The number of stillborn neonates per 1000 neonates born, including live births and stillbirths.

Neonatal mortality rate. The number of neonatal deaths per 1000 live births.

Perinatal mortality rate. The number of stillbirths plus neonatal deaths per 1000 total births.

Infant death. All deaths of liveborn infants from birth through 12 months of age.

Infant mortality rate. The number of infant deaths per 1000 live births.

Low birthweight. A newborn whose weight is <2500 g.

Very low birthweight. A newborn whose weight is <1500 g.

Extremely low birthweight. A newborn whose weight is <1000 g.

Term neonate. A neonate born any time after 37 completed weeks' gestation and up until 42 completed weeks' gestation (260 to 294 days). The American College of Obstetricians and Gynecologists and Society for Maternal-Fetal Medicine encourage specific gestational age designations (2019a). *Early term* refers to neonates born at 37 completed weeks up to $38^{6/7}$ weeks. *Full term* denotes those born at 39 completed weeks up to $40^{6/7}$ weeks. Last, *late term* describes neonates born at 41 completed weeks up to $41^{6/7}$ weeks.

Preterm neonate. A neonate born before 37 completed weeks (the 259^{th} day). A neonate born before 34 completed weeks is early preterm, whereas a neonate born between 34 and 36 completed weeks is late preterm.

Postterm neonate. A neonate born any time after completion of the 42nd week, beginning with day 295.

Abortus. A fetus or embryo removed or expelled from the uterus in the first half of gestation—20 weeks or less, or in the absence of accurate dating criteria, born weighing <500 g.

Induced termination of pregnancy. The purposeful interruption of an intrauterine pregnancy that has the intention other than to produce a liveborn neonate and that does not result in a live birth. This definition excludes retention of products of conception following fetal death.

Direct maternal death. The death of the mother that results from obstetrical complications of pregnancy, labor, or the puerperium and from interventions, omissions, incorrect treatment, or a chain of events resulting from any of these factors. An example is maternal death from exsanguination after uterine rupture.

Indirect maternal death. A maternal death that is not directly due to an obstetrical cause. Death results from previously existing disease or a disease developing during pregnancy, labor, or the puerperium that was aggravated by maternal physiological adaptation to pregnancy. An example is maternal death from complications of mitral valve stenosis.

Late maternal death. Death of a woman from direct or indirect obstetrical causes more than 42 days but less than 1 year after the pregnancy's end.

Nonmaternal death. Death of the mother that results from accidental or incidental causes not related to pregnancy. An example is death from an automobile accident or concurrent malignancy.

Pregnancy-associated death. The death of a woman, from any cause, while pregnant or within 1 calendar year of termination of pregnancy, regardless of the duration and the site of pregnancy.

Pregnancy-related death. A pregnancy-associated death that results from: (1) complications of pregnancy itself, (2) the chain of events initiated by pregnancy that led to death, or (3) aggravation of an unrelated condition by the physiological or pharmacological effects of pregnancy and that subsequently caused death.

Maternal mortality ratio. The number of maternal deaths that result from the reproductive process per 100,000 live births. Used more commonly, but less accurately, are the terms *maternal mortality rate* or *maternal death rate*. The term *ratio* is more accurate because it includes in the numerator the number of deaths regardless of pregnancy outcome—for example, live births, stillbirths, and ectopic pregnancies—whereas the denominator includes the number of live births.

PREGNANCY RATES IN THE UNITED STATES

According to the CDC, the fertility rate of women aged 15 to 44 years in the United States in 2019 was 58 live births per 1000 women. This rate began slowly trending downward in 1990 and has now dropped below that for replacement births to sustain the population level. This indicates a population decline. The birth rate decreased for all major ethnic and racial groups, for adolescents and unmarried women, and for

TABLE 1-1. Total Pregnancies and Outcomes in the United States in 2019

Outcome	Number or Percent
Total births	3,747,540
Cesarean deliveries	31.7%
Primary cesarean delivery	21.6%
Vaginal birth after cesarean	13.8%
Preterm births (<37 weeks)	10.0%
Low birthweight (<2500 g)	8.0%
Very low birthweight (<1500 g)	1.4%
Induced abortions	862,320

Data from Guttmacher 2019b; Martin, 2021.

those aged 20 to 24 years. For women older than 30 years, the birth rate rose slightly. Almost half of newborns in 2019 in the United States were minorities: Hispanic—25 percent; African-American—15 percent; and Asian—4 percent (Martin, 2021).

The total number of pregnancies and their outcomes in 2019 are shown in Table 1-1. According to the Guttmacher Institute (2019b), 45 percent of births in the United States are unintended at the time of conception. But, the overall proportion of unintended births has declined since 2008. Unmarried women, black women, and women with less education or income are more likely to have an unplanned pregnancy.

OBSTETRICAL CARE MEASURES

Several indices are used to assess obstetrical and perinatal outcomes as measures of medical care quality. As noted, the *perinatal mortality rate* includes the number of stillbirths and neonatal deaths per 1000 total births. In 2016, this rate was 6 deaths per 1000 births (Fig. 1-1). This rate has been unchanged for several years (Gregory, 2018). Rates of fetal death at 28 weeks' gestational age or more have declined since 1990, whereas rates for those between 20 and 27 weeks are static.

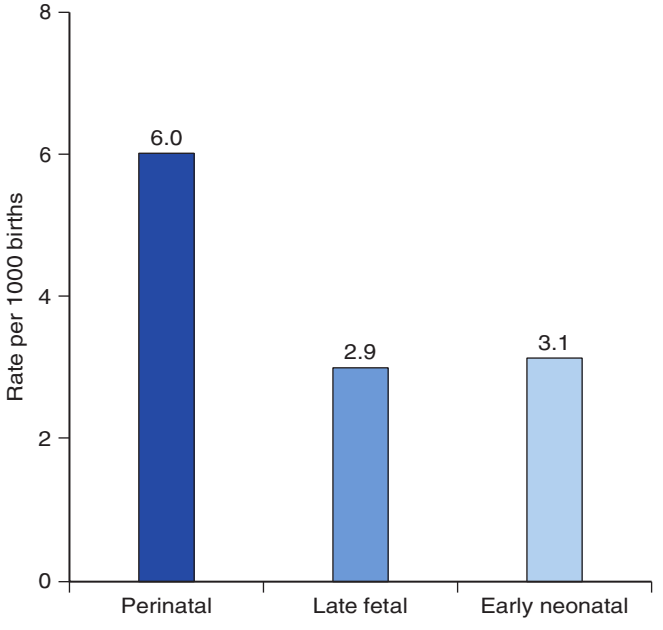

FIGURE 1-1 Perinatal, late-fetal, and early-neonatal mortality rates per 1000 births in the United States in 2016. (Data from Gregory, 2018).

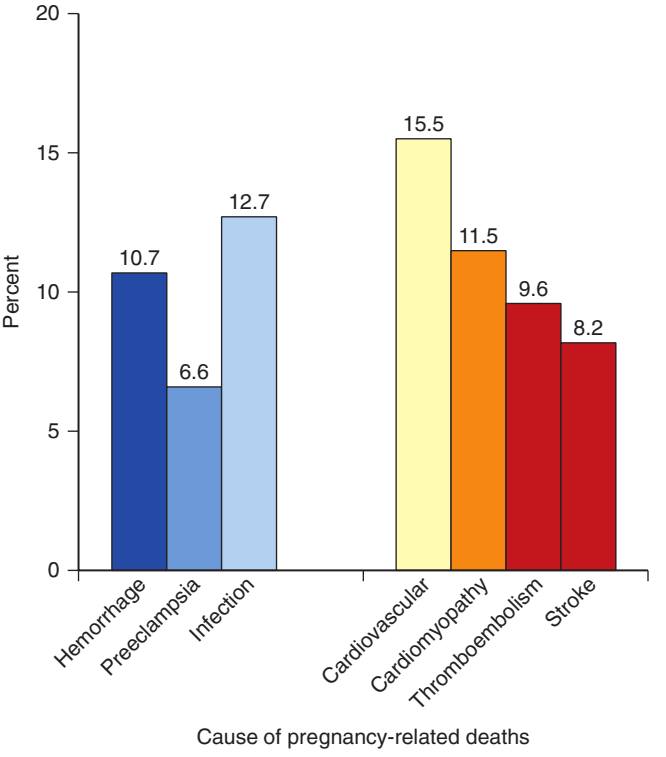

FIGURE 1-2 Some causes of and their contributions to pregnancy-related maternal deaths in the United States from 2014–2017. (Data from Centers for Disease Control and Prevention, 2020c).

Of *infant deaths*, the rate approximated 6 deaths per 1000 live births in 2018 compared with nearly 7 in 2001 (Centers for Disease Control and Prevention, 2020b). The four leading causes—congenital malformations, preterm birth, low birthweight, and maternal pregnancy complications—accounted for almost half of all infant deaths. Neonates born at the lowest gestational ages and birthweights add substantively to these mortality rates. For example, 17 percent of all infant deaths in 2018 were in those born preterm and with a low birthweight (Centers for Disease Control and Prevention, 2020d). Of particular interest are neonates with birthweights <500 g, for whom neonatal intensive care can now be offered (Chap. 45, p. 785).

Of *maternal deaths*, rates dropped precipitously in the United States during the 20th century. Pregnancy-related deaths are so uncommon as to be measured per 100,000 births. The CDC maintains data on pregnancy-related maternal deaths in its Pregnancy Mortality Surveillance System (PMSS). Its latest report described 3410 pregnancy-related deaths between 2011 and 2015 (Petersen, 2019b). Approximately 5 percent were early-pregnancy maternal deaths due to ectopic gestation or abortive outcomes. The deadly obstetrical triad of hemorrhage, preeclampsia, and infection accounted for a third of all deaths (Fig. 1-2). Thromboembolism, cardiomyopathy, and other cardiovascular disease together accounted for another third. Other significant contributors were amniotic fluid embolism (5.5 percent) and cerebrovascular accidents (8.2 percent). Anesthesia-related deaths were at an all time low—only 0.4 percent. Similar

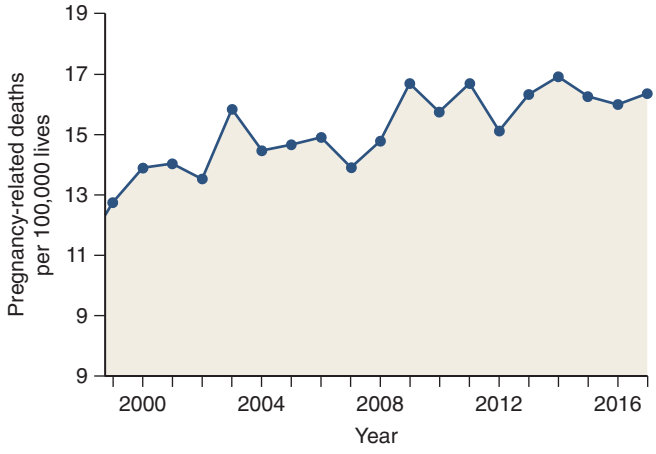

FIGURE 1-3 Trends in pregnancy-related maternal mortality in the United States from 1999–2017. (Data from Centers for Disease Control and Prevention, 2020c).

causes were reported for selected cohorts by MacDorman and associates (2017).

The pregnancy-related maternal mortality ratio was 17 deaths per 100,000 live births in 2017 (Fig. 1-3). The cause of this rise during the last 30 years may simply be that more women are dying, however, other factors explain this increase (Joseph, 2017). First, the number of pregnant women with severe chronic health conditions, which place women at higher risk, is greater (Centers for Disease Control and Prevention, 2020c). Second, the increased proportion of births to women older than 40 years contributes to higher mortality rates (Petersen, 2019b). Another is an artificial elevation caused by the International Statistical Classification of Diseases, 10th Revision (ICD-10), implemented in 1999. Additionally, improved reporting of maternal mortality contributes to the rise (MacDorman, 2016, 2017). Last, implementation of the pregnancy checkbox on the death certificate was associated with an increased identification of maternal deaths (Rossen, 2020). Thus, after accounting for the checkbox, predicted maternal mortality rates did not change significantly from 1999 through 2017.

Another consideration is the obvious disparity of higher mortality rates among black, Hispanic, and white women as shown in Figure 1-4. Racial disparities stem from health-care

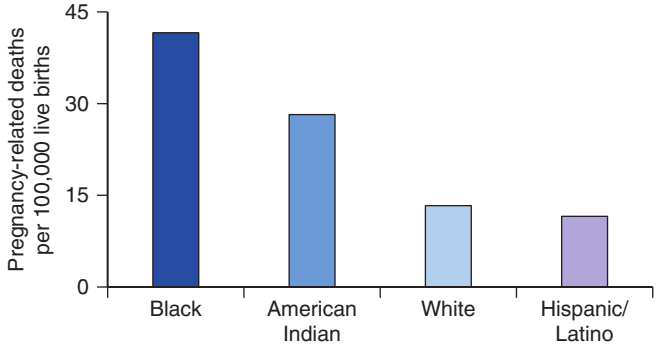

FIGURE 1-4 Pregnancy-related mortality ratio by race/ethnicity in the United States from 2014–2017. (Data from Centers for Disease Control and Prevention, 2020c).

availability, access, or use (Petersen, 2019a). The maternal mortality rate is also disparately high in rural compared with metropolitan areas (Maron, 2017).

Importantly, many maternal deaths are considered preventable. In one report, up to a third of pregnancy-related deaths in white women and up to half of those in black women were deemed preventable (Berg, 2005). One evaluation of an insured cohort reported that 28 percent of 98 maternal deaths were preventable (Clark, 2008). Thus, further efforts are imperative for obstetrics and described on page 6.

Severe Maternal Morbidity

This is defined as unintended events of labor and delivery resulting in serious short- or long-term consequences to a woman. Indicators serve as one measure to guide prevention (Table 1-2). The American College of Obstetricians and Gynecologists and the Society for Maternal-Fetal Medicine (2016) have provided lists of suggested screening topics for this purpose.

To study severe maternal morbidity (SMM), the CDC analyzed more than 50 million maternity records from 1998 to 2009 (Callaghan, 2012). They reported that 129 per 10,000 women had at least one indicator for SMM (Table 1-2). Thus, for every maternal death, approximately 200 women experience severe morbidity. As shown in Figure 1-5, SMM rates have increased during the past 15 years, and this trend is attributed to better documentation and a rise the blood transfusion rate. These numbers are greatest in smaller hospitals with <1000 deliveries annually (Hehir, 2017). Last, as with mortality rates,

TABLE 1-2. Severe Maternal Morbidity Indicators

Acute myocardial infarction
Acute renal failure
Adult respiratory distress syndrome
Amnionic fluid embolism
Cardiac arrest/ventricular fibrillation
Cardiac monitoring
Cardiac surgery
Conversion of cardiac rhythm
Disseminated intravascular coagulation
Eclampsia
Heart failure during procedure
Hysterectomy
Injuries of thorax, abdomen, and pelvis
Intracranial injuries
Puerperal cerebrovascular disorders
Pulmonary edema
Severe anesthesia complications
Sepsis
Shock
Sickle-cell crisis
Thrombotic embolism
Tracheostomy
Ventilation

Summarized from the Centers for Disease Control and Prevention, 2021.

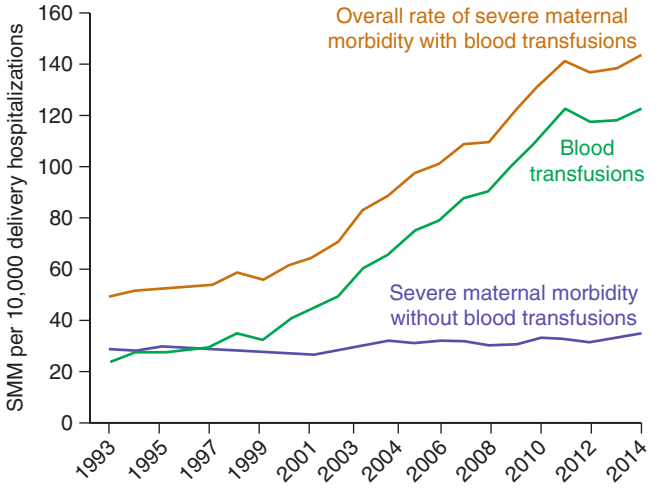

FIGURE 1-5 Rates of severe maternal morbidity (SMM) per 10,000 delivery hospitalizations. Women who received blood transfusions account for the greatest fraction of SMM. (Data from Centers for Disease Control and Prevention, 2021).

there are serious racial and ethnic disparities for SMM, and black women are disproportionately affected (Creanga, 2014).

Near Misses

Lowering medical error rates serves to diminish risks for maternal death and SMM. The terms *near misses* or *close calls* were introduced and defined as unplanned events caused by error that do not result in patient injury but have this potential (Institute for Safe Medication Practices, 2009). These are more common than injury events, but for obvious reasons, they are more difficult to identify and quantify. Systems designed to encourage reporting have been installed in various institutions and allow focused safety efforts (Clark, 2012; King, 2012; Shields, 2017). The World Health Organization (WHO) also implemented such a system. It has been validated in Brazil and accurately correlates with maternal death rates (Souza, 2012). A similar system in Britain is the *UK Obstetric Surveillance System—UKOSS* (Knight, 2005, 2008). In the United States, one is the *National Partnership for Maternal Safety* (D'Alton, 2016; Main, 2015).

TIMELY TOPICS IN OBSTETRICS

Various topics have been in the forefront since the 25th edition of this textbook. Here, we discuss several of these.

COVID-19 Pandemic

In early 2020, the severe acute respiratory syndrome (SARS)-CoV-2 virus spread rapidly around the globe, creating the greatest public health crisis since the influenza pandemic of 1918 (Chap. 67, p. 1187). As of early 2021, the disease caused by this virus and commonly known as COVID-19 is estimated to have infected more than 181 million people and caused nearly 4 million deaths (World Health Organization, 2021). Expectedly, the healthcare and political landscapes in the United States changed dramatically because of the pandemic.

Following the January 2020 declaration of a Global Health Emergency by the WHO, citywide lockdowns, state-mandated shelter-in-place orders, and public mask mandates were all implemented to help control early viral spread. Healthcare systems scrambled to acquire COVID-19 tests and personal protective equipment for staff. Wards dedicated solely to COVID-19 care opened in hospitals throughout the nation to handle substantial patient volume. Despite these measures, more than 500,000 individuals—including more than 3000 healthcare workers—died in the United States in 2020 from the infection.

Maternity wards were not spared, and traditional models of prenatal care were transformed. Namely, virtual care and drive-through prenatal care models aimed to reduce exposure risk to patients and staff (Holcomb, 2020; Turrentine, 2020). Asymptomatic or mild infections were common in pregnancy (Adhikari, 2020). Still, the effects of COVID-19 on pregnancy are not completely understood, and the effect of pregnancy on disease course is controversial. Management of severe COVID-19 infection in pregnancy requires interdisciplinary care and an understanding of pregnancy physiology and viral pathophysiology.

Preventive measures—including mRNA vaccines—have been shown to be safe and highly effective in disease prevention. However, this critical information was delayed following exclusion of pregnant individuals from initial clinical trials (Adhikari, 2021; Polack, 2020). In a report describing over 800,000 pregnancies, Chinn and colleagues (2021) found that 2.2 percent (18,715) of these women had COVID-19. When compared with women without such infections, these women had significantly increased adverse outcomes to include preterm birth, ICU admissions, intubations and mechanical ventilation, and maternal deaths. In 2021 the FDA approved COVID-19 vaccines for pregnant women.

Knowledge gained during the SARS-CoV-2 pandemic will undoubtedly shape healthcare moving forward (Cook, 2021). Indeed, a combined in-person plus audio-only virtual prenatal care model may most effectively provide services to vulnerable patients who lack internet access (Duryea, 2021).

Maternal Mortality—a Call to Arms

Almost 700 women in the United States die each year from pregnancy or its complications, and many deaths are deemed preventable. As a result, obstetricians and other stakeholders have united to address these tragedies (Chescheir, 2015). Because maternal deaths are inextricably linked to SMM indicators (see Table 1-2), several programs have been designed by national organization to avoid these events. Noted earlier, the Pregnancy Mortality Surveillance System (PMSS) collects national pregnancy-related death data to guide prevention efforts. Another, the Alliance for Innovation on Maternal Health (AIM) program, creates patient *safety bundles*, which describe evidence-based best practices for various obstetrical settings. The Joint Commission recommends that birthing centers establish protocols and implement simulation efforts (Barbieri, 2015). Moreover, national working groups target specific risks, such as thromboembolism (D'Alton, 2016).

In addition to pregnancy, the puerperium is a vulnerable period as well. One specific national effort is to establish

dedicated 1-year postpartum follow-up to ensure ongoing care. Important targets are medical disorders such as hypertension, diabetes, other cardiovascular diseases, and their consequences. To emphasize puerperal care, the concept of a "fourth trimester" has been introduced (Chap. 36, p. 634). Moreover, legislation—the MOMMA's Act—aims to expand Medicaid postpartum coverage from 60 days to 12 months (Bailey, 2021). As stated by Surgeon General Jerome Adams, "We must act now; our nation and our mothers deserve better." (Frieden, 2020).

Opioid Use Disorder

During 1999 to 2014, the national prevalence of opioid use disorder in pregnant women rose 333 percent from 1.5 to 6.5 cases per 1000 deliveries (Centers for Disease Control and Prevention, 2018). In addition to the complexities of maternal addiction, opioid use has led to an unprecedented increase in the incidence of the *neonatal opioid withdrawal syndrome* (Chap. 33, p. 605). To combat the associated adverse effects on women and their pregnancies, the American College of Obstetricians and Gynecologists (2019b) has stressed an active role by obstetricians. The College recommends universal screening by questionnaire, as well as care given to affected women by a multidisciplinary team. Therapeutic use of opioids is curtailed as best possible. Treatment of opioid use disorder with methadone or buprenorphine is challenging and discussed in Chapter 64 (p. 1150). Despite efforts, a significant decline in the prevalence of these disorders in gravidas is not in sight.

Advances in Prenatal Genetics

Several technologies help detect fetal genetic abnormalities. Since the last edition, noninvasive prenatal screening that uses cell-free DNA (cfDNA) has become commonplace in prenatal care (Zhang, 2019). Another promising technique is chromosomal microarray analysis (CMA) performed on samples of chorionic villi or amnionic fluid. These tests provide sophisticated information about gains and losses of DNA segments as small as 50 to 100 kilobases. However, although the yield with CMA is superior to that with fetal karyotyping, *most* birth defects occur in the setting of normal CMA and karyotype results.

As knowledge of the human genome has expanded, the role of specific DNA sequence abnormalities has gained attention. As an example, evaluation of fetal skeletal dysplasia may include panels of tests in which next-generation sequencing is used to identify mutations in specific genes. Whole exome sequencing (WES) analyzes all coding regions of DNA, which together account for 1.5 percent of the genome. In pregnancies with structural fetal abnormalities, and in which CMA and karyotype results are normal, WES has identified clinically significant abnormalities in approximately 10 percent of fetuses (Lord, 2019; Petrovski, 2019). In one series of fetuses with unexplained nonimmune hydrops, WES detected diagnostic genetic variants in nearly 30 percent (Sparks, 2020).

Although promising, WES technology at this time is not recommended for routine use in prenatal diagnosis (American College of Obstetricians and Gynecologists, 2020b). Limitations include high rates of genetic variants of uncertain significance, long turnaround times, and high costs. Comprehensive counseling is needed because WES may detect or suspect a finding that is unrelated but medically actionable. Genomic tests are reviewed in Chapter 16 (p. 324), and elements of counseling are discussed in Chapter 17 (p. 334).

Placenta Accreta Spectrum

Since our last edition, the cesarean delivery rate has been static and approximates 32 percent. However, rates of pregnancies complicated by placenta accreta spectrum (PAS) have grown substantially. An incidence as high as 1 case in 300 deliveries has been cited (American College of Obstetricians and Gynecologists, 2018). Sequelae of these dangerous syndromes are discussed in Chapter 43 (p. 765). To address these risks, specialized accreta surgical teams at tertiary care centers and greater antepartum transfer to these centers are both on the rise. As one prevention, national efforts have worked to avoid the *primary* cesarean delivery. However, despite these efforts, PAS will likely continue as a significant risk for SMM.

Progestogens to Prevent Preterm Birth

Progesterone derivatives to forestall preterm birth have been studied for decades. One—intramuscular 17-alpha-hydroxyprogesterone caproate (17-OHPC)—was approved by the U.S. Food and Drug Administration (FDA) under the accelerated approval process and contingent on demonstration of efficacy in a second trial. The drug is marketed as *Makena*, and subsequent, observational studies, described in Chapter 45 (p. 795), have led to questions of its efficacy (Nelson, 2021).

In 2019, results of the confirmatory trial of *Makena* efficacy—the PROLONG trial—failed to show its benefits compared with placebo for prevention of birth before 35 weeks (Blackwell, 2020). Later in 2019, an FDA Advisory Committee voted 9 to 7 to withdraw interim accelerated approval. Analyses by the committee included cross-study comparisons and subgroup analyses that did not show 17-OHPC benefits (Fig. 45-6, p. 796). In late 2020, the FDA Center for Drug Evaluation and Research (CDER) recommended drug withdrawal from the market.

Subsequently, obstetricians became polarized regarding "off label" use of the drug because it *appears safe* (Chang, 2020; Greene, 2020; Sibai, 2020). Despite findings from the PROLONG trial and the FDA's CDER, both the American College of Obstetricians and Gynecologists (2021) and the Society for Maternal-Fetal Medicine (2020) continued to endorse 17-OHPC use. This, however, is with the proviso that "uncertainty regarding benefit" be shared with the patient during decision-making. Last, the EPPPIC Group (2021) performed a metaanalysis of randomized trials evaluating progestogens for preterm birth prevention. Although not statistically significant, they concluded progestogens, which include 17-OHPC, reduced births at less than 34 weeks. The FDA's CDER (2021) continues to recommend withdrawal of 17-OHPC from the market. At this time, however, thousands of women continue to receive 17-OHPC despite its questionable efficacy.

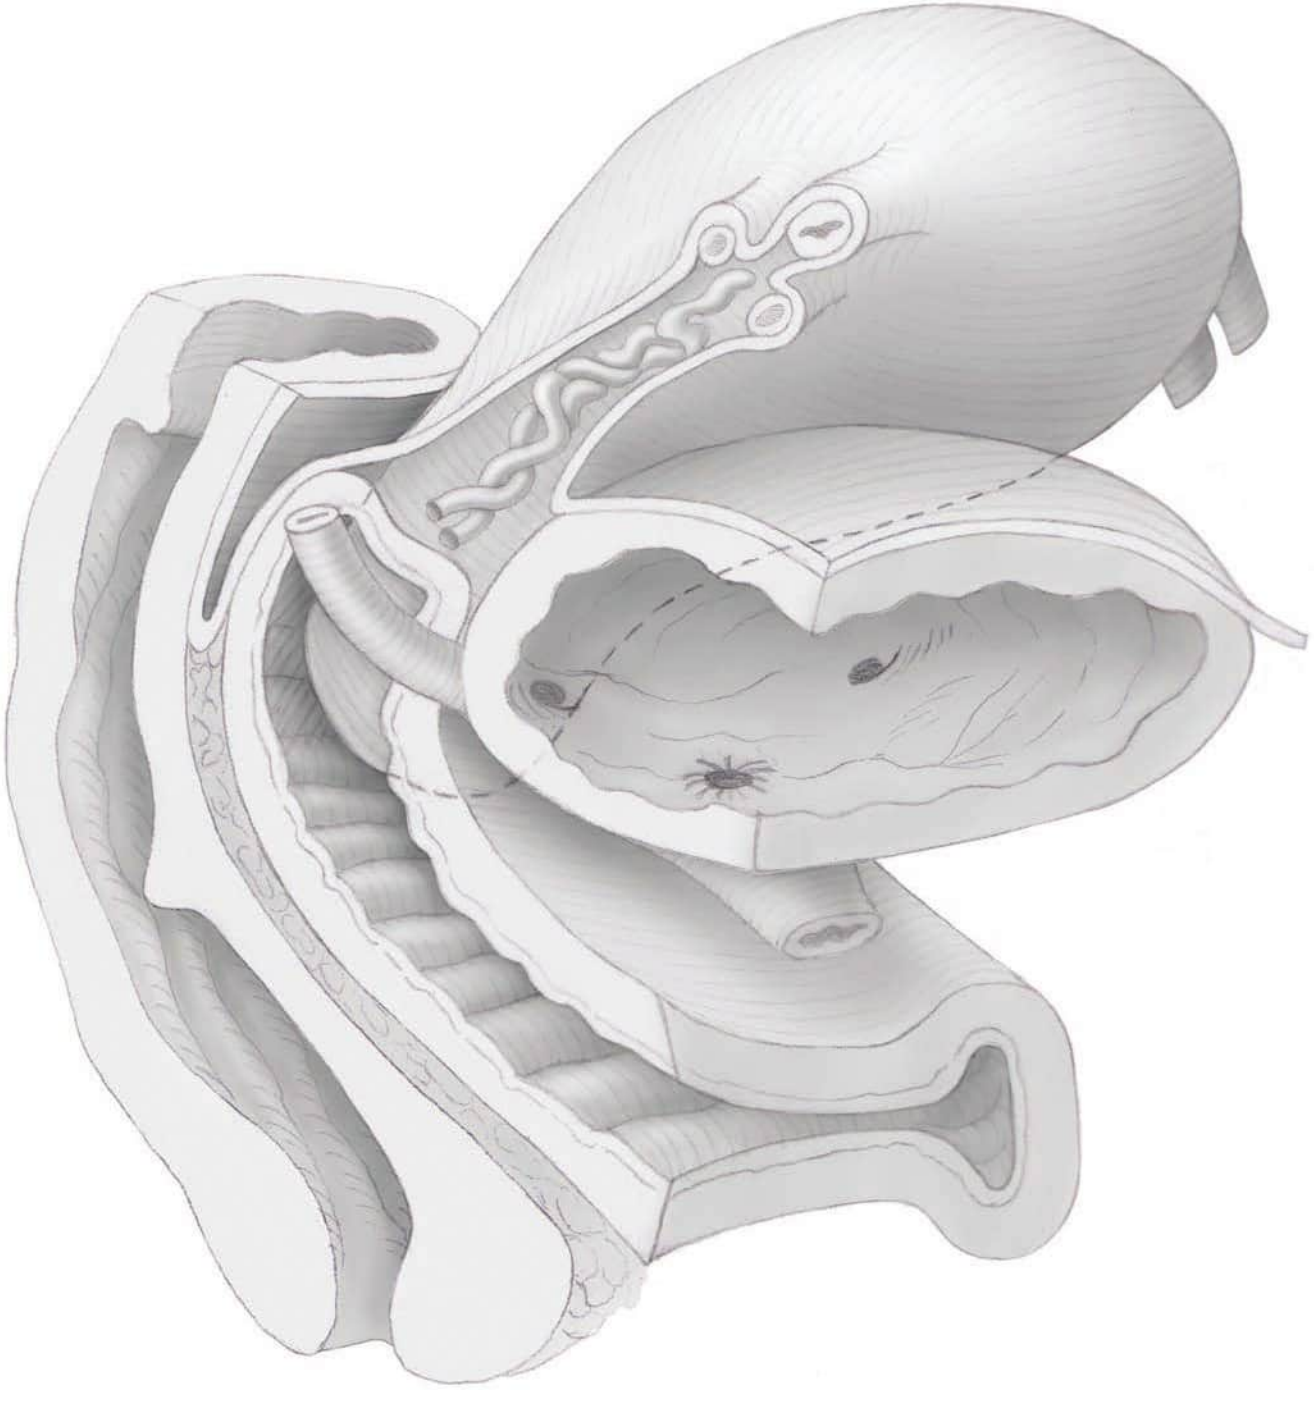
SECTION 2

MATERNAL ANATOMY AND PHYSIOLOGY



CHAPTER 2

Maternal Anatomy

ANTERIOR ABDOMINAL WALL

Skin, Subcutaneous Layer, and Fascia

The anterior abdominal wall confines abdominal viscera, stretches to accommodate the expanding uterus, and provides surgical access to the internal reproductive organs. Thus, a comprehensive knowledge of its layered structure is required to surgically enter the peritoneal cavity.

Langer lines describe the orientation of dermal fibers within the skin. In the anterior abdominal wall, they lie transversely. As a result, vertical skin incisions sustain greater lateral tension and in general develop wider scars. In contrast, low transverse incisions, such as the Pfannenstiel, follow Langer lines and lead to superior cosmetic results.

The subcutaneous layer can be separated into a superficial, predominantly fatty layer—Camper fascia—and a deeper membranous layer—Scarpa fascia. Camper fascia continues onto the perineum to provide fatty substance to the mons pubis and labia majora and then to blend with the fat of the ischioanal fossa. Scarpa fascia continues inferiorly onto the perineum as Colles fascia, (p. 18).

Beneath the subcutaneous layer, the anterior abdominal wall muscles are the midline *rectus abdominis* and *pyramidalis muscles* as well as the *external oblique*, *internal oblique*, and *transversus abdominis muscles*, which extend across the entire wall (Fig. 2-1). The fibrous aponeuroses of these three latter muscles form the primary fascia of the anterior abdominal wall. These fuse in the midline at the linea alba, which normally sonographically measures ≤15 mm wide below the umbilicus in nongravid women (Beer, 2009; Mota, 2018). An abnormally wide separation may reflect diastasis recti or ventral hernia.

These three aponeuroses also invest the rectus abdominis muscle as the rectus sheath. The construction of this sheath varies above and below a boundary, termed the arcuate line (see Fig. 2-1). Cephalad to this border, the aponeuroses invest the rectus abdominis bellies on both dorsal and ventral surfaces. Caudal to this line, all aponeuroses lie ventral or superficial to the rectus abdominis muscle, and only the thin transversalis fascia and peritoneum lie deep to the rectus (Loukas, 2008). This transition of rectus sheath composition can be seen best in the upper third of a midline vertical abdominal incision.

The paired small triangular pyramidalis muscles originate from the pubic crest and insert into the linea alba. These muscles lie atop the rectus abdominis muscle but beneath the anterior rectus sheath.

The umbilicus is covered by peritoneum, transversalis fascia, and skin and contains the umbilical ring. The ring is a defect in the linea alba through which the fetal umbilical vessels previously passed. The round ligament of the liver and the median umbilical and medial umbilical ligaments variably attach to the ring.

Transversalis Fascia and Peritoneum

Transversalis fascia is the thin fibrous tissue layer between the inner surface of the transversus abdominis muscle and the

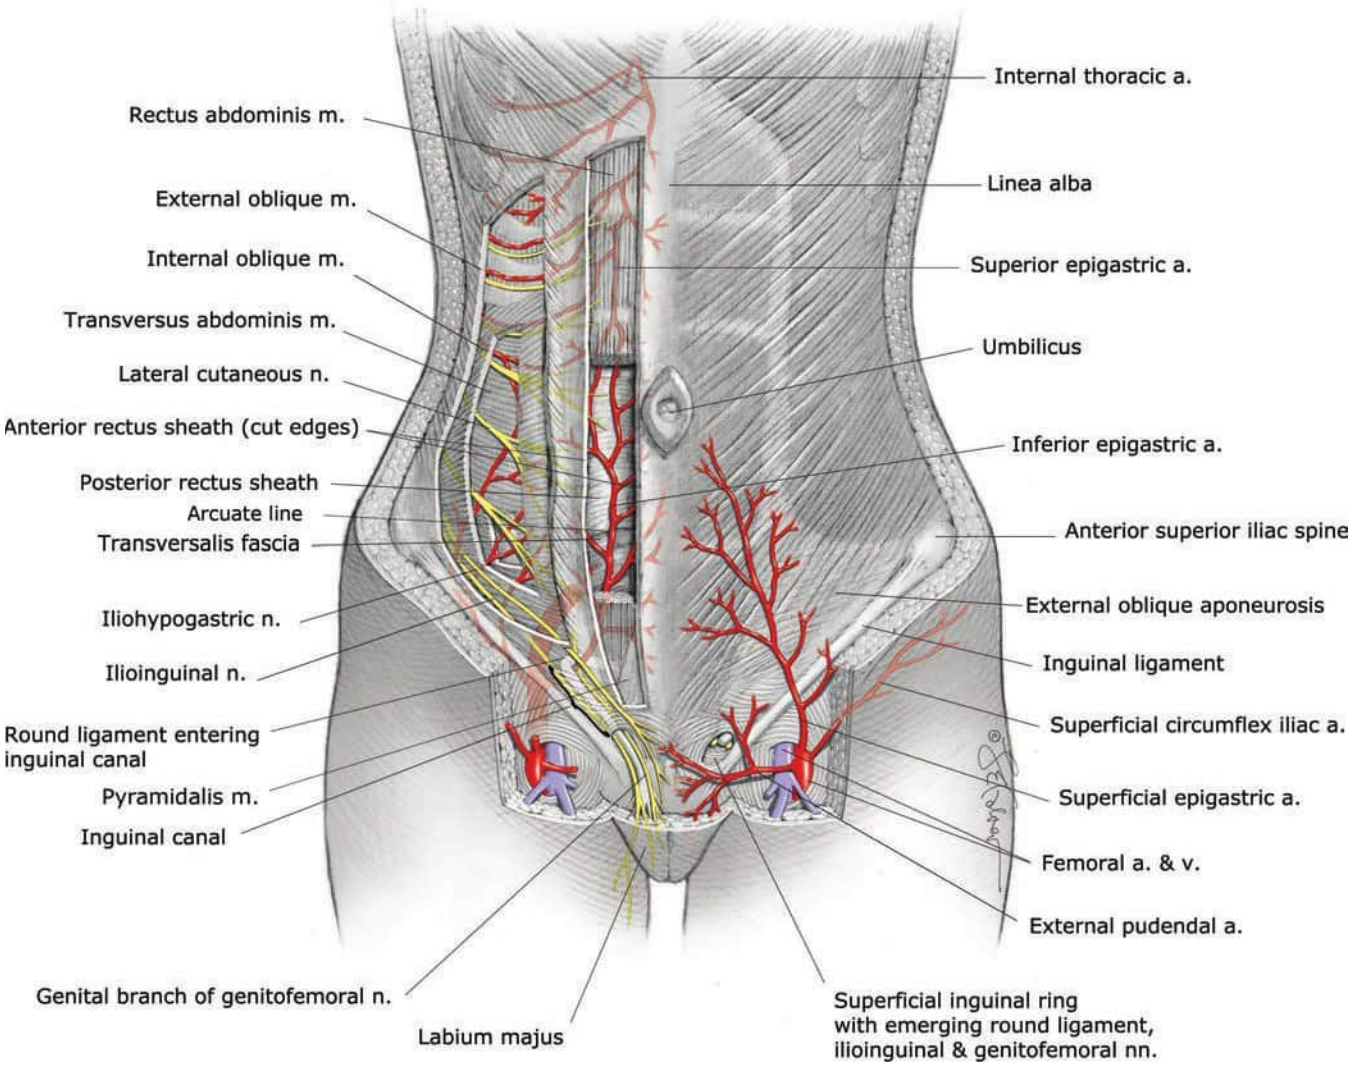


FIGURE 2-1 Anterior abdominal wall anatomy. (Modified with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Halvorson LM, et al (eds): Williams Gynecology, 4th ed. New York, NY: McGraw Hill; 2020.)

preperitoneal fat. Inferiorly, the transversalis fascia blends with the periosteum of the pubic bones.

The peritoneum contains a single layer of epithelial cells and a supporting connective tissue. The visceral peritoneum densely wraps around the abdominopelvic viscera, whereas the parietal peritoneum lines the inner surface of the abdominal walls. In the anterior abdominal wall, five elevations of parietal peritoneum converge toward the umbilicus and are known as umbilical ligaments.

The single *median umbilical ligament* is formed by the urachus, a fibrous fetal remnant that extends from the bladder apex to the umbilicus. Clinically, this ligament may be seen at laparotomy during peritoneal incision as a white, midline, fibrous cord. The paired *medial umbilical ligaments* are formed by the obliterated fetal umbilical arteries. The paired *lateral umbilical ligaments* contain the patent inferior epigastric vessels (see Fig. 2-1).

■ Blood Supply and Lymphatics

The *superficial epigastric*, *superficial circumflex iliac*, and *superficial external pudendal arteries* arise from the femoral artery just below the inguinal ligament within the femoral triangle (see Fig. 2-1). These vessels supply the skin and subcutaneous layers of the anterior abdominal wall and mons pubis. The superficial epigastric vessels are surgically important and course diagonally from their origin toward the umbilicus. With a low transverse skin incision, these vessels can usually be identified at a depth halfway between the skin and the anterior rectus sheath. They lie above the Scarpa fascia and several centimeters from the midline. Ideally, these vessels are identified and surgically occluded. Lymphatics run cephalad–caudad on the lower abdomen (Tourani, 2015). Most channels lie in the dermis, and a smaller density is found between the Camper and Scarpa fascias (Friedman, 2015).

More deeply, the bilateral *inferior epigastric artery* and vein are respective branches of the external iliac vessels and supply anterior abdominal wall muscles, nerves, and fascia. Of surgical relevance, the inferior epigastric vessels initially course lateral to and then posterior to the rectus abdominis muscles, which they supply. A deep system of lymphatics follows these arteries (Tourani, 2015).

Clinically, when a Maylard incision is used for cesarean delivery, the inferior epigastric vessels may be lacerated during muscle transection. Preventively, identification and surgical

occlusion are preferable. These vessels rarely may rupture spontaneously or traumatically during pregnancy to create a rectus sheath hematoma (Eckhoff, 2016; Gibbs, 2016).

On each side of the lower anterior abdominal wall, the Hesselbach triangle is the region bounded laterally by the inferior epigastric vessels, inferiorly by the inguinal ligament, and medially by the lateral border of the rectus abdominis muscle. Hernias that protrude through the abdominal wall in the boundaries of the Hesselbach triangle are termed direct inguinal hernias. In contrast, indirect inguinal hernias bulge through the deep inguinal ring, which lies lateral to this triangle, and enter the inguinal canal. Here, contents may exit out the superficial inguinal ring.

Innervation

The entire anterior abdominal wall is innervated by intercostal nerves ($T_{7–11}$), the subcostal nerve (T_{12}), and the iliohypogastric and the ilioinguinal nerves (L_1). The intercostal and subcostal nerves are anterior rami of the thoracic spinal nerves and run along the lateral and then anterior abdominal wall between the transversus abdominis and internal oblique muscles (Fig. 2-2). This space, termed the transversus abdominis plane, can be used for postcesarean analgesia blockade (Chap. 25, p. 480) (Ng, 2018).

Near the rectus abdominis lateral borders, anterior branches of the intercostal and subcostal nerves travel superficially to pierce the posterior sheath, rectus muscle, and then anterior sheath to reach the skin. Thus, these nerve branches may be severed during a Pfannenstiel incision creation during the step in which the overlying anterior rectus sheath is separated from the rectus abdominis muscle (Chap. 30, p. 552).

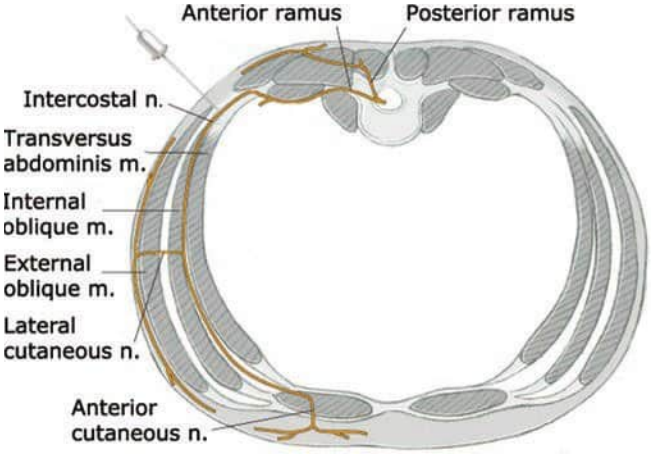

FIGURE 2-2 Intercostal and subcostal nerves are the anterior rami of spinal nerves. In this figure, an intercostal nerve extends ventrally between the transversus abdominis and internal oblique muscles. During this path, the nerve gives rise to lateral and anterior cutaneous branches, which innervate the anterior abdominal wall. As shown by the inserted needle, the transversus abdominis plane (TAP) block takes advantage of this anatomy. (Modified with permission from Hawkins JL: Anesthesia for the pregnant woman. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al: Cunningham and Gilstraps's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

The iliohypogastric and ilioinguinal nerves originate from the anterior ramus of the first lumbar spinal nerve. They emerge lateral to the psoas major muscle and travel across the quadratus lumborum in the retroperitoneum and toward the iliac crest. Near this crest, both nerves pierce the transversus abdominis muscle and course ventromedially. At a site 2 to 3 cm medial to the anterior superior iliac spine, the nerves then pierce the internal oblique muscle and course superficial to it toward the midline (Whiteside, 2003). The iliohypogastric nerve perforates the external oblique aponeurosis near the lateral rectus border to provide sensation to the suprapubic skin (see Fig. 2-1). The ilioinguinal nerve in its course medially travels through the inguinal canal and exits through the superficial inguinal ring, which forms by splitting of external abdominal oblique aponeurosis fibers. This nerve supplies the skin of the mons pubis, upper labia majora, and medial upper thighs.

The ilioinguinal and iliohypogastric nerves can be severed during a low transverse incision or entrapped during closure, especially if incisions extend beyond the lateral borders of the rectus abdominis muscle (Rahn, 2010). These nerves carry sensory information only, and injury leads to loss of sensation within the areas supplied. Rarely, chronic pain may develop (Verhagen, 2018).

The T_{10} dermatome approximates the level of the umbilicus. Analgesia to this level is suitable for labor and vaginal birth. Regional analgesia for cesarean delivery or for puerperal sterilization ideally extends to T_4.

PERINEUM

This diamond-shaped area has boundaries that mirror those of the bony pelvic outlet (p. 28). These are the pubic symphysis anteriorly, ischiopubic rami and ischial tuberosities anterolaterally, sacrotuberous ligaments posterolaterally, and coccyx posteriorly. An arbitrary line joining the ischial tuberosities divides the perineum into an anterior triangle, also called the urogenital triangle, and a posterior triangle, termed the anal triangle (Fig. 2-3).

Vulva

Mons Pubis, Labia, and Clitoris

The vulva includes all structures visible externally in the urogenital triangle. These are the mons pubis, labia majora, labia minora, clitoris, hymen, vestibule, urethral opening, greater vestibular (Bartholin) glands, minor vestibular glands, and paraurethral glands (see Fig. 2-3). The vulva receives innervations and vascular support from the pudendal nerve (p. 22).

The mons pubis is a fat-filled cushion overlying the symphysis pubis. After puberty, the mons pubis skin is covered by hair that forms the triangular escutcheon, whose base aligns with the upper margin of the symphysis pubis. In men and some hirsute women, the escutcheon extends farther onto the anterior abdominal wall toward the umbilicus and thus is diamond shaped.

Labia majora usually are 7 to 8 cm long, 2 to 3 cm wide, and 1 to 1.5 cm thick. They are continuous directly with the

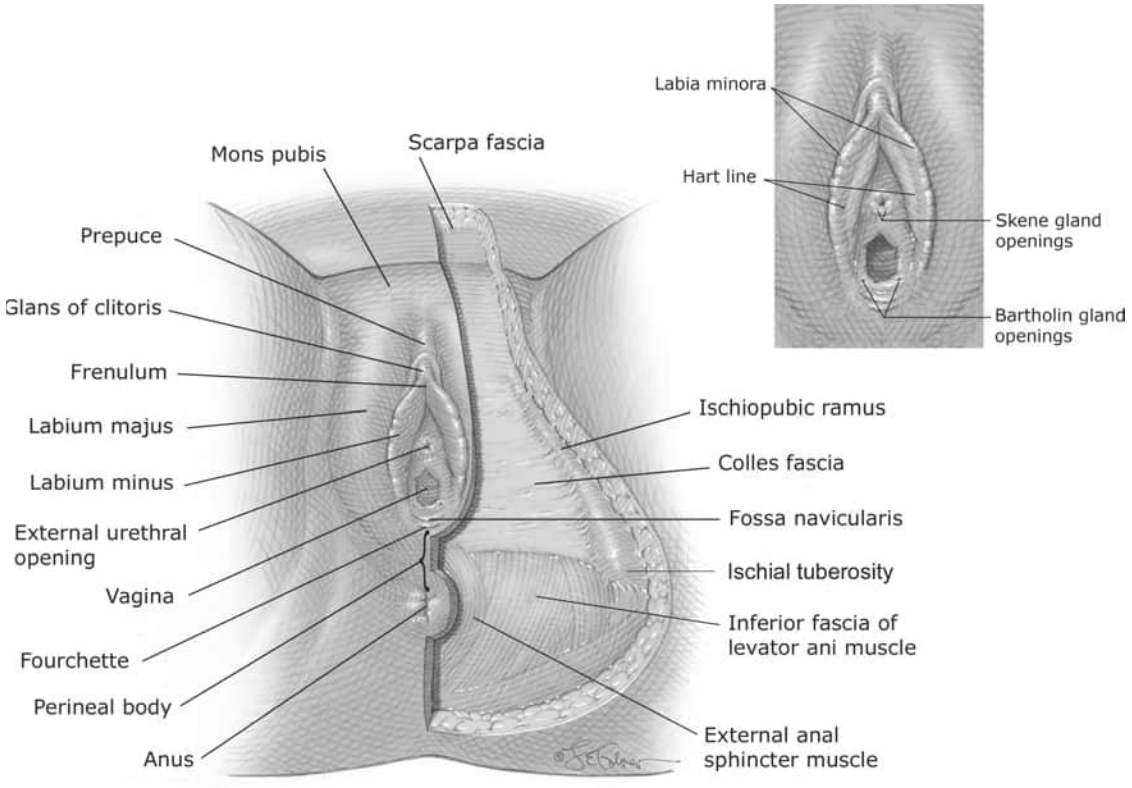

FIGURE 2-3 Vulvar structures and subcutaneous layer of urogenital triangle. **Inset:** Vestibule boundaries and openings onto the vestibule. (Modified with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Halvorson LM, et al (eds): Williams Gynecology, 4th ed. New York, NY: McGraw Hill; 2020.)

mons pubis superiorly, and the round ligaments terminate at their upper borders. Hair covers the labia majora, and apocrine, eccrine, and sebaceous glands are abundant. Beneath the skin, a dense connective tissue layer is nearly void of muscular elements but is rich in elastic fibers and fat. This fat mass provides bulk to the labia majora and is supplied with a rich venous plexus. During pregnancy, this plexus may develop varicosities from pressure created by the growing uterus.

Each labium minus is a thin tissue fold that lies medial to each labium majus. The labia minora begin at the fourchette and extend superiorly, where each divides into two lamellae. From each side, the lower lamellae fuse to form the frenulum of the clitoris, and the upper lamellae merge to form the prepuce (see Fig. 2-3). The labia minora dimensions vary greatly among reproductive-aged women (Cao, 2015; Lykkebo, 2017). In one large study, the mean length was 4 cm (range 0.5 to 10 cm) and mean lateral span was 1.5 (range 0.1 to 6 cm) (Kreklau, 2018).

Structurally, the labia minora are composed of connective tissue with many small vessels, elastin fibers, but very little smooth muscle. Nerve fibers are numerous (Ginger, 2011a; Schober, 2015). The epithelia of the labia minora differ by location. Thinly keratinized stratified squamous epithelium covers the outer surface of each labium. On their inner surface, the lateral portion is covered by this same epithelium up to a demarcating line, termed the Hart line. Medial to this line, each labium is covered by squamous epithelium that is nonkeratinized. Labia minora lack hair follicles, eccrine glands, and apocrine glands but have many sebaceous glands (Wilkinson, 2011).

The clitoris is the principal female erogenous organ (Fig. 2-4). It is located beneath the prepuce, above the frenulum and urethra, and projects downward toward the vaginal opening. The clitoris rarely exceeds 2 cm in length and is composed of a glans, a corpus or body, and two crura. The glans is usually less than 0.5 cm in diameter and is covered by stratified squamous epithelium. Nerve bundles are prominent and correspond to the paired dorsal nerves of the clitoris (Jackson, 2019). The clitoral body contains two corpora cavernosa. Extending from the clitoral body, each corpus cavernosum diverges laterally to form a long, narrow crus. Each crus lies along the inferior surface of its respective ischiopubic ramus and deep to the ischiocavernosus muscle. The clitoral blood supply stems from branches of the internal pudendal artery. Specifically, the *deep artery of the clitoris* supplies the clitoral body, whereas the *dorsal artery of the clitoris* supplies the glans and prepuce.

Vestibule

In adult women, the vestibule is an almond-shaped area that is enclosed by the Hart line laterally, the hymen medially, the clitoral frenulum anteriorly, and the fourchette posteriorly (see Fig. 2-3). The vestibule is usually perforated by six openings: the urethra, the vagina, two greater vestibular (Bartholin) gland ducts, and ducts of the two largest paraurethral glands—the Skene glands. The posterior portion of the vestibule between the fourchette and the vaginal opening is called the vestibular fossa (Hill, 2021). It is usually observed only in nulliparas.

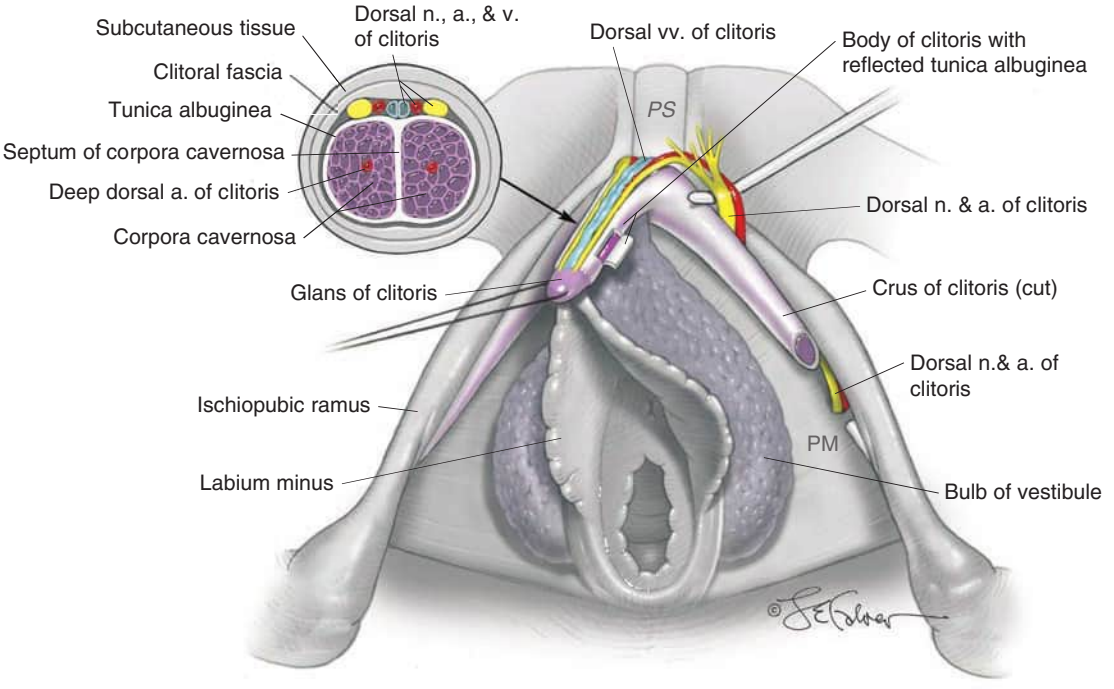

FIGURE 2-4 Clitoris and associated vulvar structures in superficial space of urogenital triangle. Inset: cross section through proximal body of clitoris. PM = perineal membrane; PS = pubic symphysis. (Modified with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Halvorson LM, et al (eds): Williams Gynecology, 4th ed. New York, NY: McGraw Hill; 2020.)

The bilateral Bartholin glands are 0.5 to 1 cm in diameter. On their respective side, each lies inferior to the vestibular bulb (bulb of vestibule) and deep to the inferior end of the bulbospongiosus muscle (former bulbocavernosus muscle). A duct extends medially from each gland, measures 1.5 to 2 cm long, and opens distal to the hymeneal ring. One duct opens at 5 and the other at 7 o'clock on the vestibule. Following trauma or infection, either duct may swell and obstruct to form a cyst or, if infected, an abscess. In contrast, the minor vestibular glands are shallow glands lined by simple mucin-secreting epithelium and open along the Hart line.

The paraurethral glands are a collective arborization of glands whose numerous small ducts open into the urethra and predominantly along its entire inferior aspect (Costa, 2016; Huffman, 1948). The two largest are called Skene glands, and their ducts typically lie distally and near the urethral meatus. Clinically, inflammation and duct obstruction of any of the paraurethral glands can lead to urethral diverticulum formation (Chap 56, p. 1007). The urethral opening or meatus is in the midline of the vestibule, 1 to 1.5 cm below the pubic arch, and a short distance above the vaginal opening.

■ Vagina and Hymen

In adult women, the hymen is a thin membrane that surrounds all or much of the vaginal opening in an annular or crescent form. Mainly elastic fibers, collagen, and fine vessels compose the hymen. Nerve fibers are few and localize to its base. Both outer and inner hymeneal surfaces are covered by nonkeratinized stratified squamous epithelium (Mahran, 1964). The aperture of the intact hymen ranges in diameter from pinpoint to one that admits one or even two fingertips. As a rule, the hymen is torn at several sites during first coitus. However, identical tears may form by other penetration, for example, by tampons used during menstruation. The torn edges soon reepithelialize.

Proximal to the hymen, the vagina is a muscular tube that extends to the uterus and is interposed lengthwise between the bladder and the rectum (Fig. 2-5). Total vaginal length is 9 to 10 cm (Collins, 2017; Patnam, 2019). Anteriorly, the vagina is separated from the bladder and urethra by connective tissue—the vesicovaginal septum. Posteriorly, between the lower portion of the vagina and the rectum, similar tissues together form the rectovaginal septum. The upper fourth of the vagina is separated from the rectum by the rectouterine pouch, also called the cul-de-sac or pouch of Douglas (Balgobin, 2020).

Normally, the anterior and posterior walls of the vaginal lumen lie in contact. The vaginal apex is subdivided by the cervix into anterior, posterior, and two lateral fornices. Clinically, the internal pelvic organs usually can be palpated through the thin walls of these fornices.

The vaginal lining is composed of nonkeratinized stratified squamous epithelium and underlying lamina propria. In premenopausal women, this lining is thrown into numerous thin transverse ridges, known as rugae. Deep to this, a muscular layer contains smooth muscle, collagen, and elastin. Beneath this, an adventitial layer consists of collagen and elastin (Maldonado, 2020; Mazloomdoost, 2017). No true fascia separates the vagina from the bladder or from the rectum.

The vagina lacks glands. Instead, it is lubricated by a transudate that originates from the vaginal subepithelial capillary

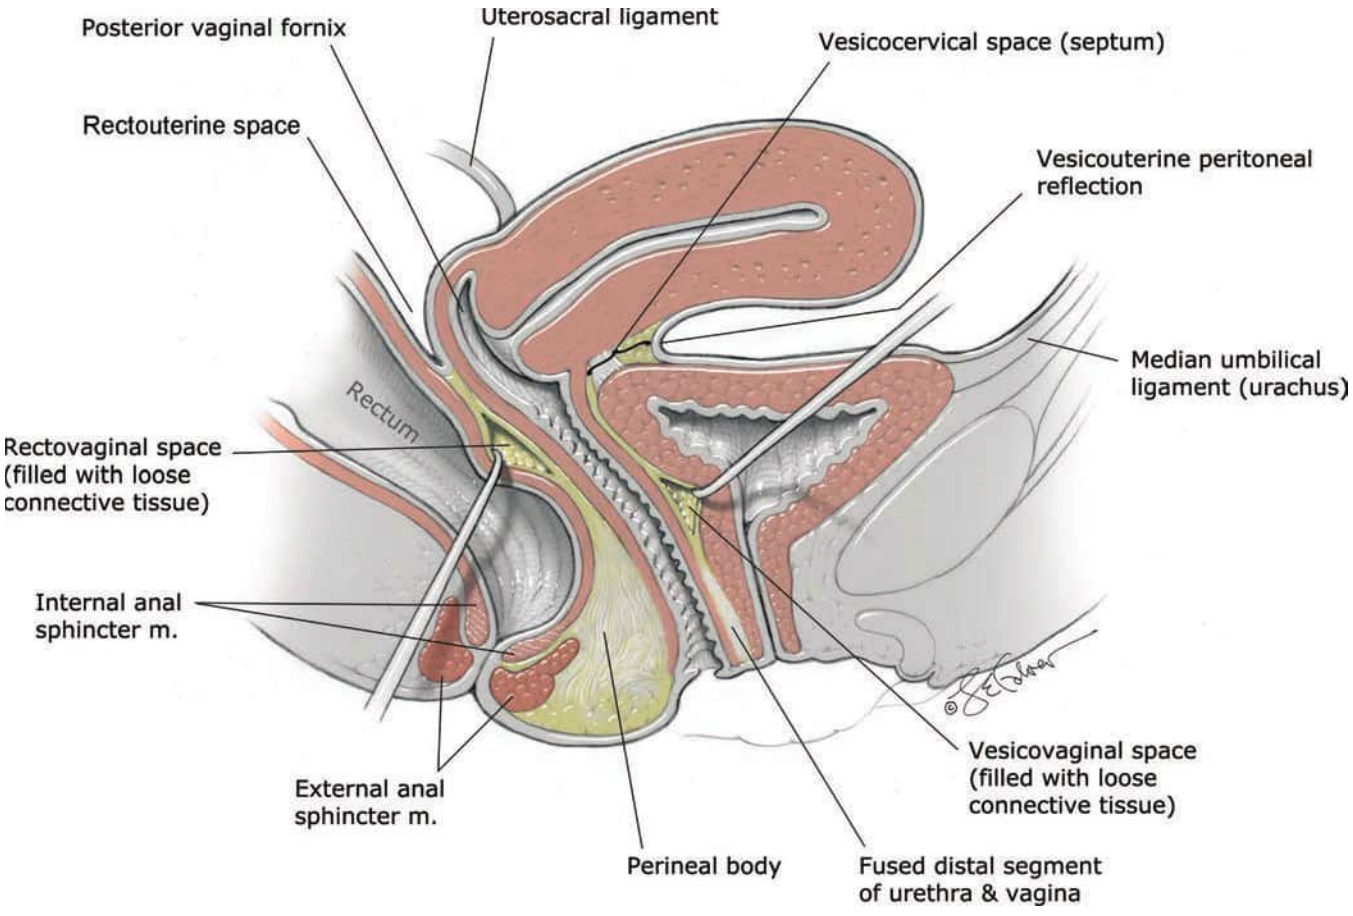

FIGURE 2-5 Vagina and surrounding anatomy. (Modified with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Halvorson LM, et al (eds): Williams Gynecology, 4th ed. New York, NY: McGraw Hill; 2020.)

plexus and crosses the permeable epithelium (Kim, 2011). Due to increased vascularity during pregnancy, vaginal secretions are notably increased. At times, this may be confused with amniotic fluid leakage, and clinical differentiation of these two is described in Chapter 22 (p. 426).

After birth-related epithelial trauma and healing, fragments of stratified epithelium occasionally are embedded beneath the vaginal surface. Similar to its native tissue, this buried epithelium continues to shed degenerated cells. As a result, epidermal inclusion cysts, which are filled with debris, may commonly form.

The vagina has an abundant vascular supply. The proximal portion is supplied by the cervical branch of the uterine artery and by the vaginal artery. The latter may variably arise from the uterine or inferior vesical artery or directly from the internal iliac artery. The middle rectal artery contributes supply to the posterior vaginal wall, whereas the distal walls receive contributions from the internal pudendal artery. At each level, vessels supplying each side of the vagina course medially across the anterior or posterior vaginal wall and form midline anastomoses.

An extensive venous plexus also surrounds the vagina and follows the course of the arteries. Lymphatics from the lower third, along with those of the vulva, drain primarily into the inguinal lymph nodes. Those from the remainder drain into the pelvic lymph nodes.

Perineal Body

This fibromuscular pyramidal mass lies in the midline at the junction between the urogenital and anal triangles (Figs. 2-3 and 2-5) (Oh, 1973; Soga, 2007). Clinically, it measures 3.5 to 5 cm in nulliparas from the posterior midline hymen to the mid-anal opening, which are standard pelvic organ prolapse-quantification (POP-Q) landmarks (Komorowski, 2014; Reimers, 2016). It lengthens slightly during pregnancy, and during second-stage labor, one study showed that it stretches >65 percent (Meriwether, 2016). It serves as the junction for several structures and provides significant perineal support (Shafik, 2007). Superficially, the bulbospongiosus, superficial transverse perineal, and external anal sphincter muscles converge on the perineal body. More deeply, the perineal membrane, portions of the pubococcygeus muscle, and internal anal sphincter contribute (Larson, 2010).

The perineal body is incised during episiotomy incision and is torn with second-, third-, and fourth-degree lacerations. Data conflict as to whether a shorter perineal body length predisposes to higher-order lacerations (Deering, 2004; Dua, 2009; Hokenstad, 2015; Meriwether, 2016).

Urogenital Triangle

Superficial Space

The urogenital triangle is bounded by the pubic rami superiorly, the ischial tuberosities laterally, and the superficial

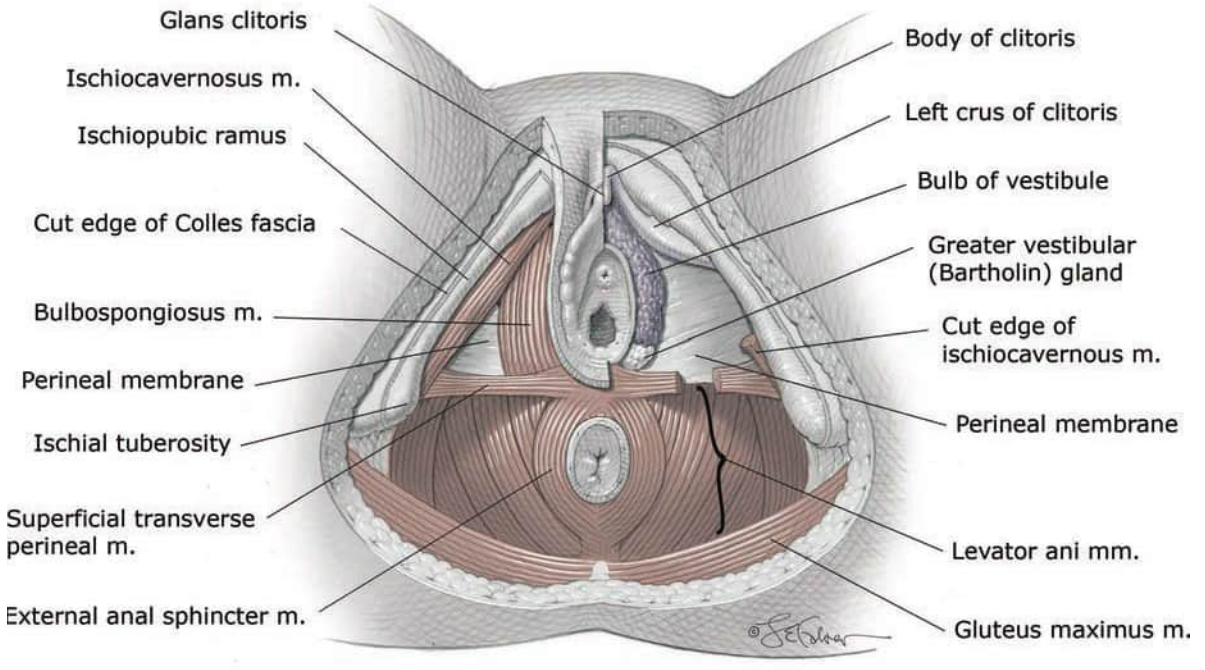

FIGURE 2-6 Superficial space of the urogenital triangle and anal triangle. Structures on the left side of the image can be seen after removal of Colles fascia. Those on the right side are noted after removal of the superficial muscles of the urogenital triangle. (Modified with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Halvorson LM, et al (eds): Williams Gynecology, 4th ed. New York, NY: McGraw Hill; 2020.)

transverse perineal muscles posteriorly (Fig. 2-6). It is divided into superficial and deep spaces by the perineal membrane. This membranous partition is a dense fibrous sheet that was previously known as the inferior fascia of the urogenital diaphragm. The perineal membrane attaches laterally to the ischiopubic rami, medially to the distal third of the urethra and vagina, posteriorly to the perineal body, and anteriorly to the arcuate ligament of the pubis (Stein, 2008). It lies at the depth of the hymeneal ring.

The superficial space has the perineal membrane as its deep wall and the Colles fascia as its superficial one. As noted earlier, the Colles fascia is the continuation of the Scarpa fascia onto the perineum. On the perineum, the Colles fascia securely attaches laterally to the pubic rami and fascia lata of the thigh, inferiorly to the superficial transverse perineal muscle and inferior border of the perineal membrane, and medially to the urethra, clitoris, and vagina. As such, the superficial space of the urogenital triangle is a relatively closed compartment.

This superficial space contains several important structures, which include the Bartholin glands, vestibular bulbs, clitoral body and crura, branches of the pudendal vessels and nerve, and the ischiocavernosus, bulbospongiosus, and superficial transverse perineal muscles. Of this muscular trio, the ischiocavernosus muscles each attach on their respective side to the medial aspect of the ischial tuberosity inferiorly and the ischiopubic ramus laterally. Anteriorly, each attaches to a clitoral crus and may help maintain clitoral erection by compressing the crus to obstruct venous drainage. Each bulbospongiosus muscle overlies a vestibular bulb and Bartholin gland. Anteriorly, they attach to the body of the clitoris and posteriorly, to the perineal body. Some more-recent anatomical studies instead describe that the bulbospongiosus muscles blend medially with the external anal sphincter (Baramee, 2020; Plochocki, 2016). The muscles constrict the vaginal lumen and aid release of Bartholin gland secretions. They also may contribute to clitoral erection by compressing the deep dorsal vein of the clitoris. The bulbospongiosus and ischiocavernosus muscles also pull the clitoris downward. Last, the superficial transverse perineal muscles are narrow strips that attach to the ischial tuberosities laterally and the perineal body medially.

Each vestibular bulb, also called bulb of vestibule, is an almond-shaped aggregation of veins that lie beneath the bulbospongiosus muscle on either side of the vestibule (Jeppson, 2018). They measure 5 cm long and 2 cm wide (Jackson, 2019). The bulbs terminate inferiorly at approximately the middle of the vaginal opening and extend upward toward the clitoris. Their anterior extensions merge in the midline, below the clitoral body. During childbirth, veins in the vestibular bulb may be lacerated or may rupture to create a hematoma enclosed within the superficial space of the urogenital triangle.

Deep Space

This space lies above or deep to the perineal membrane and below the inferior investing fascia of the levator ani muscle. It contains portions of urethra and vagina, certain portions of internal pudendal artery branches, and muscles of the striated urogenital sphincter complex (Fig. 2-7).

Urethra. The female urethra measures 3 to 4 cm and originates within the bladder trigone (p. 27) (Hamner, 2018; Rahn, 2007). The distal two thirds of the urethra are fused with the

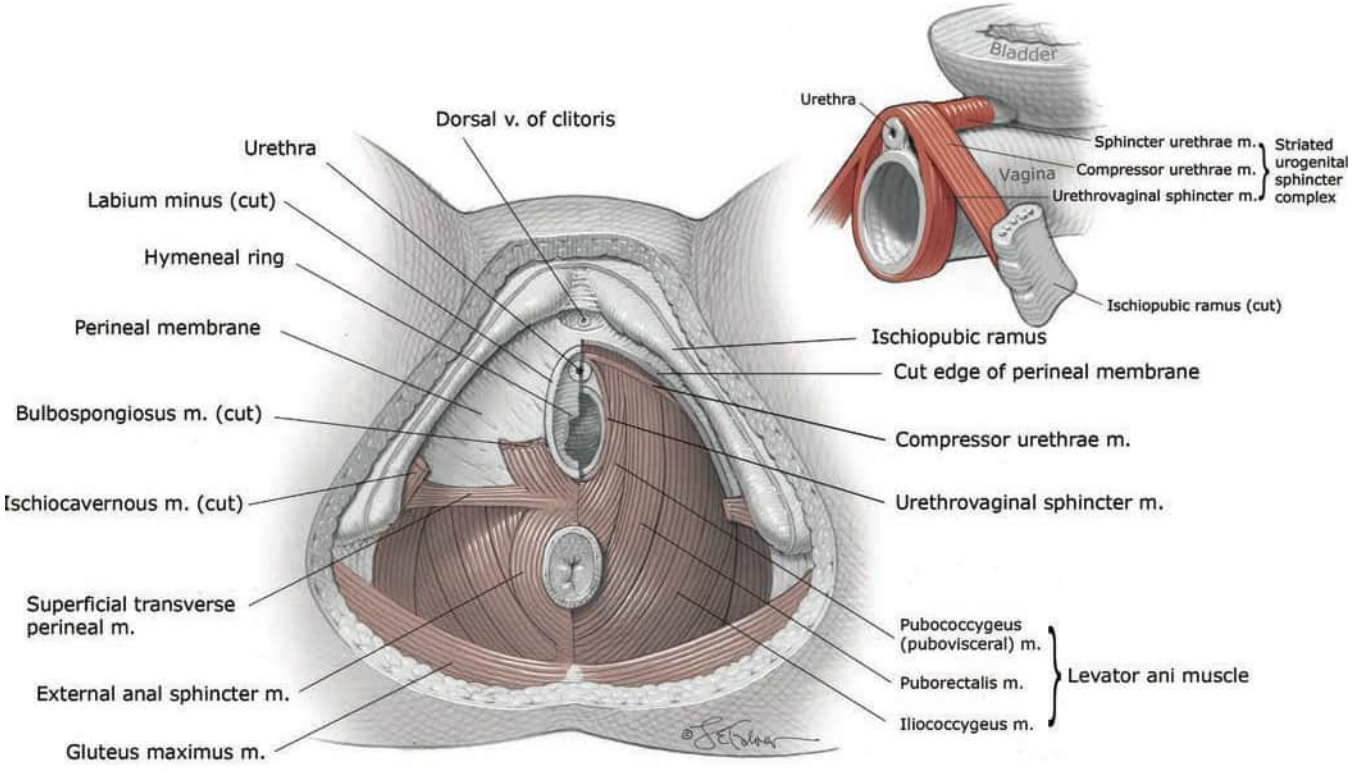

FIGURE 2-7 Deep space of urogenital triangle. Structures on the right side of the image can be seen after removal of the perineal membrane. Also shown are structures that attach to the perineal body: bulbospongiosus, superficial transverse perineal, external anal sphincter, and puboperinealis muscles as well as perineal membrane. (Modified with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Halvorson LM, et al (eds): Williams Gynecology, 4th ed. New York, NY: McGraw Hill; 2020.)

anterior vaginal wall. The epithelial lining of the urethra is transitional epithelium at the urethrovesical junction. It then changes to a pseudostratified columnar along its proximal length but is a nonkeratinized stratified squamous epithelium distally (Carlile, 1987).

The walls of the urethra consist of two layers of smooth muscle, an inner longitudinal and an outer circular. This is in turn surrounded by a circular layer of skeletal muscle referred to as the sphincter urethrae (see Fig. 2-7). Approximately at the junction of the middle and lower third of the urethra and within the deep perineal space, two straplike skeletal muscles called the sphincter urethrovaginalis and the compressor urethrae are found. Together with the sphincter urethrae, these constitute the external urethral sphincter (EUS), also called the striated urogenital sphincter complex (Mistry, 2020). The EUS supplies constant tonus and provides emergency reflex contraction to sustain continence.

Distal to the level of the perineal membrane, the walls of the urethra consist of fibrous tissue, serving to direct the urine stream. Here, the urethra has a prominent submucosal layer that is lined by hormonally sensitive stratified squamous epithelium. Within the submucosal layer on the dorsal (vaginal) surface of the urethra lie most paraurethral glands (p. 16).

The urethra receives its blood supply from branches of the inferior vesical, vaginal, or internal pudendal arteries. The pudendal nerve provides somatic innervation to the EUS. The urethra's smooth muscle receives sympathetic and parasympathetic innervation from the inferior hypogastric plexus (p. 26) (Colleselli, 1998).

■ Pelvic Diaphragm

The pelvic diaphragm spans the pelvic outlet and lies deep to the urogenital and anal triangles (p. 17). This broad muscular floor provides substantial support to the pelvic viscera and is composed of the coccygeus and levator ani muscles (see Fig. 2-7). The levator ani muscle, in turn, contains the pubococcygeus, puborectalis, and iliococcygeus muscles. The pubococcygeus muscle is also termed the pubovisceral muscle and is subdivided based on points of insertion and function. These include the pubovaginalis, puboperinealis, and puboanalis muscles, which insert into the vagina, perineal body, and anus, respectively (Kearney, 2004).

Vaginal birth can damage the levator ani muscle or its innervation (DeLancey, 2003; Weidner, 2006). Evidence suggests that levator ani trauma may predispose women to later pelvic organ prolapse (Berger, 2018; Dietz, 2008). Current research efforts aim to minimize these injuries.

■ Anal Triangle

This triangle contains the anal canal, anal sphincter complex, and ischioanal fossae. The sphincter complex consists of the internal anal sphincter, external anal sphincter, and puborectalis muscle. The anal triangle also contains branches of the pudendal nerve and internal pudendal vessels.

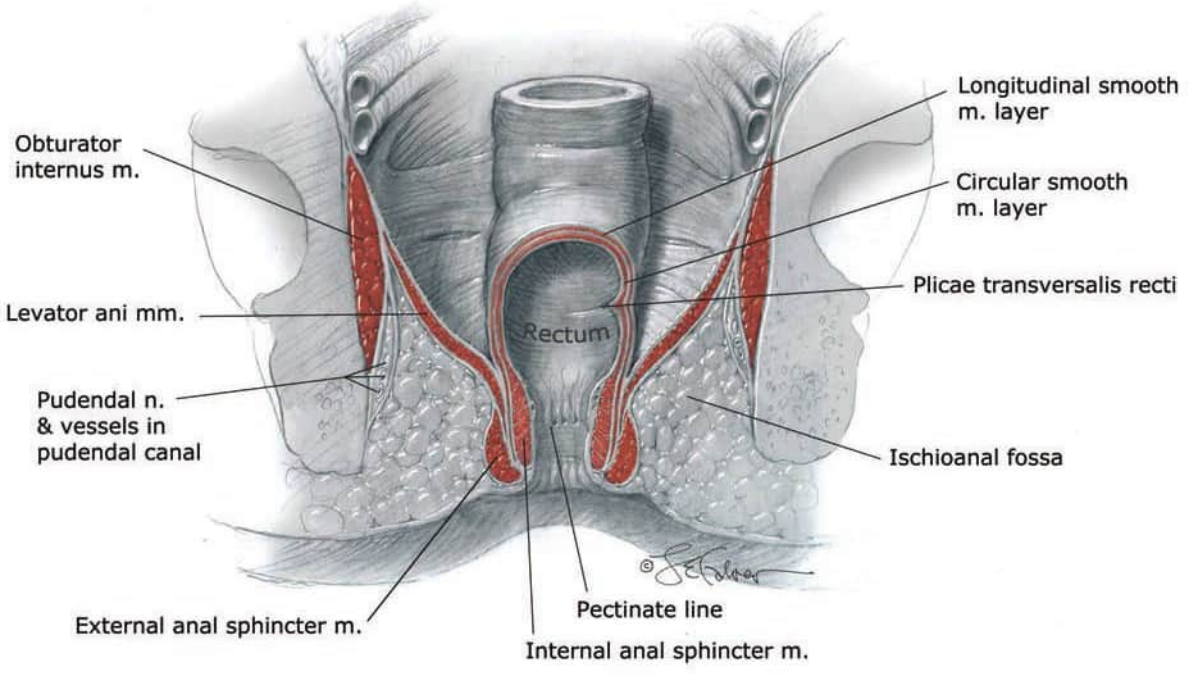

FIGURE 2-8 Anal canal and ischioanal fossa. (Modified with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Halvorson LM, et al (eds): Williams Gynecology, 4th ed. New York, NY: McGraw Hill; 2020.)

Anal Canal

This is the distal continuation of the rectum. Canal mucosa is a columnar epithelium proximally. However, at the pectinate line, also termed dentate line, simple stratified squamous epithelium begins and continues to the anal verge (Fig. 2-8). The anal verge is defined as the transition point at which a keratin layer and skin adnexa join the squamous epithelium. Two definitions describe anal canal boundaries. The *surgical* anal canal begins at the levator ani muscle, ends at the anal verge, and measures 4 cm. The *anatomical* anal canal lies between the pectineal line and anal verge and is 2 cm long (Nivatvongs, 1981).

The anal canal has several tissue layers. Inner layers include the anal mucosa, the internal anal sphincter, and an intersphincteric space that contains continuation of the rectum's longitudinal smooth muscle layer. An outer layer contains the external anal sphincter caudally and the puborectalis muscle cephalad.

Within the anal canal, three highly vascularized submucosal arteriovenous plexuses, termed anal cushions, aid complete closure of the canal and fecal continence when apposed. Increasing uterine size, excessive straining, and hard stool create raised pressure that ultimately leads to degeneration and subsequent laxity of the cushion's supportive connective tissue base. These cushions then protrude into and downward through the anal canal. This leads to venous engorgement within the cushions—now termed hemorrhoids. Venous stasis results in inflammation, erosion of the cushion's epithelium, and bleeding.

External hemorrhoids are those that arise distal to the pectinate line. They are covered by stratified squamous epithelium and receive sensory innervation from the inferior rectal nerve. Accordingly, pain and a palpable mass are typical complaints. Following resolution, a hemorrhoidal tag may remain and is composed of redundant anal skin and fibrotic tissue. In contrast, internal hemorrhoids are those that form above the pectinate line and are covered by insensitive anorectal mucosa. These may prolapse or bleed but rarely become painful unless they undergo thrombosis or necrosis.

Anal Sphincter Complex

Two sphincters surround the anal canal to provide fecal continence—the external and internal anal sphincters. Both lie near the vagina and may be torn during vaginal delivery. The internal anal sphincter (IAS) is a distal continuation of the rectal circular smooth muscle layer. It receives predominantly parasympathetic fibers, which pass through the pelvic splanchnic nerves. Along its length, this sphincter is supplied by the superior, middle, and inferior rectal arteries. The IAS contributes the bulk of anal canal resting pressure for fecal continence and relaxes prior to defecation. The IAS measures 3 to 4 cm in length, and at its distal margin, it overlaps the external sphincter for 1 to 2 cm (DeLancey, 1997). The distal site at which this overlap ends, called the intersphincteric groove, is palpable on digital examination. It is 2 to 3 mm thick (Rociu, 2000).

In contrast, the external anal sphincter (EAS) is a striated muscle ring that anteriorly attaches to the perineal body and posteriorly connects to the coccyx via the anococcygeal ligament. The EAS measures 1.5 to 2.5 cm deep and 6 to 15 mm thick (Fenner, 1998; Stewart, 2018). The EAS is considered to have one or more subdivisions, although the precise composition is disputed (Lee, 2018). Often, a surrounding fibrous capsule is described, but this most likely is perineal body rather than a true EAS sheath (Maldonado, 2020).

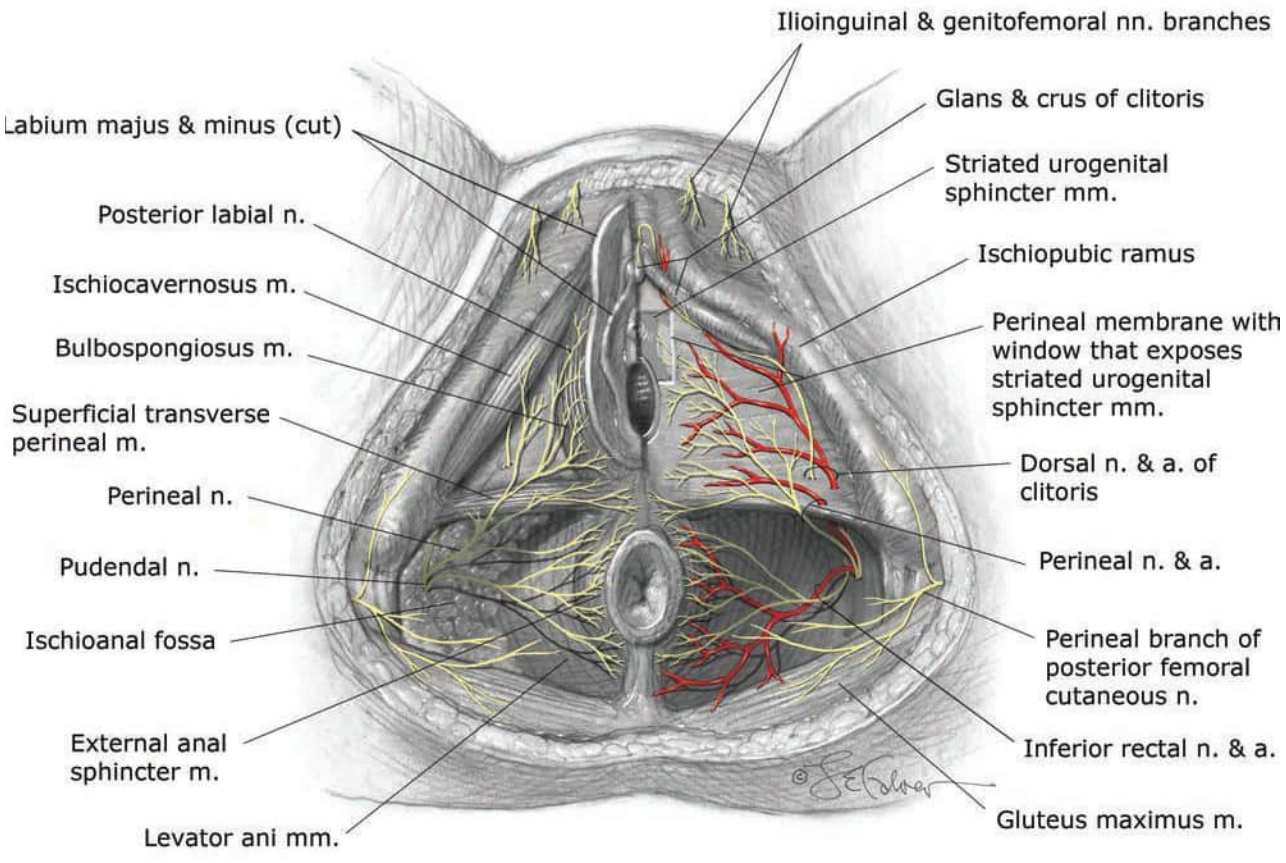

FIGURE 2-9 Branches of pudendal nerve and artery. (Modified with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Halvorson LM, et al (eds): Williams Gynecology, 4th ed. New York, NY: McGraw Hill; 2020.)

The EAS maintains a constant resting contraction to aid continence, provides additional squeeze pressure when continence is threatened, yet relaxes for defecation. The EAS receives blood supply from the inferior rectal artery, which is a branch of the internal pudendal artery. Somatic motor innervation derives from the inferior rectal branch of the pudendal nerve supply. Clinically, the IAS and EAS may be involved in third- and fourth-degree lacerations during vaginal delivery, and reunion of these rings is integral to defect repair (Chap. 27, p. 511).

Ischioanal Fossae

These two fat-filled wedge-shaped spaces are found on either side of the anal canal and constitute the bulk of the anal triangle (Figs. 2-8 and 2-9). Formerly known also as ischiorectal fossae, each fossa has skin as its superficial base, whereas its deep border is formed by the levator ani muscle. Other borders include: laterally, the obturator internus muscle and ischial tuberosity; medially, the anal sphincter complex and levator ani muscle; posteriorly, the gluteus maximus muscle and sacrotuberous ligament; and anteriorly, the inferior border of the urogenital triangle.

The fat found within each fossa provides support to surrounding organs yet allows rectal distention during defecation and vaginal stretching during delivery. Clinically, injury to vessels in the anal triangle can lead to hematoma formation in the ischioanal fossa. Moreover, the two fossae communicate posteriorly through the *deep postanal space*. This connection lies between the pelvic floor muscles and anococcygeal ligament (Llauger, 1998). As a result, episiotomy infection or hematoma may extend from one fossa into the other.

Pudendal Nerve

This is formed from the anterior rami of S_{2-4} spinal nerves. It courses between the piriformis and coccygeus muscles and exits through the greater sciatic foramen at a location posterior to the sacrospinous ligament and just medial to the ischial spine (Maldonado, 2015). Thus, when injecting local anesthetic for a pudendal nerve block, the ischial spine serves as an identifiable landmark (Chap. 25, p. 471). The pudendal nerve then runs beneath the sacrospinous ligament and above the sacrotuberous ligament as it reenters the lesser sciatic foramen to course across the obturator internus muscle. Atop this muscle, the nerve lies within the pudendal canal, also known as the Alcock canal. This space is formed by splitting of the obturator internus investing fascia (Shafik, 1999). In general, the pudendal nerve is relatively fixed as it courses behind the sacrospinous ligament and within the pudendal canal. Accordingly, it may be at risk of stretch injury during downward displacement of the pelvic floor during childbirth (Lien, 2005).

The pudendal nerve leaves this canal to enter the perineum and divides into three terminal branches (see Fig. 2-9). The first of these, the dorsal nerve of the clitoris, runs between the ischiocavernosus muscle and perineal membrane to supply the clitoral glans (Ginger, 2011b). Second, the perineal nerve runs superficial to the perineal membrane (Montoya, 2011). It divides into posterior labial branches and muscular branches, which serve the labial skin and the urogenital triangle muscles, respectively. Last, the inferior rectal branch runs through the ischioanal fossa to supply the external anal sphincter, the anal mucosa, and the perianal skin (Mahakkanukrauh, 2005).

The major blood supply to the perineum is from the internal pudendal artery, and its branches mirror the divisions of the pudendal nerve. Relevant to pudendal nerve blockade, the internal pudendal artery is the closest vascular structure, within 5 to 8 mm. It runs deep to the spine in most cases as it exits the greater sciatic foramen (Dueñas-Garcia, 2017; Roshanravan, 2007).

INTERNAL GENERATIVE ORGANS

Uterus

The nonpregnant uterus lies in the pelvic cavity between the bladder anteriorly and the rectum posteriorly. Anterior and posterior uterine walls are lined by serosa, that is, visceral peritoneum (Fig. 2-10). This peritoneum continues from the posterior wall to create the rectouterine space (see Fig. 2-5). It continues anteriorly to create the vesicouterine pouch. Clinically, during cesarean delivery, the peritoneum of the vesicouterine pouch is sharply incised, and the vesicocervical space is entered. This space is a well-defined loose connective tissue layer between the cervix and bladder (Balgobin, 2020). Dissection caudally within this space lifts the bladder safely off the cervix and lower uterine segment for hysterotomy and delivery (Chap. 30, p. 553).

The uterus is pear shaped and consists of two major but unequal parts. The upper, larger portion is the body or corpus, whereas the lower smaller cervix projects into the vagina. The isthmus is the union site of these two. It is of special obstetrical significance because it forms the lower uterine segment during pregnancy. At each superolateral margin of the body is a uterine cornu, from which a fallopian tube emerges. This area also contains the origins of the round and uteroovarian ligaments. Between the points of fallopian tube insertion is the convex upper uterine segment termed the fundus.

The bulk of the uterine body, but not the cervix, is muscle. The inner surfaces of the uterine walls lie almost in contact, and the intervening cavity forms a mere slit. The nulligravid uterus measures 6 to 8 cm in length compared with 9 to 10 cm in multiparas. The uterus averages 60 g and typically weighs more in parous women (Langlois, 1970; Sheikhazadi, 2010).

Pregnancy stimulates remarkable uterine growth due to muscle fiber hypertrophy. The uterine fundus, a previously flattened

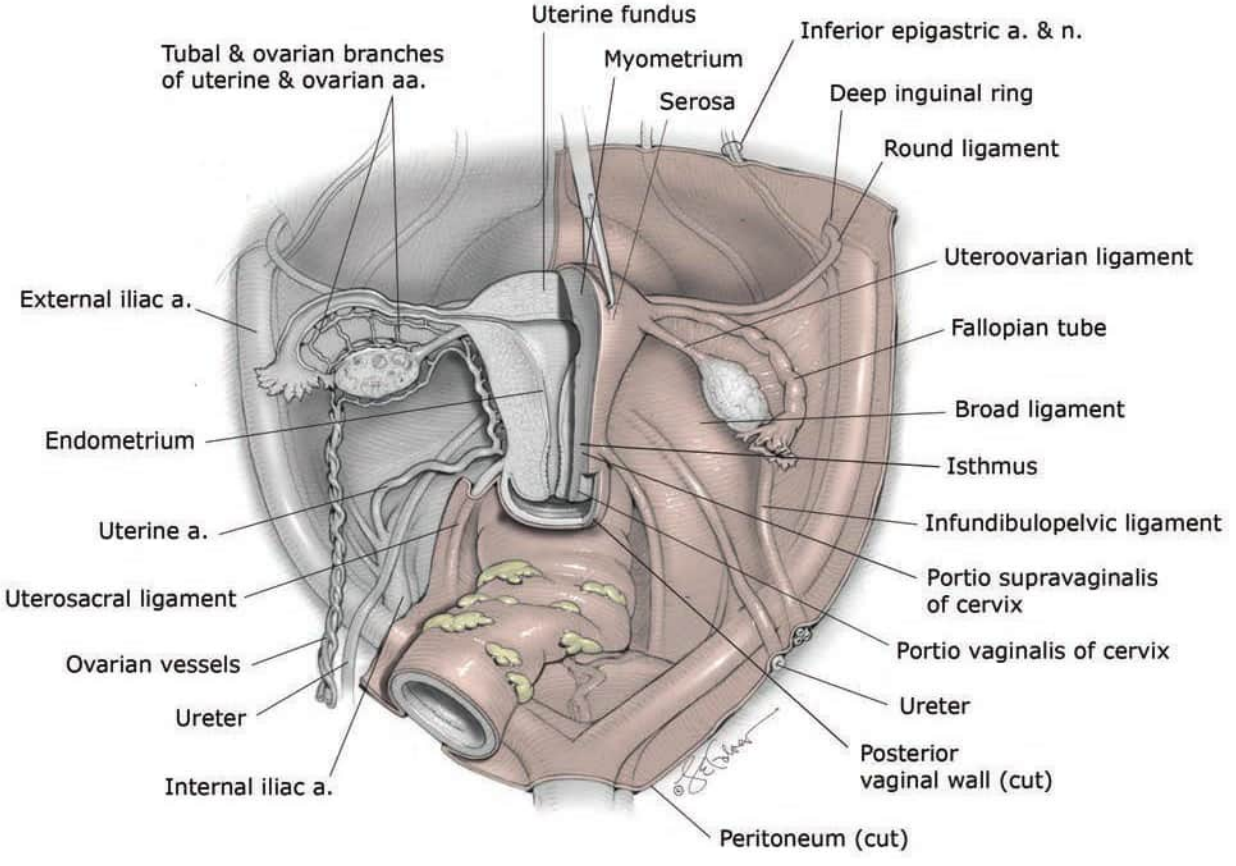

FIGURE 2-10 Uterus, adnexa, and associated anatomy. (Modified with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Halvorson LM, et al (eds): Williams Gynecology, 4th ed. New York, NY: McGraw Hill; 2020.)

convexity between tubal insertions, now becomes dome shaped. Moreover, the round ligaments appear to insert at the junction of the middle and upper thirds of the organ. The fallopian tubes elongate, but the ovaries grossly appear unchanged.

Cervix

This portion of the uterus is cylindrical and has small apertures at each end—the internal os and external os. The endocervical canal runs through the cervix and connects these ora. The cervix is divided into upper and lower portions by the vagina's attachment to its outer surface. The upper portion—the *portio supravaginalis*—begins at the internal os, which corresponds to the level of the vesicouterine peritoneum (see Figs. 2-5 and 2-10). The lower cervical portion protrudes into the vagina as the *portio vaginalis*.

Before childbirth, the external cervical os is a small, regular, oval opening. After labor, especially vaginal childbirth, the orifice is converted into a transverse slit that is divided such that there are the so-called anterior and posterior cervical lips. If torn deeply during labor or delivery, the cervix may heal in such a manner that it appears irregular, nodular, or stellate (Fig. 36-1, p. 635).

The cervical surface that radially surrounds the external os is called the ectocervix and is lined predominantly by nonkeratinized stratified squamous epithelium. In contrast, the endocervical canal is covered by a single layer of mucin-secreting columnar epithelium, which creates deep cleftlike infoldings or "glands." Commonly during pregnancy, the endocervical epithelium moves out and onto the ectocervix in a physiological process termed eversion (Chap. 4, p. 53).

The cervical stroma is composed mainly of collagen, elastin, and proteoglycans, but very little smooth muscle. As described in Chapter 21 (p. 406), changes in the amount, composition, and orientation of these components lead to cervical ripening prior to labor. In early pregnancy, increased vascularity within the cervix stroma beneath the epithelium creates an ectocervical blue tint that is characteristic of the Chadwick sign. Cervical edema leads to softening—the Goodell sign, whereas isthmic softening is the Hegar sign.

Myometrium and Endometrium

Most of the uterus is composed of myometrium, which contains smooth muscle bundles united by connective tissue with many elastic fibers. Interlacing myometrial fibers surround myometrial vessels and contract to compress these. This anatomy allows hemostasis at the placental site during third-stage labor.

The uterine cavity is lined with endometrium, which is composed of an overlying epithelium, invaginating glands, and a supportive, vascular stroma. Throughout the menstrual cycle, the endometrium varies greatly (Chap. 5, p. 83). It is divided into a functionalis layer, which is sloughed with menses, and a basalis layer, which serves to regenerate the functionalis layer following each menses. During pregnancy, the endometrium undergoes dramatic hormonally driven alterations and is termed decidua.

Ligaments

Several ligaments extend from the uterine surface toward the pelvic sidewalls and include the round, broad, cardinal, and uterosacral ligaments (see Fig. 2-10). Despite their appellation, the round and broad ligaments provide no substantial uterine support, which contrasts with the cardinal and uterosacral ligaments.

The round ligament originates somewhat below and anterior to the origin of the fallopian tubes. Clinically, this orientation can aid tube identification during puerperal sterilization (Chap. 39, p. 682). Each round ligament extends laterally and down into the inguinal canal, through which it passes, to terminate in the upper portion of the ipsilateral labium majus. The *artery to the round ligament*, formerly the Sampson artery, is a small branch of the uterine artery and runs within the ligament. In nonpregnant women, the round ligament varies from 3 to 5 mm in diameter and is composed of smooth muscle bundles separated by fibrous tissue septa (Mahran, 1965). During pregnancy, these ligaments hypertrophy and increase appreciably in both length and diameter. Rare, round ligament varicosities can mimic an inguinal hernia, and color Doppler interrogation of the mass aids diagnosis (Yonggang, 2017).

The broad ligaments are two winglike structures that extend from the lateral uterine margins to the pelvic sidewalls. Each broad ligament consists of a double-layer drape of peritoneum. The anterior and posterior layers of this drape are termed the anterior and posterior leaves, respectively. In forming the broad ligament, this peritoneum folds over structures extending from each cornu. Peritoneum that folds over the fallopian tube is termed the mesosalpinx, that around the round ligament is the mesoteres, and that over the ovarian ligament is the mesovarium. Peritoneum that extends beneath the fimbriated end of the uterine tube toward the pelvic wall forms infundibulopelvic ligament, which is also the *suspensory ligament of the ovary*. This contains nerves and the ovarian vessels, and during pregnancy, these vessels, especially the venous plexuses, are dramatically enlarged. Specifically, the diameter of the ovarian vascular pedicle increases from 0.9 cm to reach 2.6 cm at term (Hodgkinson, 1953).

The cardinal ligament—formerly the transverse cervical ligament or the Mackenrodt ligament—anchors medially to the uterus and upper vagina. The cardinal ligament is the thick base of the broad ligament. As such, during cesarean hysterectomy, sturdy clamps and suture are required for its transection and ligation.

Each uterosacral ligament originates with a posterolateral attachment to the supravaginal portion of the cervix and inserts into the fascia over the sacrum, with some variations (Ramanah, 2012; Umek, 2004). These ligaments are composed of connective tissue, small neurovascular bundles, and some smooth muscle. Covered by peritoneum, these ligaments form the lateral boundaries of the rectouterine space.

The term parametrium describes the connective tissues adjacent and lateral to the uterus within the broad ligament. Paracervical tissues are those adjacent to the cervix, whereas paracolpium is tissue lateral to the vaginal walls.

Pelvic Blood Supply

During pregnancy, uterine vasculature, which is supplied principally from the uterine and ovarian arteries, markedly hypertrophies (see Fig. 2-10). The uterine artery is a main branch of

the internal iliac artery (prior hypogastric artery) and enters the base of the broad ligament. From its origin, the uterine artery courses medially to the lateral side of the uterus. Approximately 2 cm lateral to the cervix, the uterine artery crosses over the ureter. This proximity is important surgically, as the ureter may be injured or ligated during hysterectomy when the uterine vessels are clamped and ligated.

Once the uterine artery reaches the cervix, it divides. The smaller cervicovaginal artery supplies blood to the lower cervix and upper vagina. Instead, the main uterine artery branch turns abruptly upward and travels cephalad along the lateral margin of the uterus. Along this path, the uterine artery gives rise to the arcuate arteries. Indicated by the name, each branch arches across either the anterior or posterior uterine wall and courses within the myometrium just beneath the serosal surface. Arcuate vessels from each side anastomose at the uterine midline. From the arcuate arteries, radial arteries originate at right angles and travel inward through the myometrium. Upon entering the endometrium/decidua, they branch to become either basal arteries or spiral arteries. The coiled spiral arteries supply the functionalis layer. The basal arteries, also called the straight arteries, extend only into the basalis layer.

As the uterine artery courses cephalad, it gives rise to the artery of the round ligament. At the each cornu, the uterine artery divides into three terminal branches. First, the tubal branch makes its way through the mesosalpinx and supplies part of the fallopian tube; whereas the fundal branch penetrates the uppermost uterus. Third, the ovarian branch of the uterine artery forms an anastomosis with the terminal branch of the ovarian artery.

The ovarian artery is a direct branch of the aorta and enters the broad ligament through the infundibulopelvic ligament. At the ovarian hilum, it divides into smaller branches that enter the ovary. As the ovarian artery runs along the hilum, it also sends several branches through the mesosalpinx to supply the fallopian tubes. Its main stem, however, traverses the entire length of the broad ligament toward the uterine cornu. Here, it forms an anastomosis with the ovarian branch of the uterine artery. This dual uterine blood supply creates a vascular reserve to prevent uterine ischemia if ligation of the uterine or internal iliac artery is performed to control postpartum hemorrhage.

Uterine veins accompany their respective arteries. As such, the arcuate veins unite to form the uterine vein, which empties into the internal iliac vein and then the common iliac vein. Some of the blood from the upper uterus, the ovary, and the upper part of the broad ligament is collected by several veins. These terminate in the ovarian vein. From here, the right ovarian vein empties into the vena cava. The left ovarian vein empties into the left renal vein.

Blood supply to the pelvis is predominantly provided by branches of the internal iliac artery (Fig. 2-11). These branches

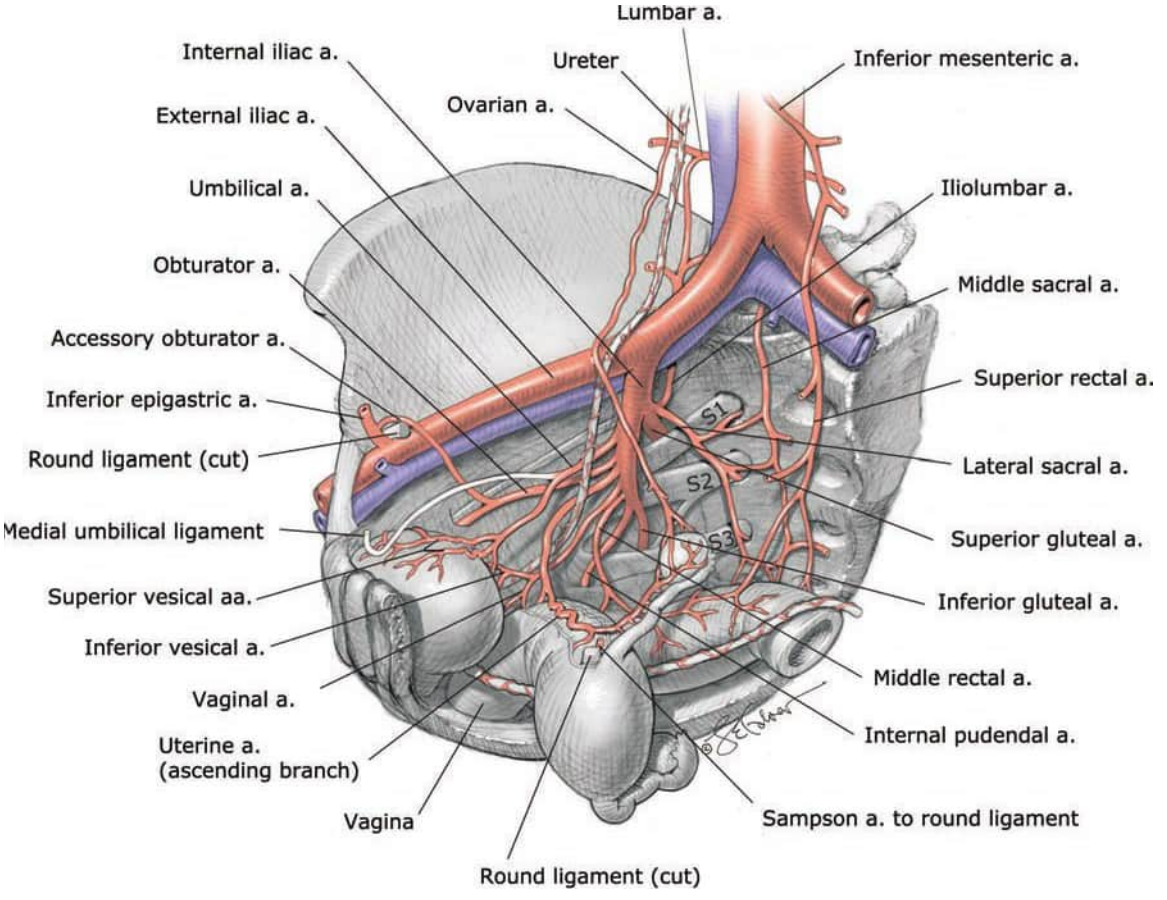

FIGURE 2-11 Pelvic arteries. (Modified with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Halvorson LM, et al (eds): Williams Gynecology, 4th ed. New York, NY: McGraw Hill; 2020.)

are organized into anterior and posterior divisions, and subsequent branches are highly variable between individuals. The anterior division provides blood supply to the pelvic organs and perineum and includes the inferior gluteal, internal pudendal, middle rectal, vaginal, uterine, and obturator arteries, as well as the umbilical artery and its continuation as the superior vesical artery. The posterior division branches extend to the buttock and thigh and include the superior gluteal, lateral sacral, and iliolumbar arteries. For this reason, during internal iliac artery ligation, many advocate ligation distal to the posterior division to avoid compromise to the areas supplied by this division (Bleich, 2007).

Pelvic Lymphatics

The lymphatic vessels from the uterine corpus generally empty into two nodal groups. Those from the cervix and lower uterine segment travel to the pelvic lymph nodes, which then drain into the paraaortic nodes. Vessels from the fundus, after joining lymphatics from the adnexa, directly terminate in the paraaortic lymph nodes. Vaginal lymphatic channels have extensive anastomoses. As a result, any node in the pelvis, groin, or anorectal area may drain any part of the vagina. Lymphatics of the vulva and distal vagina typically empty into the superficial inguinal nodal group. From here, lymph travels through the deep femoral lymphatics to the pelvic nodal groups.

Pelvic Innervation

As a brief review, the peripheral nervous system is divided into a somatic division, which innervates skeletal muscle, and an autonomic division, which innervates smooth muscle, cardiac muscle, and glands. Pelvic visceral innervation is predominantly autonomic, which is further divided into sympathetic and parasympathetic components.

Sympathetic innervation to pelvic viscera begins with the *superior hypogastric plexus*, also termed the presacral nerve (Fig. 2-12). This plexus is formed by sympathetic fibers arising from spinal levels T_{10} through L_2. At the level of the sacral promontory, the superior hypogastric plexus divides into a *right* and a *left hypogastric nerve*, which run downward along their respective pelvic sidewalls (Ripperda, 2017).

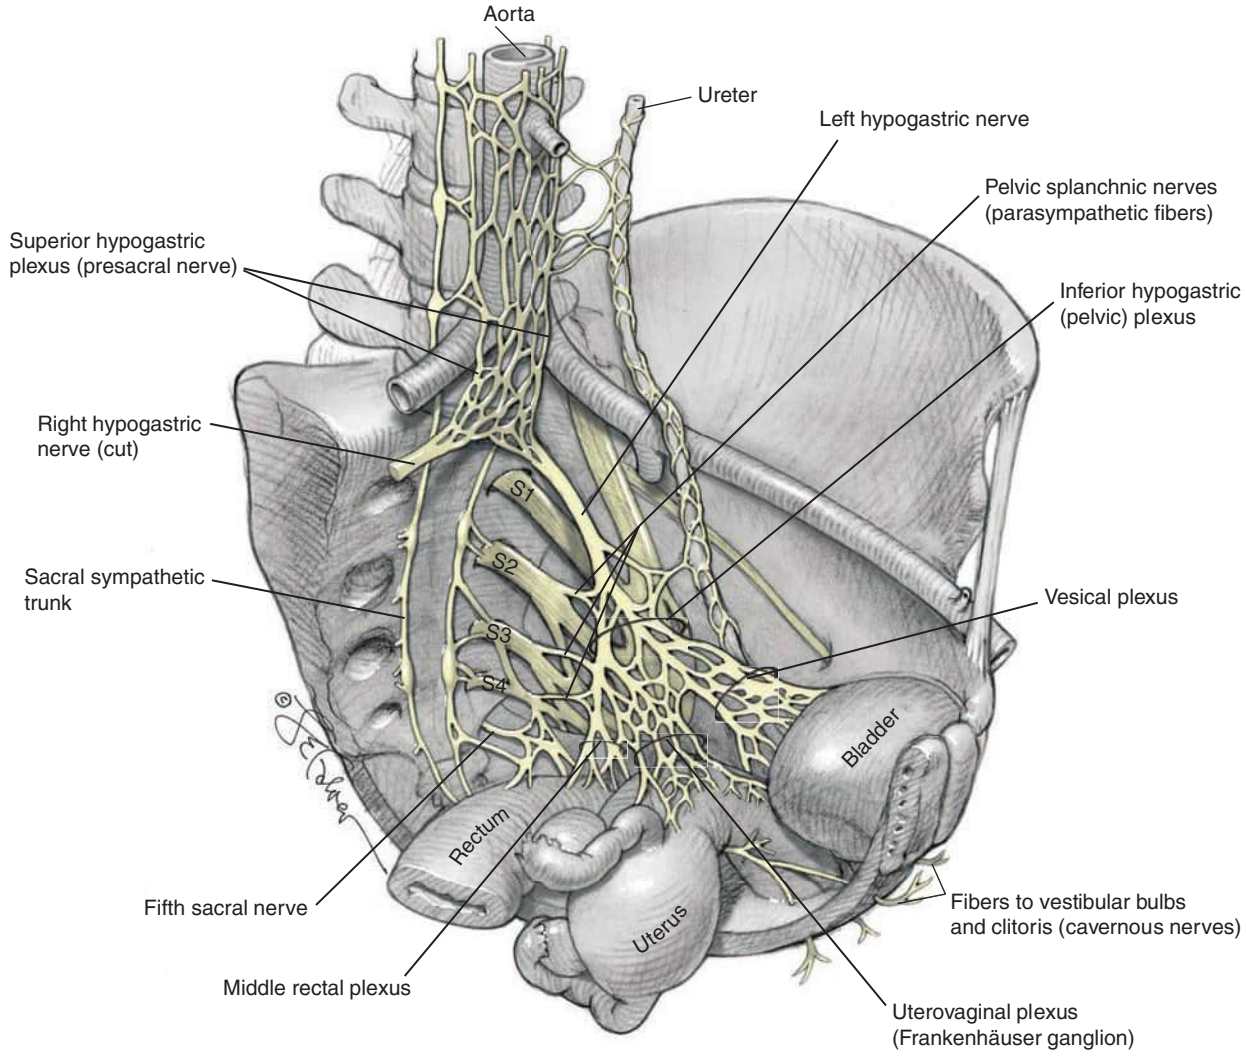

FIGURE 2-12 Pelvic innervation. (Modified with permission from Corton MM: Anatomy. In Hoffman BL, Schorge JO, Halvorson LM, et al (eds): Williams Gynecology, 4th ed. New York, NY: McGraw Hill; 2020.)

In contrast, parasympathetic innervation to the pelvic organs derives from spinal levels S_2 through S_4. Anterior rami of the spinal nerves for those levels combine on each side to form the *pelvic splanchnic nerves*, also termed nervi erigentes.

Blending of the two hypogastric nerves (sympathetic) and the two pelvic splanchnic nerves (parasympathetic) gives rise to the *inferior hypogastric plexus*, also termed the pelvic plexus. From here, fibers of this plexus extend to the bladder, uterus, upper vagina, and rectum (Ripperda, 2017; Spackman, 2007). Extensions of the inferior hypogastric plexus also reach the perineum to innervate the clitoris and vestibular bulbs (Montoya, 2011).

For the uterus, most of its afferent sensory fibers ascend through the inferior hypogastric plexus and enter the spinal cord via T_{10} through T_{12} and L_1 spinal nerves. These transmit the painful stimuli of contractions to the central nervous system. For the cervix and upper part of the birth canal, sensory nerves pass through the pelvic splanchnic nerves to the second, third, and fourth sacral nerves. Last, those from the lower portion of the birth canal pass primarily through the pudendal nerve. Anesthetic blocks used during delivery target these levels of innervation.

Ovaries

Along the pelvic sidewall, each ovary usually rests in the ovarian fossa, which is a slight depression between the external and internal iliac vessels. During childbearing years, ovaries variably measure 2.5 to 5 cm in length, 1.5 to 3 cm in width, and 0.6 to 1.5 cm in thickness.

The ovarian ligament, also called the uteroovarian ligament, originates from the posterolateral uterine cornu and extends to the uterine pole of the ovary (see Fig. 2-10). Measuring a few centimeters long and 3 to 4 mm in diameter, this ligament is made up of muscle and connective tissue and is covered by peritoneum—the mesovarium. Blood supply reaches the ovary through the mesovarium to enter the ovarian hilum.

The ovary consists of an outer cortex and inner medulla. In young women, the cortex is smooth, white, and lined by a single layer of cuboidal epithelium. This epithelium is supported by an inner connective tissue condensation, the tunica albuginea. Beneath this, the ovarian cortex contains oocytes and developing follicles. The medulla is composed of loose connective tissue, numerous arteries and veins, and a small amount of smooth muscle.

The ovaries are supplied with both sympathetic and parasympathetic nerves. The sympathetic nerves are derived primarily from the ovarian plexus that accompanies the ovarian vessels and originates in the renal plexus. Others derive from the plexus that surrounds the ovarian branch of the uterine artery. Parasympathetic input is from the vagus nerve. Sensory afferents follow the ovarian artery and enter at T_{10} spinal cord level.

Fallopian Tubes

Each of these serpentine tubes extend laterally 8 to 14 cm from their respective uterine cornu. Along their length, they contain an interstitial portion, isthmus, ampulla, and infundibulum (Fig. 2-13). Most proximal, the interstitial portion is embodied within the uterine muscular wall. Next, the narrow 2- to 3-mm wide isthmus widens gradually into the 5- to 8-mm wide ampulla. Last, the infundibulum is the funnel-shaped fimbriated distal extremity of the tube, which opens into the abdominal cavity. These latter three extrauterine portions are covered by the mesosalpinx, which is a superior extension of the broad ligament and described next.

In cross section, the uterine tube contains a mesosalpinx, myosalpinx, and endosalpinx. The outer of these, the mesosalpinx, is a single-cell mesothelial layer functioning as visceral peritoneum. In the myosalpinx, smooth muscle is arranged in an inner circular and an outer longitudinal layer. The tubal musculature undergoes rhythmic contractions constantly, the rate of which varies with cyclical ovarian hormonal changes.

FIGURE 2-13 The fallopian tube of an adult woman with cross-sectioned illustrations of the gross structure in several portions: **(A)** isthmus, **(B)** ampulla, and **(C)** infundibulum. Below these are photographs of corresponding histological sections. (Reproduced with permission from Dr. Kelley S. Carrick.)

The *endosalpinx* (tubal mucosa) is a single layer of columnar epithelium made up of ciliated, secretory, and intercalary cells resting on a sparse lamina propria. Clinically, its close proximity to the underlying myosalpinx contributes to easy invasion by ectopic trophoblast. The tubal mucosa is arranged in longitudinal folds that become progressively more complex toward the fimbria. In the ampulla, the lumen is occupied almost completely by the arborescent mucosa. The current produced by the tubal cilia flows toward the uterine cavity. Tubal peristalsis created by cilia and muscular layer contraction aids ovum transport (Croxatto, 2002).

The tubes are supplied richly with elastic tissue, blood vessels, and lymphatics. Their sympathetic innervation is extensive, in contrast to their parasympathetic innervation. This nerve supply derives partly from the ovarian plexus and partly from the inferior hypogastric plexus. Sensory afferent fibers ascend to T_{10} spinal cord levels.

LOWER URINARY TRACT

Bladder

Anteriorly, the bladder rests against the inner surface of the pubic bones and then, as it fills, also against the anterior abdominal wall. Posteriorly, it rests against the vagina and cervix. The bladder is divided into a dome and a base approximately at the level of the ureteral orifices. The dome is thin walled and distensible, whereas the base is thicker and undergoes less distention during filling. The vesical trigone lies in the bladder base and contains both ureteral orifices and the internal urinary meatus. The urethral lumen begins at this meatus and then courses through the bladder base for less than 1 cm. This region where the urethral lumen traverses the bladder base is the bladder neck.

The bladder wall consists of coarse bundles of smooth muscle known as the detrusor muscle, which extends into the proximal part of the urethra. A submucosal layer intervenes between this detrusor muscle and the mucosa. The bladder mucosa consists of transitional epithelium and underlying lamina propria.

The blood supply to the bladder arises from the superior vesical arteries, which are branches of the patent portion of the umbilical artery and supply the dome (see Fig. 2-11). The inferior vesical arteries supply the base and variably arise from either the umbilical, uterine, or vaginal artery (de Treigny, 2017). The nerve supply to the bladder arises from the inferior hypogastric plexus (see Fig. 2-12).

Ureter

As the ureter enters the pelvis, it crosses over the bifurcation of the common iliac artery and passes just medial to the ovarian vessels (see Fig. 2-10). As the ureter descends into the pelvis, it lies medial to the internal iliac branches and anterolateral to the uterosacral ligaments. The ureter then traverses through the cardinal ligament approximately 1 to 2 cm lateral to the cervix. Near the level of the uterine isthmus, it courses below the uterine artery and travels anteromedially toward the bladder base. In this path, it runs close to the upper third of the anterior vaginal wall (Jackson, 2019; Rahn, 2007). Finally, the ureter enters the bladder and travels obliquely for approximately 1.5 cm before opening at the ureteral orifices.

The pelvic ureter receives blood supply from the vessels it passes: the common iliac, internal iliac, uterine, and superior vesical vessels. The ureter's course runs medial to these vessels, and thus its blood supply reaches the ureter from lateral sources. This is important during ureteral isolation. Vascular anastomoses on the connective tissue sheath enveloping the ureter form a longitudinal network of vessels.

PELVIC SKELETAL ANATOMY

Pelvic Bones and Joints

The pelvis is composed of four bones—the sacrum, coccyx, and two innominate bones. Each innominate bone is formed by the fusion of three bones—the ilium, ischium, and pubis (Fig. 2-14). Both innominate bones are joined to the sacrum at the sacroiliac joint. Anteriorly, they are joined at the symphysis pubis. This consists of fibrocartilage and the superior and inferior pubic ligaments. The latter ligament is frequently designated the *arcuate ligament of the pubis*.

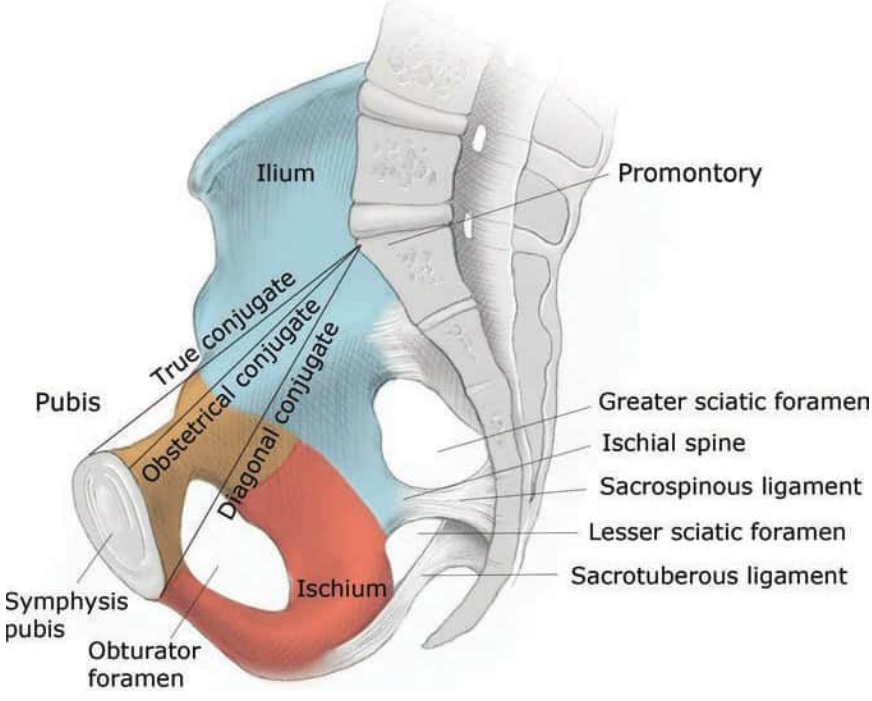

FIGURE 2-14 The innominate bone is composed of the pubis (*brown*), ischium (*red*), and ilium (*blue*). Of the three anteroposterior diameters of the pelvic inlet, only the diagonal conjugate can be measured clinically. The important obstetrical conjugate is derived by subtracting 1.5 cm from the diagonal conjugate.

These pelvic joints have a limited degree of mobility but can relax remarkably during pregnancy. For example, at term, the sacroiliac joint can glide upward. This is greatest in dorsal lithotomy position and may increase the diameter of the outlet by 1.5 to 2.0 cm for delivery (Borell, 1957). Sacroiliac joint mobility also likely aids the McRoberts maneuver to release an obstructed shoulder in cases of shoulder dystocia (Chap. 27, p. 502). These changes may also contribute to the success of the modified squatting position to hasten second-stage labor (Gardosi, 1989). Squatting may increase the interspinous diameter and the pelvic outlet diameter (Russell, 1969, 1982).

Planes and Diameters of the Pelvis

The pelvis is conceptually divided into false and true components. The false pelvis lies above the linea terminalis, and the true pelvis is below this boundary (Fig. 2-15). The false pelvis is bounded posteriorly by the lumbar vertebra and laterally by the iliac fossa. In front, the boundary is formed by the lower portion of the anterior abdominal wall.

The true pelvis is described by four imaginary planes:

1. The plane of the pelvic inlet—the superior strait.
2. The plane of the pelvic outlet—the inferior strait.
3. The plane of the midpelvis—the least pelvic dimensions.
4. The plane of greatest pelvic dimension—of no obstetrical significance.

Pelvic Inlet

The pelvic inlet is bounded posteriorly by the promontory, laterally by the linea terminalis, and anteriorly by the horizontal pubic rami and the symphysis pubis. During labor, fetal head engagement is defined by the fetal head's biparietal diameter passing through this plane.

Four diameters of the pelvic inlet are usually described: anteroposterior, transverse, and two oblique diameters. Of these, distinct anteroposterior diameters have been described using specific landmarks. Most cephalad, the anteroposterior diameter, termed the *true conjugate*, extends from the uppermost margin of the symphysis pubis to the sacral promontory (see Fig. 2-14). The clinically important *obstetrical conjugate* is the shortest, and thus the most limiting, distance between the sacral promontory and the symphysis pubis. Normally, this measures 10 cm or more, but unfortunately, it cannot be measured directly with examining fingers. Thus, the obstetrical conjugate is estimated indirectly by subtracting 1.5 to 2 cm from the *diagonal conjugate*. To measure the diagonal conjugate, a hand with the palm oriented laterally extends its index finger to the promontory. The distance from the fingertip to the point at which the lowest margin of the symphysis strikes the same finger's base is the diagonal conjugate.

The transverse diameter is constructed at right angles to the obstetrical conjugate and represents the greatest distance between the linea terminalis on either side (see Fig. 2-15). It usually intersects the obstetrical conjugate at a point approximately 5 cm in front of the promontory and measures approximately 13 cm.

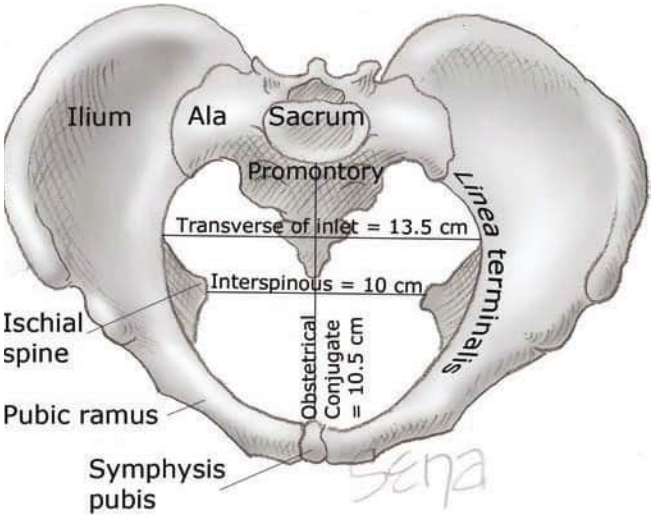

FIGURE 2-15 Axial view of a normal female pelvis. The clinically important obstetrical conjugate and transverse diameter of the pelvic inlet are illustrated. The interspinous diameter of the midpelvis also is marked.

Midpelvis and Pelvic Outlet

The midpelvis is measured at the level of the ischial spines, also called the midplane or plane of least pelvic dimensions (see Fig. 2-15). During labor, the degree of fetal head descent into the true pelvis may be described by station, and the midpelvis and ischial spines serve to mark zero station. The interspinous diameter is 10 cm or slightly greater and is usually the smallest overall pelvic diameter. The anteroposterior diameter through the level of the ischial spines normally measures at least 11.5 cm.

The pelvic outlet consists of two approximately triangular areas whose boundaries mirror those of the perineum described earlier (p. 14). They have a common base, which is a line drawn between the two ischial tuberosities. The apex of the posterior triangle is the tip of the sacrum, and the lateral boundaries are the sacrotuberous ligaments and the ischial tuberosities. The anterior triangle is formed by the descending inferior rami of the pubic bones. These rami unite at an angle of 90 to 100 degrees to form a rounded arch under which the fetal head must pass. Unless there is significant pelvic bony disease, the pelvic outlet seldom obstructs vaginal delivery.

Pelvic Shapes

The Caldwell–Moloy (1933, 1934) anatomical classification of the pelvis is based on shape, and its concepts aid an understanding of labor mechanisms. Specifically, the greatest transverse diameter of the inlet and its division into anterior and posterior segments are used to classify the pelvis as gynecoid, anthropoid, android, or platypelloid. The posterior segment determines the type of pelvis, whereas the anterior segment determines the tendency. These are both determined because many pelves are not pure but are mixed types. For example, a gynecoid pelvis with an android tendency means that the posterior pelvis is gynecoid and the anterior pelvis is android shaped.

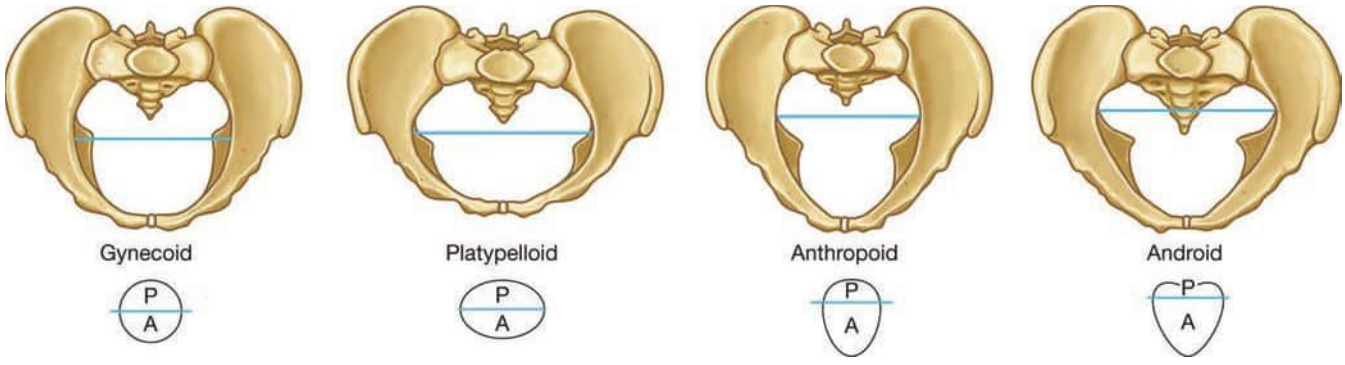

FIGURE 2-16 The four parent pelvic types of the Caldwell–Moloy classification are shown by anatomic and schematic drawings. In each, the blue line passes through the widest transverse diameter and divides the pelvic inlets into posterior (P) and anterior (A) segments. Mixed types are formed by combining anterior and posterior inlet segments from different parent types.

From viewing the four basic types in Figure 2-16, the configuration of the gynecoid pelvis would intuitively seem suited for delivery of most fetuses. Indeed, Caldwell (1939) reported that the gynecoid pelvis was found in almost half of women.

CHAPTER 3

Congenital Genitourinary Abnormalities

In females, the external genitalia, gonads, and müllerian ducts each derive from different primordia and in close association with the urinary tract and hindgut. Abnormal embryogenesis can lead to reproductive organs that predispose to infertility, subfertility, miscarriage, or preterm delivery.

GENITOURINARY TRACT DEVELOPMENT

Urinary System

Between the 3rd and 5th gestational weeks, an elevation of intermediate mesoderm on each side of the fetus begins to develop into the urogenital tract. This *urogenital ridge* divides into the *genital ridge*, destined to become the gonads, and into the *nephrogenic ridge* (Fig. 3-1). Each nephrogenic ridge produces a mesonephros (mesonephric kidney). Recall that evolution of the renal system passes sequentially from the mesonephric stage to reach the permanent metanephric system (de Bakker, 2019; Upadhyay, 2014). Each nephrogenic ridge also gives rise to a mesonephric duct, also termed wolffian duct, and to a paramesonephric duct, also called müllerian duct.

The early urinary tract develops from the mesonephric ducts (Fig. 3-2A). Between the 4th and 5th weeks, each mesonephric duct gives rise to a ureteric bud, which grows cephalad (Fig. 3-2B). As each bud lengthens, it induces differentiation of the metanephros, which will become the final kidney (Fig. 3-2C) (Davidson, 2019). The metanephros ascends to its final position by the 9th week because of disproportionate growth of the embryo's caudal region (Jain, 2018). Each ureteric bud also gives rise to an elongation that becomes the metanephric duct or future ureter.

The cloaca begins as a common opening for the embryonic urinary, genital, and alimentary tracts (Gupta, 2014). By the 7th week, it is divided by the urorectal septum to create the hindgut and the urogenital sinus (Fig. 3-2D) (Valentini, 2016). The urogenital sinus is considered in three parts: (1) the cephalad or vesicle portion, which forms the urinary bladder; (2) the middle or pelvic portion, which creates the female urethra; and (3) the caudal or phallic part, which gives rise to the distal vagina and to the greater vestibular (Bartholin) and paraurethral glands.

Near the end of the first trimester, each mesonephros degenerates, and without testosterone, the mesonephric ducts regress as well. The ureterovesical junction forms from incorporation of the metanephric ducts into the bladder at the trigone. Abnormalities of this process lead to obstruction and vesicoureteral reflux (Liaw, 2018).

Genital Tract

The fallopian tubes, uterus, and upper vagina derive from the müllerian ducts (see Fig. 3-2B). Linear spatial development of these organs along the duct length is guided by several genes and notably by *Hox* genes (Du, 2004; Jacquinet, 2016). These ducts extend downward and then turn medially to meet and

Also, migration of sympathetic cells from the spinal ganglia to a region above the developing kidney.

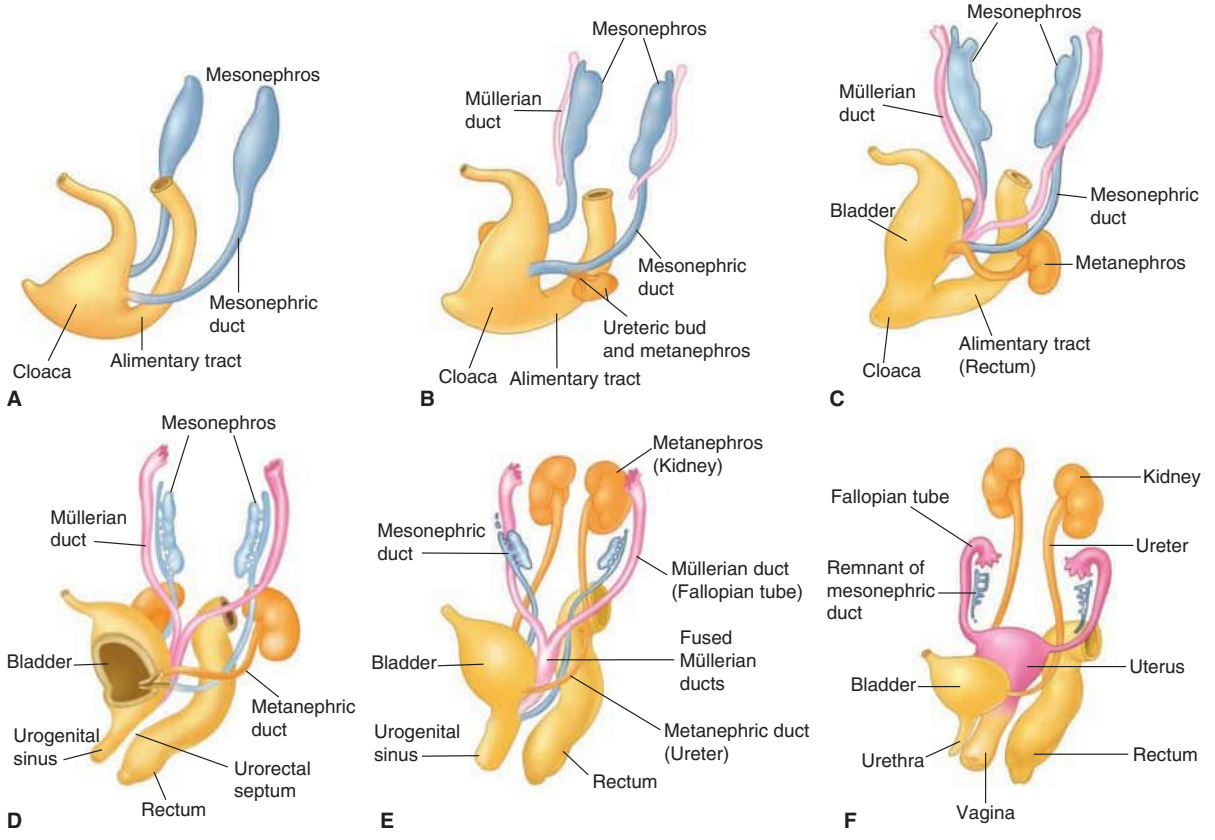

FIGURE 3-2 Embryonic development of the female genitourinary tract **(A–F)**. (Reproduced with permission from Shatzkes DR, Haller JO, Velcek FT: Imaging of uterovaginal anomalies in the pediatric patient, Urol Radiol 1991;13(1):58–66.)

fuse together in the midline. The uterus is formed by this union of the two müllerian ducts at approximately the 10th week (Fig. 3-2E) (Spencer, 2012). Fusion to create the uterus begins in the middle and then extends both caudally and cephalad. With cellular proliferation at the upper portion, a thick wedge of tissue creates the characteristic piriform uterine shape. At the same time, dissolution of cells at the lower pole forms the first uterine cavity (Fig. 3-2F). As the upper wedge-shaped septum is slowly reabsorbed, the final uterine cavity is usually formed by the 20th week (Toaff, 1984). If the two müllerian ducts fail to fuse, two separate uterine horns remain. In contrast, resorption failure of the common tissue between them results in various degrees of persistent uterine septum.

As the distal end of the fused müllerian ducts contacts the urogenital sinus, this induces endodermal outgrowths from the sinus, which are termed the sinovaginal bulbs. These bulbs proliferate and fuse to form the vaginal plate, which later resorbs to form the vaginal lumen. Vaginal canalization is generally completed by the 20th week (Crosby, 1962). However, the lumen remains separated from the urogenital sinus by the hymeneal membrane. This membrane further degenerates to leave only the hymeneal ring.

The close association of the mesonephric (wolffian) and paramesonephric (müllerian) ducts explains the potential to see simultaneous abnormalities in their end organs. Nearly half of females with uterovaginal malformations have associated urinary tract defects, and this association is explored later (p. 40) (Kenney, 1984; Semmens, 1962). With müllerian anomalies, ovaries are functionally normal but have a higher incidence of anatomical maldescent into the pelvis (Allen, 2012).

As discussed, the mesonephric ducts usually degenerate in the female. However, persistent remnants may become clinically apparent. Mesonephric, that is wolffian, vestiges can persist as Gartner duct cysts. These are typically located in the proximal anterolateral vaginal wall but may be found at other sites along the vaginal length. Most cysts are asymptomatic and benign and usually do not require surgical excision or drainage.

Intraabdominal wolffian remnants in the female include a few blind tubules in the mesovarium—the epoöphoron—and similar ones adjacent to the uterus—paroöphoron (see Fig. 3-2F) (Moore, 2020). The epoöphoron or paroöphoron may develop into clinically identifiable benign cysts in the adult.

Gonads

Because of separate gonadal and müllerian derivation, women with müllerian defects typically have functionally normal ovaries. At approximately 4 weeks, gonads form from the genital ridge, also known as the gonadal ridge. This ridge forms from the coelomic epithelium covering the medioventral surface of the mesonephros (Smith, 2014). Recall that coelomic epithelium arises from mesoderm and invests the body cavity's inner surface (Ariza, 2016). Next, strands of these epithelial cells extend into the underlying mesenchyme as the primary sex cords.

Another gonadal component is the primordial germ cell, the future oogonia. By the 6th week, primordial germ cells have migrated from the yolk sac along the dorsal mesentery to enter the genital ridge mesenchyme (see Fig. 3-1) (Fujimoto, 1977; Hen, 2019). The primordial germ cells are then incorporated into the primary sex cords.

In the 7th week, the sexes can be distinguished. Testes are recognized during microscopic sectioning by their well-defined radiating testis cords, which derived from the primary sex cords. These cords develop into the seminiferous tubules and rete testis. The rete testis connects with small tubes arising off the mesonephric duct. These small tubes become the efferent ducts that drain into the epididymis and then into the vas deferens, which are main mesonephric duct derivatives. After the 8th week, gonads begin to differ grossly as well (Shen, 2018).

In the female embryo, the primary sex cords give rise to the medullary cords, which persist only for a short time. The coelomic epithelium again proliferates into the underlying mesenchyme, and these strands are the cortical cords. By the 16th week, the cortical cords begin to form isolated cell clusters called primordial follicles. These follicles contain the oogonia, which derive from primordial germ cells, and a single surrounding layer of follicular cells, derived from the cortical cords. Follicular cells are supporting nutrient cells.

By 8 months, the ovary has become a long, narrow, lobulated structure that is attached to the body wall by the mesovarium. The coelomic epithelium has been separated by a band of connective tissue—the tunica albuginea—from the cortex. At this stage, the cortex contains follicles and is well defined from the inner medulla, which is composed of abundant blood vessels, lymphatic vessels, and nerve fibers.

External Genitalia

Early development of the external genitalia is similar in both sexes. By 6 weeks' gestation, three external protuberances have developed surrounding the cloacal membrane. These are the left and right cloacal folds, which meet ventrally to form the genital tubercle (Fig. 3-3A). With division of the cloacal membrane into anal and urogenital membranes in the early 7th week, the cloacal folds become the anal and urethral folds, respectively. Lateral to the urethral folds, genital swellings arise, and these become the labioscrotal folds. Between the urethral folds, the urogenital sinus extends onto the surface of the enlarging genital tubercle to form the urethral groove. Late in week 7, the urogenital membrane ruptures, exposing the cavity of the urogenital sinus to amnionic fluid.

The genital tubercle elongates to form the phallus in males and the clitoris in females. Still, it is not possible to visually differentiate between male and female external genitalia until week 12. In the male fetus, dihydrotestosterone (DHT) forms locally by the 5-α reduction of testosterone. DHT prompts the anogenital distance to lengthen, the phallus to enlarge, and the labioscrotal folds to fuse and form the scrotum (see Fig. 3-3B).

In the female fetus, without DHT, the anogenital distance does not lengthen, and the labioscrotal and urethral folds do not fuse (see Fig. 3-3C). The genital tubercle bends caudally to become the clitoris, and the urogenital sinus forms the

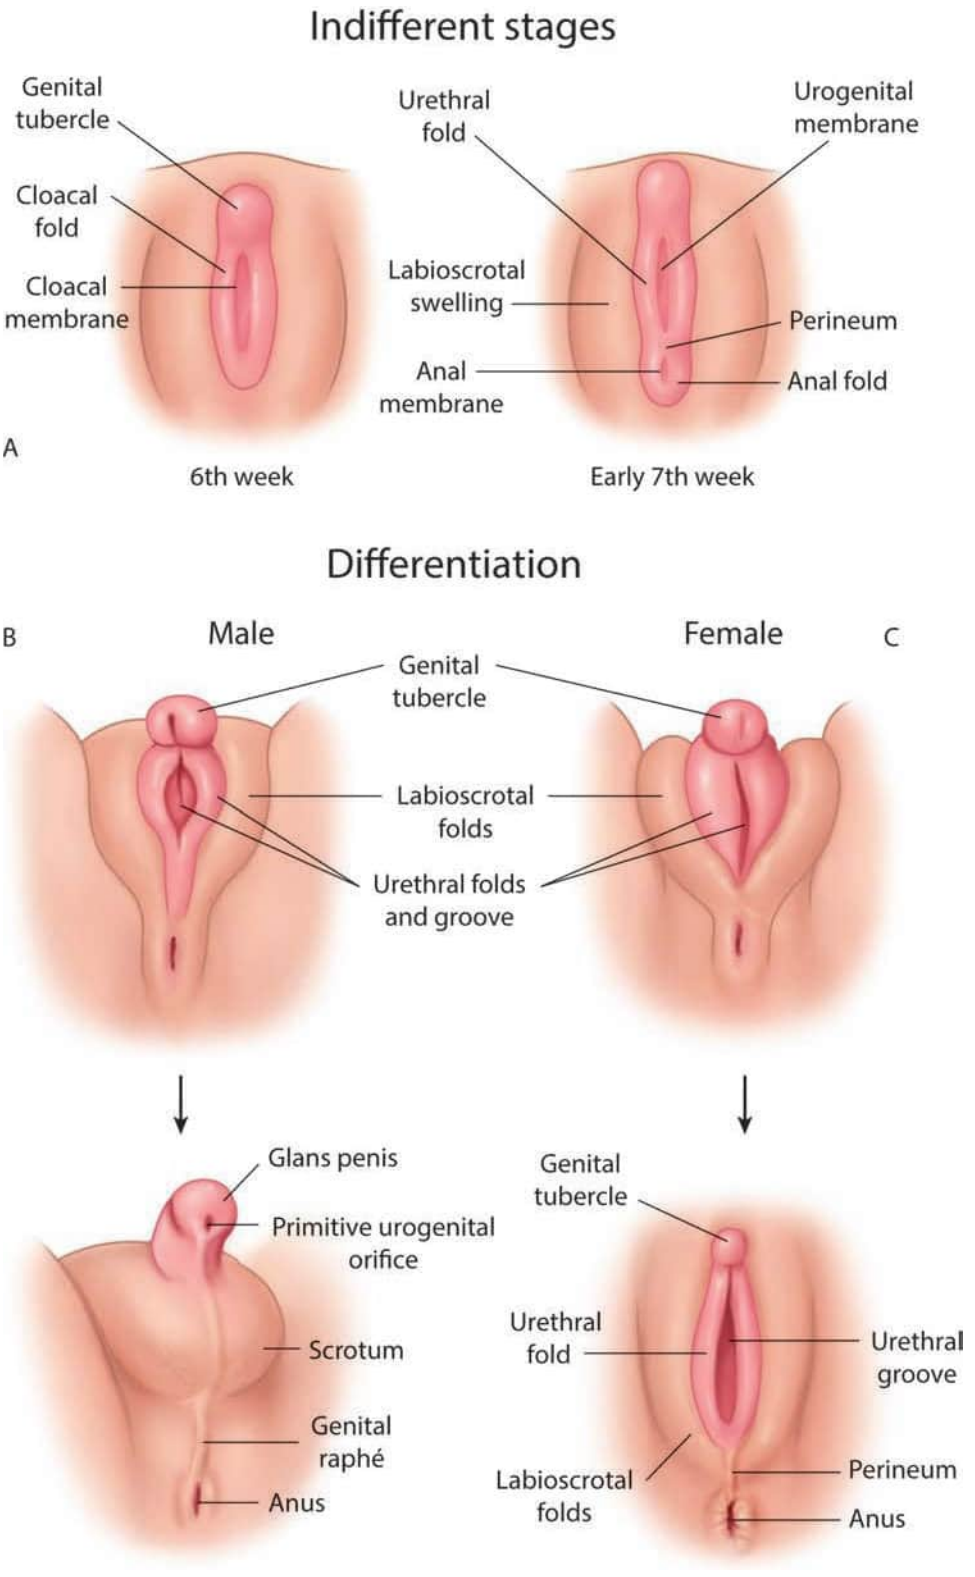

FIGURE 3-3 Development of the external genitalia. **A.** Indifferent stage. **B.** Virilization of external genitalia. **C.** Feminization.

vestibule of the vagina. The labioscrotal folds create the labia majora, whereas the urethral folds persist as the labia minora. Female external genitals are differentiated by 11 weeks, whereas male external genital differentiation is complete by 14 weeks.

To differentiate phenotypic gender early, first-trimester sonography relies on the angle of the genital tubercle off a horizontal line drawn parallel to the lumbosacral skin surface (Fig. 3-4) (Efrat, 2006). Specifically, male gender is assigned if the angle is >30°, and female gender if the angle is <10°.

SEXUAL DIFFERENTIATION

Defining gender incorporates genetic gender, gonadal gender, and phenotypic gender. *Genetic gender*—XX or XY—is established at fertilization. However, for the first 6 weeks, male and female embryos are morphologically indistinguishable.

Gonadal gender is heralded by the differentiation of the primordial gonad into a testis or an ovary. If a Y chromosome is present, the gonad begins developing into a testis. Testis development is directed by the *sex-determining region (SRY)* gene, located on the short arm of the Y chromosome (Sinclair, 1990). In addition, testis development requires other autosomal genes that include *SOX9*, *WT1*, *DAX1*, *WNT4*, and *NR5A1(SF1)* (Grinspon, 2019). Identified mutations in these and others are linked to disorders of sex development, described next.

The importance of the *SRY* gene is demonstrated in several paradoxical conditions. For example, 46,XX phenotypic males can result from translocation of the Y chromosome fragment containing *SRY* to the X chromosome during meiosis of male germ cells (Yue, 2019). Similarly, 46,XY individuals can appear phenotypically female if they carry a mutation in the *SRY* gene (Helszer, 2013).

Last, *phenotypic gender* begins at 8 weeks' gestation. Before this, urogenital tract development in both sexes is homologous. Thereafter, differentiation of the internal and external genitalia to the male phenotype is dependent on testicular function and response. In its absence, female differentiation ensues irrespective of genetic gender (Table 3-1) (She, 2017).

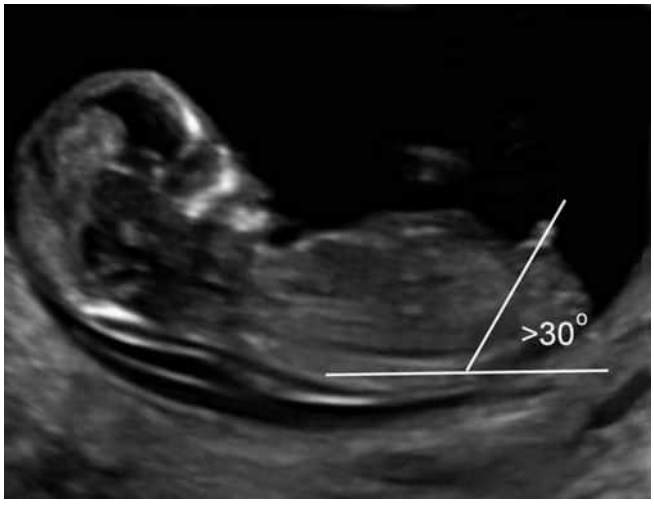

FIGURE 3-4 First-trimester transvaginal sonogram shows a male fetus, whose phallus lies at an angle that is ≥30 degrees above the horizontal. The horizontal line aligns with the fetal lumbosacral skin. (Reproduced with permission from Dr. Ashley Zink.)

In males, the Sertoli cells of the fetal testis secrete a protein called antimüllerian hormone (AMH), also named müllerian-inhibiting substance (MIS). It acts locally as a paracrine factor to cause müllerian duct regression (Grinspon, 2020; Mäkelä, 2019). Thus, it prevents development of the uterus, fallopian tube, and upper vagina. Sertoli cells secrete AMH before differentiation of Leydig cells, which synthesize testosterone. AMH is secreted as early as 7 weeks, and müllerian duct regression is completed by 9 to 10 weeks. Because AMH acts locally near its site of formation, if a testis were absent on one side, the müllerian duct on that side would persist, and the uterine horn and fallopian tube would develop on that side.

Through stimulation initially by human chorionic gonadotropin (hCG), and later by fetal pituitary luteinizing hormone (LH), Leydig cells secrete testosterone. This hormone acts directly on the wolffian duct to promote development of the vas deferens, epididymis, and seminal vesicles. Testosterone also enters fetal blood and acts on the external genitalia. In these tissues, testosterone is converted to 5α-DHT to cause virilization of the external genitalia. Leydig cells also produce insulin-like factor 3, which prompts embryonic testes to descend by acting on the gubernaculum (Ivell, 2009).

DISORDERS OF SEX DEVELOPMENT

Definitions

Abnormal sex development may involve the gonads, internal duct system, or external genitalia. Current classification of *disorders of sex development (DSDs)* include: (1) sex chromosome DSDs, (2) 46,XY DSDs, and (3) 46,XX DSDs (Table 3-2) (Hughes, 2006). Rates vary depending on included entities and approximate 1 case in every 5000 births (Lee, 2016).

Other terms describe abnormal phenotypic findings. First, some DSDs have abnormal, underdeveloped gonads, that is, *gonadal dysgenesis*. With this, a poorly formed testis is called a *dysgenetic testis*. A poorly formed ovary is a *streak gonad*. Underdeveloped gonads ultimately fail, which creates low sex steroid hormone levels but elevated follicle-stimulating hormone (FSH) and LH levels.

A second term, *ambiguous genitalia*, describes genitalia that do not appear clearly male or female. Abnormalities can include hypospadias, undescended testes, micropenis or enlarged clitoris, labial fusion, and labial mass.

Last, *ovotesticular* defines a rare state characterized by ovarian and testicular tissue in the same individual. It was formerly termed true hermaphroditism. In these cases, different gonad types can be paired. Pair combinations may include a normal testis, a normal ovary, a streak gonad, a dysgenetic testis, or an *ovotestis*. In the last, both ovarian and testicular elements are combined within the same gonad.

With ovotesticular cases, the internal ductal system structure depends on the type of ipsilateral gonad and its function. Specifically, the amount of AMH and testosterone determines the degree to which the internal ductal system is retained or

TABLE 3-1. Embryonic Urogenital Structures and Their Adult Homologues

Indifferent Structure	Female	Male
Genital ridge	Ovary	Testis
Primordial germ cells	Ova	Spermatozoa
Sex cords	Granulosa cells	Seminiferous tubules, Sertoli cells
Gubernaculum	Uteroovarian and round ligaments	Gubernaculum testis
Mesonephric tubules	Epoöphoron, paroöphoron	Efferent ductules, paradidymis
Mesonephric ducts	Gartner duct	Epididymis, vas deferens, ejaculatory duct
Paramesonephric ducts	Uterus, fallopian tubes, upper vagina	Prostatic utricle, appendix of testis
Urogenital sinus	Bladder, urethra	Bladder, urethra
	Vagina	Prostatic utricle
	Paraurethral glands	Prostate glands
	Greater (Bartholin) and lesser vestibular glands	Bulbourethral glands
Genital tubercle	Clitoris	Glans penis
Urogenital folds	Labia minora	Floor of penile urethra
Labioscrotal swellings	Labia majora	Scrotum

TABLE 3-2. Disorders of Sex Development (DSD) Classification

Sex Chromosome DSD
45,X Turner[a]
47,XXY Klinefelter[a]
45,X/46,XY Mixed gonadal dysgenesis
46,XX/46,XY Ovotesticular DSD
46,XY DSD
Testicular development abnormalities
Complete gonadal dysgenesis
Partial gonadal dysgenesis
Ovotesticular
Testicular regression syndrome
Androgen production or action defects
Androgen synthesis
Androgen receptor
LH/hCG receptor
AMH
Persistent müllerian duct syndrome
Other structure-affecting syndrome

AMH = antimüllerian hormone; hCG = human chorionic gonadotropin; LH = luteinizing hormone.

reabsorbed (p. 35). With inadequate AMH, müllerian duct derivatives persist. With inadequate testosterone, external genitalia are usually ambiguous and undermasculinized. Ovotesticular development may be found in all three of the DSD categories, and each of these sections describes examples (see Table 3-2).

Germ Cell Cancer

This cancer can develop in dysgenetic gonads of patients bearing all or part of the Y chromosome. On the Y chromosome, the gene for *testis-specific protein Y (TSPY)* is one putative cancer-predisposing gene. Other risks include disturbed gonadal development, delayed germ cell maturation, and presence of a gonadoblastoma (Cools, 2014). The last is a benign tumor that contains germ cells and immature granulosa cells (Roth, 2018).

Germ cell cancer (GCC) risk varies among DSD types, but for some, gonadectomy may be recommended by a multispecialty DSD team (Lee, 2016). Early surgery benefits those with higher GCC risk and those in whom gonadal hormones may run counter to preferred pubertal development for the individual's chosen gender identity. Later surgery may benefit those with low GCC risk and in whom gonadal hormones would advance desired pubertal development (van der Zwan, 2015).

In addition to dysgenetic gonads, undescended testes also have higher GCC rates (Kolon, 2014). Instead of gonadectomy, orchiopexy, which translocates and fixes a testis into the scrotum, may be protective (Radmayr, 2016; Walsh, 2007).

Sex Chromosome DSD

Cases in this first DSD category typically arise from an abnormal number of sex chromosomes, that is, *sex chromosome aneuploidy (SCA)*. The population rate approximates 1 case per 2500 births (Howard-Bath, 2018).

Discussed fully in Chapter 17 (p. 333), prenatal screening methods allow detection of aneuploidies, including SCAs (Norton, 2016). Sonographically, a thick nuchal translucency or the presence of cystic hygromas is associated with an increased SCA risk (American College of Obstetricians and Gynecologists, 2020; Reiss, 2017). Cell-free DNA present in the maternal blood is another common aneuploidy screening tool (Fig. 16-14, p. 328) (Huang, 2018; Vogel, 2019). Its selection solely for gender identification and without a medical indication is not recommended by the American College of Medical Genetics and Genomics (Gregg, 2016). Still, with cell-free DNA use for other indications, antenatal detection of SCAs will likely rise. Interpretation and management of findings is discussed in Chapter 17 (p. 335). Advantageously, early recognition of sex chromosome DSD offers an opportunity for patient education. Decisions to end or continue pregnancies are best guided by clinical geneticists. For continued pregnancies, prenatal diagnosis allows early postnatal interventions (Gravholt, 2017).

Turner Syndrome

This develops from de novo loss or severe structural abnormality of one X chromosome in a phenotypic female. Most affected fetuses are spontaneously aborted. However, 1 in 2000 female live births are affected (Lin, 2019). In survivors with Turner syndrome, phenotype varies but nearly all affected patients have short stature. Associated problems can include hypertension; cardiac abnormalities, especially aortic coarctation, bicuspid aortic valve, and QT-interval prolongation; and renal, skeletal, and otolaryngological anomalies. A webbed posterior neck results from cystic hygromas. Metabolic concerns are diabetes mellitus (DM), autoimmune thyroiditis, celiac disease, and elevated liver enzymes (Gravholt, 2019). Two streak ovaries are typically found, and this syndrome is the most common form of gonadal dysgenesis that leads to primary ovarian insufficiency (POI). POI is the depletion or dysfunction of ovarian follicles that leads to failing sex hormone production. The uterus and vagina are normal and respond to prescribed hormones (Matthews, 2017).

Despite eventual POI, women with Turner syndrome may conceive with assisted reproductive technologies (ART) and rarely spontaneously (Hovatta, 1999; Oktay, 2016). In gravidas with Turner syndrome, cardiac morbidity stems from aortic dissection, aortic valve stenosis, and hypertension. For

this reason, maternal–fetal medicine preconceptional counseling and cardiologist evaluation is essential. For aortic dissection, risk rises as the aortic diameter increases. The ascending *aortic size index (ASI)*, which is the aortic diameter divided by body surface area, better reflects risk because it accounts for short stature. Conception should be avoided with an ASI >2.5 cm/m^2 or with an ASI of 2.0 to 2.5 cm/m^2 plus comorbid aortic dissection risk factors. These include bicuspid aortic valve, transverse aortic arch elongation, aortic coarctation, and hypertension (Gravholt, 2017; Silberbach, 2018). The American Society for Reproductive Medicine (2012) recommends against pregnancy with an ASI >2 cm. Even without identified risk, aortic dissection can develop in pregnancy (Carlson, 2007).

If conception is planned, preconceptional evaluation includes echocardiography, combined computed tomography plus cardiac magnetic resonance (CMR) imaging of the heart/aorta, 24-hour ambulatory blood pressure monitoring, exercise testing to reveal exercise-induced hypertension, and electrocardiogram (Gravholt, 2017). Cardiac disorders may require surveillance with serial echocardiograms.

This syndrome carries higher fetal rates of miscarriage, preterm birth, and small-for-gestational age. Preeclampsia, gestational diabetes, and cholestasis of pregnancy are other maternal risks (Dotters-Katz, 2016a; Grewal, 2021). Thus, baseline serum tests ideally assess renal, liver, and thyroid function and screen for DM (Bouet, 2016). These complications and cephalopelvic disproportion account for cesarean delivery rates of 40 to 80 percent in gravidas with Turner syndrome (Cadoret, 2018; Campens, 2021; Dotters-Katz, 2016a).

Klinefelter Syndrome

This syndrome has an estimated prevalence of 1 case per 650 newborn males fetuses (Bojesen, 2003; Radicioni, 2010). With chromosome complement of 47,XXY, these individuals tend to be tall, undervirilized males with gynecomastia and two small, firm testes. They have greatly reduced fertility from hypogonadism due to gradual testicular failure. These men are at increased risk for mediastinal germ cell tumors, osteoporosis, hypothyroidism, DM, breast cancer, cardiovascular abnormalities, and neurobehavioral disorders (Groth, 2013).

Affected fetuses may show a thick NT during first-trimester sonography (Gruchy, 2011). Antepartum risks include preterm birth, cesarean delivery, small-for-gestational-age fetus, and neonatal death (Dotters-Katz, 2016b).

47,XXX and 47,XYY Karyotypes

These rare karyotypes are found in 1 in 10,000 newborn females and 2 in 10,000 newborn males, respectively (Berglund, 2019). Sonographically, fetuses with either karyotype may show a thick NT and fetal-growth restriction (Gruchy, 2016). Phenotypic range is wide, but both may be taller, show subtle facial and skeletal dysmorphisms, and display neurobehavioral problems such as autism spectrum and attention-deficit/hyperactivity disorders (Bardsley, 2013; Urbanus, 2020; Widby 2016). Hormone levels and fertility are unaffected in most, although POI and semen abnormalities may be seen, respectively.

Sex Chromosomal Ovotesticular DSD

In the sex chromosome DSD group, ovotesticular DSD may arise from a 46,XX/46,XY karyotype. Here, an ovary, testis, or ovotestis may be paired. For others, ovotesticular DSD arises from a chromosomal mosaic such as 45,X/46,XY. With this karyotype, *mixed gonadal dysgenesis* shows a streak gonad on one side and either a dysgenetic testis or normal testis on the other. For this reason, phenotypic gender varies widely.

46,XY DSD

Insufficient androgen exposure of a fetus destined to be a male leads to 46,XY DSD—formerly called male pseudohermaphroditism. Testes are often present, and the uterus is generally absent due to the normal action of AMH. These individuals are usually sterile from abnormal spermatogenesis and a small phallus that is inadequate for coitus. Described next, the etiology of 46,XY DSD may stem from abnormal testis development or from abnormal androgen production or action (see Table 3-2). Rarely, 46,XY DSD may be part of another metabolic syndrome that alters structural development, such as Smith-Lemli-Opitz syndrome (Neri, 1999).

46,XY Gonadal Dysgenesis

This spectrum of abnormal gonad underdevelopment includes complete, partial, or mixed 46,XY gonadal dysgenesis. These are defined by karyotype and by the amount of abnormal testicular tissue. Because of the potential for GCC, gonadectomy is often recommended (p. 36).

Of these, *complete gonadal dysgenesis* results from a mutation in the *SRY* gene or in other genes with testis-determining effects (Hutson, 2014). Swyer syndrome reflects *SRY* defects, whereas Frasier and Denys-Drash syndromes have *WT1* mutations. With both mutations, underdeveloped dysgenetic gonads fail to produce androgens or AMH, which results a normal prepubertal female phenotype and a normal müllerian system.

Partial gonadal dysgenesis defines those with gonad development intermediate between normal and dysgenetic testes. Depending on percentages, wolffian and müllerian structures and genital ambiguity are variably expressed.

Mixed gonadal dysgenesis is one type of ovotesticular DSD. As discussed in the last section, one gonad is streak, and the other is a normal testis or a dysgenetic testis. The phenotype is wide ranging.

Last, *testicular regression* can follow initial testis development (McElreavey, 2020). The phenotypic spectrum is broad and depends on the timing of testis failure.

Abnormal Androgen Production or Action

Some cases of 46,XY DSD stem from abnormalities in: (1) testosterone biosynthesis, (2) LH-receptor function, (3) AMH function, or (4) androgen-receptor action. First, the sex-steroid biosynthesis pathway can suffer enzymatic defects that block testosterone production. Depending on blockade timing and degree, undervirilized males or phenotypic females may result. In contrast to these central enzymatic defects, peripheral defects can be causative. Namely, abnormal action of 5α-reductase

type 2 enzyme impairs conversion of testosterone to DHT and blunts virilization.

Second, hCG/LH receptor abnormalities within the testes can lead to Leydig cell hypoplasia and decreased testosterone production. In contrast, disorders of AMH and AMH receptors result in persistent müllerian duct syndrome (PMDS). These patients appear as males but have a persistent uterus and fallopian tubes due to failed AMH action.

Last, the androgen receptor may be defective and result in androgen-insensitivity syndrome (AIS). Resistance to androgens may be incomplete and result in varying degrees of virilization and genital ambiguity. Milder forms may lead to poorly virilized men with severe male-factor infertility.

Those with complete androgen-insensitivity syndrome (CAIS) are phenotypically normal females. Girls often present at puberty with primary amenorrhea. External genitalia appear normal; pubic and axillary hair are scant or absent; the vagina is markedly shortened; and the uterus and fallopian tubes are absent. However, these individuals develop breasts during puberty due to conversion of androgen to estrogen. Testes may be palpable in the labia or groin or may lie intraabdominally. Traditionally, testes are removed. However, women with AIS have a low risk of GCC, and retention until after puberty allows hormone-mediated breast and bone mass development. Despite hormone replacement after ultimate gonadectomy, many individuals describe hormone-related mood imbalance. New cancer-surveillance protocols may allow gonad retention (Cools, 2017; Weidler, 2019).

46,XX DSD

This DSD group may stem from abnormal ovarian development or from excess androgen exposure.

Abnormal Ovarian Development

Disorders of ovarian development in those with a 46,XX complement include: (1) gonadal dysgenesis, (2) testicular DSD, and (3) ovotesticular DSD.

With *46,XX gonadal dysgenesis*, similar to Turner syndrome, streak gonads develop. These lead to hypogonadism, prepubertal normal female genitalia, and normal müllerian structures. However, other Turner stigmata are absent.

With *46,XX testicular DSD*, several genetic mutations lead to testis-like formation. Most commonly, defects stem from *SRY* translocation onto one paternal X chromosome. Less often, other genes with testis-determining effects are activated. Regardless, AMH prompts müllerian system regression, and androgens promote wolffian system development and external genitalia masculinization. Spermatogenesis, however, is absent because needed genes on the long arm of the Y chromosome are lacking. These persons are not usually diagnosed until puberty or during infertility evaluation.

With *46,XX ovotesticular DSD*, individuals possess a unilateral ovotestis with a contralateral ovary or testis, or bilateral ovotestes. An overexpression of *SOX* genes, which are testis promoting, or deficient ovarian promoting genes are implicated (Grinspon, 2019). Phenotypic findings depend on the degree of androgen exposure.

Androgen Excess

Discordance between female gonadal sex and phenotypically masculine external genitalia may also result from excessive fetal androgen exposure. The prior term was female pseudohermaphroditism. In affected individuals, the ovaries and female internal ductal structures such as the uterus, cervix, and upper vagina develop. Thus, patients are potentially fertile. The external genitalia, however, are variably virilized depending on the amount and timing of androgen exposure. The embryonic clitoris, labioscrotal folds, and urogenital sinus are commonly affected by elevated androgen levels. Virilization may range from modest clitoromegaly to posterior labial fusion and a phallus with a penile urethra. Degrees of virilization can be described by the *Prader score*, which ranges from 0 for a normal-appearing female to 5 for a normal, virilized male. The *external genitalia score* is another and similarly ranges from 0 to 12, respectively (Ahmed, 2000; van der Straaten, 2020).

Fetal, placental, or maternal sources can provide the excessive androgen levels. Maternally derived androgen excess may come from virilizing ovarian tumors such as luteoma and Sertoli-Leydig cell tumor or from virilizing adrenal tumors. Fortunately, these neoplasms infrequently cause fetal effects because of the placental syncytiotrophoblast's tremendous ability to convert C_{19} steroids—androstenedione and testosterone—into estradiol via the enzyme aromatase (Chap. 5, p. 101). As another source, drugs such as testosterone, danazol, and other androgen derivatives may virilize.

Of fetal sources, exposure can arise from fetal congenital adrenal hyperplasia (CAH). This stems from a fetal enzyme deficiency in the steroidogenic pathway and leads to androgen accumulation. Most cases have a 21-hydroxylase deficiency. Rarely, others involve deficient 3β-hydroxysteroid dehydrogenase, 17α-hydroxylase, cholesterol side-chain cleavage enzyme, P450 oxidoreductase, or 11β-hydroxylase (El-Maouche, 2017; Narasimhan, 2019). CAH is a frequent cause of virilization, and its approximate incidence in the United States is 1 case in 18,000 live births (Chan, 2013; Pearce, 2016).

With CAH, phenotypes depend on the enzyme defect's location in the steroidogenic pathway and its severity (Miller, 2011). Classically, deficient enzymes block corticosteroid production, which feeds back to raise adrenocorticotropic hormone (ACTH) levels. This prompts increased levels of precursors, which detour into pathways that generate androgens. With severe deficiency, affected newborns also have blocked aldosterone production that leads to life-threatening salt wasting. This is typified by hyponatremia, hyperkalemia, metabolic acidosis, and hypovolemia (Bizzarri, 2016). Other mutations may prompt fetal virilization alone (Auchus, 2015).

The mildest abnormalities present later and are described as "nonclassic," "late-onset," or "adult-onset" CAH. In these patients, adrenal axis activation at puberty increases steroidogenesis and unmasks mild enzymatic deficiency. Excess androgen provides negative feedback to gonadotropin-releasing hormone (GnRH) receptors in the hypothalamus. These patients often have hirsutism, acne, and anovulation. Thus, late-onset CAH may mimic polycystic ovarian syndrome (McCann-Crosby, 2014).

In some instances, CAH can be diagnosed antenatally. Early maternal dexamethasone therapy can dampen androgen excess to minimize virilization (Chap. 19, p. 369). Cell-free DNA can identify fetal gonadal gender. If Y-chromosome cell-free DNA is identified, androgens will not harm the male fetus and maternal dexamethasone treatment can be stopped (Tardy-Guidollet, 2014).

Of rare placental sources, placental aromatase deficiency from a fetal *CYP19* gene mutation causes accumulation of placental androgen and underproduction of placental estrogens (Chap. 5, p. 102) (Jones, 2007). Consequently, both the mother and the 46,XX fetus are virilized.

Gender Assignment

Delivery of a newborn with a DSD is a potential medical emergency and can also create possible long-lasting psychosexual and social ramifications for the individual and family. Ideally, once the affected neonate is stable, parents are encouraged to hold the child. The newborn is referred to as "your baby," and suggested terms include "phallus," "gonads," "folds," and "urogenital sinus" to reference underdeveloped structures. An obstetrician explains that the genitalia are incompletely formed and emphasizes the situation's seriousness and need for rapid consultation and laboratory testing.

Because similar or identical phenotypes may have several etiologies, identification of a specific DSD may require several diagnostic tools (McCann-Crosby, 2015). Relevant historical questions seek prior obstetrical outcomes, medication inventory, consanguinity, germane antenatal testing and sonography results, and family history of genetic or structural anomalies. Signs of maternal hyperandrogenism are sought. Neonatal physical examination evaluates: (1) ability to palpate gonads in the labioscrotal or inguinal regions, (2) ability to palpate uterus during rectal examination, (3) phallus size, (4) other syndromic features, and (5) genitalia pigmentation, which derives from increased melanocyte-stimulating hormone levels that can accompany ACTH secretion. The newborn metabolic condition is assessed, and hyperkalemia, hyponatremia, and hypoglycemia may indicate CAH. Other neonatal tests include genetic studies, hormone measurements, imaging, and in some cases endoscopic, laparoscopic, and gonadal biopsy. Sonography or magnetic resonance (MR) imaging can help identify müllerian/wolffian structures, gonad location, and associated malformations such as renal anomalies.

BLADDER AND PERINEAL ABNORMALITIES

During embryo formation, a bilaminar cloacal membrane lies at the caudal end of the germinal disc and forms the infraumbilical abdominal wall. Normally, an ingrowth of mesoderm between the ectodermal and endodermal layers leads to formation of the lower abdominal musculature and pelvic bones. Without this reinforcement, the cloacal membrane may prematurely rupture. Depending on the infraumbilical defect's extent, cloacal exstrophy, bladder exstrophy, or epispadias may result, and all are rare.

Cloacal exstrophy, also known as the omphalocele, bladder exstrophy, imperforate anus, spina bifida (OEIS) complex, affects approximately 1 in 300,000 live births (Keppler-Noreuil, 2007; Woo, 2010). With *bladder exstrophy*, the bladder lies outside the abdomen, is open, drains directly into amnionic fluid, and thus does not fill. Sonography in the first trimester may show a thin-walled, lower-abdominal cystic structure and a thick NT (Mallmann, 2014; Tonni, 2011). During second-trimester scans, findings are a midline, infraumbilical, anterior-abdominal-wall defect, failure to see the bladder, and associated OEIS defects (Ben-Neriah, 2007). Prenatal karyotyping is recommended. Delivery route is usually dictated by the associated spina bifida defect. Postnatal repair is complex, and individuals may struggle with urinary and fecal incontinence and the challenges of neonatal gender assignment (Woo, 2010).

With *bladder exstrophy*, associated findings often include abnormal external genitalia and a widened symphysis pubis. At the same time, however, the uterus, fallopian tubes, and ovaries are typically normal except for occasional müllerian duct fusion defects. Although often not identified in affected fetuses, sonographic indicators are inability to see the bladder, solid mass between the umbilical arteries, low umbilical insertion into the abdomen, divergent pubic rami, normal amnionic fluid volume, and in males, a small penis with anteriorly displaced scrotum (Mallmann, 2019). The differential diagnosis includes bladder exstrophy or agenesis, bilateral ectopic ureters, patent urachus, cloacal exstrophy, and simple nonvisualization of the bladder. MR imaging may be a helpful adjunct (Goldman, 2013). Fetal karyotyping is considered if genitalia are ambiguous. For an affected fetus, the prenatal course is typically routine, and cesarean delivery is reserved for obstetrical indications.

For a gravida with bladder exstrophy herself, pregnancy is associated with greater risk for antepartum pyelonephritis, urinary retention, ureteral obstruction, pelvic organ prolapse, miscarriage, preterm birth, and breech presentation. The American Urological Association has published management guidelines for pregnancy (Eswara, 2016). Due to the extensive adhesions from prior repair and altered anatomy typically encountered, some recommend planned early cesarean delivery at a tertiary center (Deans, 2012; Greenwell, 2003). Dy and coworkers (2015) described using paramedian abdominal wall and vertical uterine incisions.

Epispadias without bladder exstrophy is rare and develops in association with other anomalies such as a widened, patulous urethra; absent or bifid clitoris; nonfused labial folds; and flattened mons pubis. Vertebral abnormalities and pubic symphysis diathesis are also common.

Clitoral anomalies are rare. One is clitoral duplication or bifid clitoris, which usually develops in association with bladder exstrophy or epispadias. With *female phallic urethra*, the urethra opens at the clitoral tip. Last, *clitoromegaly* noted at birth suggests fetal exposure to excessive androgens (p. 38). Without a DSD, idiopathic congenital clitoromegaly in females born extremely premature is rare but well-recognized, and observation is recommended (Williams, 2013).

As noted, the hymen marks the embryological boundary between structures derived from the müllerian and urogenital sinus. *Hymeneal anomalies* include imperforate, microperforate,

cribriform (sievelike), navicular (boat-shaped), and septate hymens. They result from failure of the inferior end of the vaginal plate—the hymeneal membrane—to canalize. Rarely, with an imperforate hymen, secretions may markedly accumulate in the fetal uterus and vagina, that is, hydrometrocolpos (HMC). Most cases of HMC are asymptomatic and resolve postnatally as mucus is reabsorbed and estrogen levels decline. Rarely, perinatal urinary tract obstruction results from mass effect and is relieved with cruciate incision of the hymen (Grimstad, 2019).

Fetal HMC sonographically appears as a cystic mass behind the bladder. The differential diagnosis includes reproductive tract outlet obstruction of the hymen, vagina, or cervix; ureterocele; megacystis; ovarian, urachal, or mesenteric cyst; anterior meningocele; bowel or bladder duplications; and urogenital sinus or cloacal dysgenesis. Rare associated syndromes are McKusick-Kaufman, Ellis-van Creveld, or Bardet-Biedl syndromes (Garcia Rodriguez, 2018).

MÜLLERIAN ABNORMALITIES

Four principal abnormalities arise from defective müllerian duct embryological steps: (1) agenesis of both ducts, either focally or along the entire duct length; (2) unilateral maturation of one müllerian duct with incomplete or absent development of the opposite side; (3) absent or faulty midline fusion of the ducts; or (4) defective canalization. Various classifications have been proposed, and Table 3-3 shows the one from the American Fertility Society (1988). This classification system is the most widely used, although several others have been created (Grimbizis, 2013, 2016; Ludwin, 2018b).

TABLE 3-3. Classification of Müllerian Anomalies

- **I. Segmental müllerian hypoplasia or agenesis**
  - a. Vaginal
  - b. Cervical
  - c. Uterine fundal
  - d. Tubal
  - e. Combined anomalies
- **II. Unicornuate uterus**
  - a. Communicating rudimentary horn
  - b. Noncommunicating horn
  - c. No endometrial cavity
  - d. No rudimentary horn
- **III. Uterine didelphys**
- **IV. Bicornuate uterus**
  - a. Complete—division to internal os
  - b. Partial
- **V. Septate uterus**
  - a. Complete—septum to internal os
  - b. Partial
- **VI. Arcuate**
- **VII. Diethylstilbestrol related**

Data from American Fertility Society: The American Fertility Society classifications of adnexal adhesions, distal tubal occlusion, tubal occlusion secondary to tubal ligation, tubal pregnancies, Müllerian anomalies and intrauterine adhesions, Fertil Steril 1988 Jun;49(6):944–955.

A müllerian anomaly is suspected if a vaginal septum, blind-ending vagina, or duplicated cervix is found. Amenorrhea may be an initial complaint for those with agenesis of a müllerian component. In those with outlet obstruction but functioning endometrium, pelvic pain may arise from occult blood that accumulates and distends the vagina, uterus, or fallopian tubes (Kapczuk, 2018; Patel, 2016). Endometriosis and its associated dysmenorrhea, dyspareunia, and chronic pain are also frequent with outlet obstruction (Matalliotakis, 2017).

Comorbid Renal Anomalies

Renal anomalies most frequently accompany unicornuate uterus, uterine didelphys, and anomalies with an ipsilateral obstructive vaginal septum. Less often, partial bicornuate, and partial septate uteri are associated (Heinonen, 2018). When müllerian anomalies are identified, the urinary system can be evaluated with sonography, MR imaging, or intravenous pyelography (Hall-Craggs, 2013). The last two are advantageous because ureteral anatomy can be affected too. An absent unilateral kidney is the most common finding. On the other hand, if renal agenesis is found first, reproductive-tract imaging in early puberty may help identify müllerian anomalies early (Friedman, 2018).

Müllerian Agenesis (Class I)

Class I segmental defects are caused by müllerian hypoplasia or agenesis as shown in Figure 3-5 (American Fertility Society, 1988). These developmental defects can affect the vagina, cervix, uterus, or fallopian tubes and may be isolated or may coexist with other müllerian anomalies.

Vaginal Abnormalities

Of these, vaginal agenesis is the most profound and may be isolated or associated with other müllerian anomalies. One example is the Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome, in which upper vaginal agenesis is typically associated with uterine hypoplasia or agenesis. Less often, this syndrome also displays additional abnormalities and is known by the acronym MURCS (müllerian duct aplasia, renal aplasia, and cervicothoracic somite dysplasia) (Rall, 2015).

The obstetrical significance of vaginal anomalies depends greatly on the degree of obstruction. Complete vaginal agenesis, unless corrected surgically, precludes pregnancy by vaginal intercourse. With MRKH syndrome, a functional vagina can be created, but uterine agenesis proscribes childbearing. In these women, however, ova can be retrieved for in vitro fertilization (IVF) and carriage by a surrogate mother (Reichman, 2010). Uterine transplantation is experimental but holds promise for these women (Johannesson, 2021; Jones, 2019).

Of other vaginal anomalies, congenital septa may form longitudinally or transversely, and each can arise from a fusion or resorption defect. A *longitudinal septum* divides the vagina into right and left portions. It may be complete and extend the

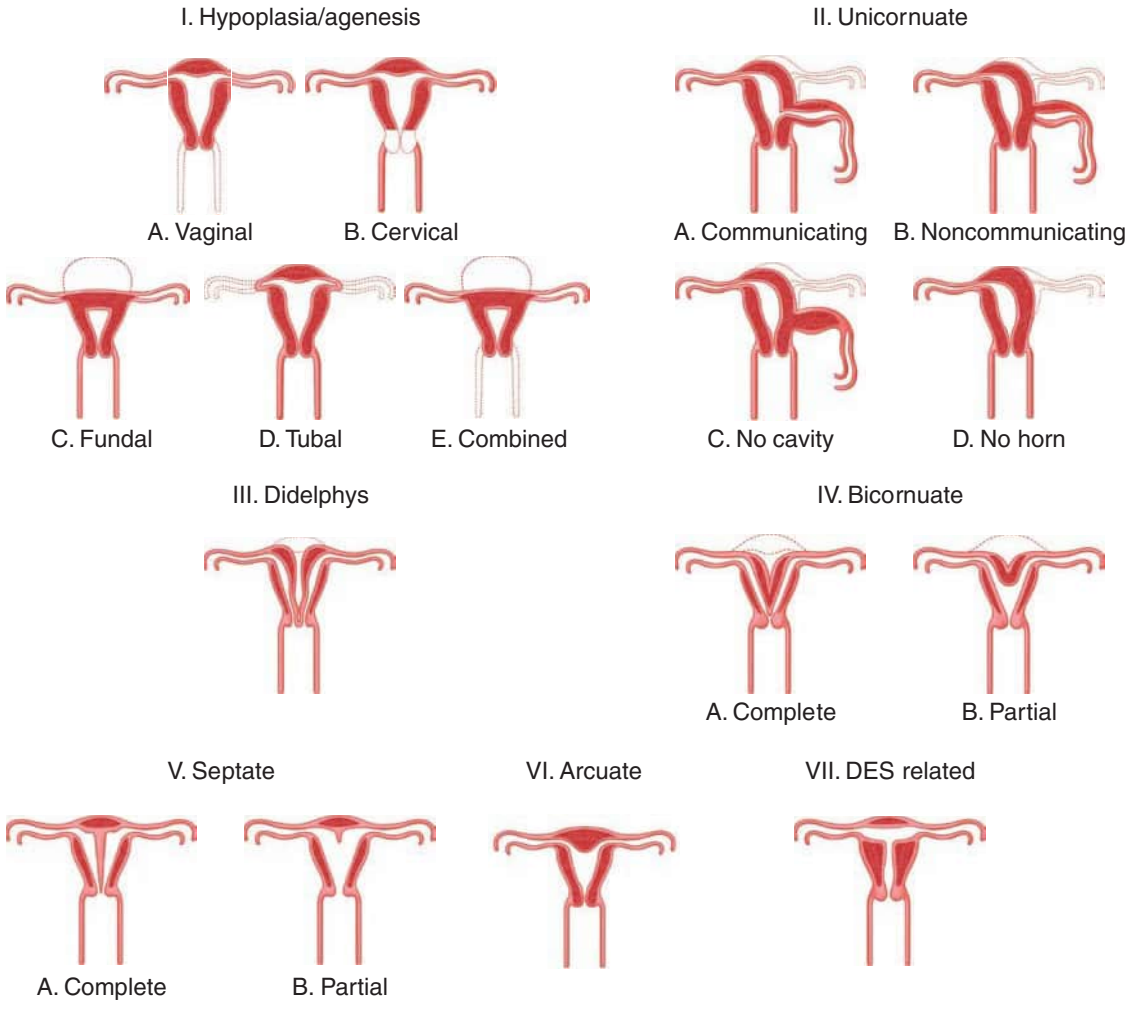

FIGURE 3-5 Classification of müllerian anomalies. DES = diethylstilbestrol.

entire vaginal length. A partial septum usually forms high in the vagina but may develop at lower levels. These septa are often associated with other müllerian anomalies (Haddad, 1997).

During examination, the provider can usually guide a speculum up along one side of the septum. Similarly, in labor, a complete longitudinal vaginal septum usually does not cause dystocia because the fetus can descend through one vaginal side, which dilates sufficiently. An incomplete distal longitudinal septum, however, may interfere with descent, and antepartum resection is preferred (Hoffman, 2020). Rarely, a woman with an incomplete distal longitudinal septum instead presents in labor. During second-stage labor, this septum usually becomes attenuated by pressure from the fetal head. After ensuring adequate analgesia, the attachment of the septum to the posterior vaginal wall is isolated between two clamps, transected, and ligated. Following placenta delivery, the superior attachment is similarly isolated between clamps and transected, while carefully avoiding urethral injury.

A *transverse septum* poses an obstruction of variable thickness. It may develop at any depth within the vagina, but most lie in the lower third (Williams, 2014). Septa may or may not be perforate, and thus obstruction or infertility is possible.

In labor, perforate strictures may be mistaken for the upper limit of the vaginal vault, and the septal opening is misidentified as an undilated cervix (Kumar, 2014). If encountered during labor, and after the cervix has dilated completely, the head impinges on the septum and causes it to bulge downward. If the septum does not spontaneously yield, slightly stretching its opening usually leads to further dilation. Occasionally cruciate incisions that avoid the urethra and rectum are required to permit delivery (Blanton, 2003; Levin, 1963). For a thick transverse septum, cesarean delivery may be necessary.

■ Cervical Abnormalities

Developmental abnormalities of the cervix include partial or complete agenesis, duplication, or a longitudinal dividing septum. Complete agenesis is incompatible with pregnancy. IVF with gestational surrogacy or with transmyometrial embryo transfer are options (Al-Jaroudi, 2011; Xu, 2009). Instead, surgical correction by uterovaginal anastomosis successfully relieves outlet obstruction, but subsequent pregnancy and live birth rates are low (Mikos, 2020). Significant complications including deaths have accompanied such corrective surgery. Some experts recommend hysterectomy for complete cervical agenesis and reserve reconstruction attempts for carefully selected patients with cervical dysgenesis (Roberts, 2011; Rock, 2010).

Uterine Abnormalities

From a large variety, a few of the more common congenital uterine malformations are shown in Table 3-3. Assessing an accurate population prevalence is difficult because the best diagnostic techniques are invasive. The prevalence found with imaging ranges from 0.4 to 10 percent, and rates in women with recurrent miscarriage are significantly higher (Byrne, 2000; Dreisler, 2014; Saravelos, 2008). In a general population, the most frequent finding is arcuate uterus, followed in descending order by septate, bicornuate, didelphic, and unicornuate classes (Chan, 2011b).

As a group, these anomalies pose greater risk for miscarriage, malpresentation, preterm birth, and poor fetal growth (Chan, 2011a; Hua, 2011; Reichman, 2009). Vaginal delivery is the preferred delivery route when feasible. The cervix of the pregnancy-containing uterus or horn will typically dilate sufficiently. Similarly, any proximal longitudinal septum will stretch to permit fetal descent.

Müllerian uterine anomalies may be discovered first during pelvic examination, cesarean delivery, tubal sterilization, or infertility evaluation. Depending on clinical presentation, sonography, hysterosalpingography (HSG), MR imaging, laparoscopy, and hysteroscopy may also be diagnostic. Each has limitations and thus may be combined to completely define anatomy.

If a müllerian anomaly is suspected, two-dimensional transvaginal sonography (2-D TVS) is initially performed in most clinical settings. For this indication, the pooled accuracy for 2-D TVS is 90 to 92 percent (Pellerito, 1992). Three-dimensional (3-D) TVS is more accurate than 2-D TVS because it provides uterine images from virtually any angle. The diagnostic accuracy of 3-D TVS approaches 97 percent (Vaz, 2017). Thus, coronal images can be constructed, and these are essential in evaluating both internal and external uterine contours. Both 2-D and 3-D TVS are suitable for use in pregnancy (Fig. 3-6).

Several studies reported good concordance between 3-D TVS and MR imaging of müllerian uterine anomalies (Deutch, 2008; Graupera, 2015). MR imaging is often preferred for complex anatomy, especially cases for which corrective surgery is planned. MR imaging provides clear delineation of both the internal and external uterine anatomy and has a reported accuracy of up to 100 percent for müllerian anomaly evaluation (Bermejo, 2010; Pellerito, 1992). Moreover, secondary diagnoses such as renal or skeletal anomalies can be concurrently evaluated. MR imaging without contrast is safe in pregnancy.

Saline infusion sonography (SIS) is a technique that instills fluid into the uterine cavity to distend and define cavity shape. It improves delineation of internal uterine morphology. However, SIS is contraindicated in pregnancy. It requires a patent endometrial cavity.

In women undergoing fertility evaluation, HSG is usually selected for uterine cavity and tubal patency assessment. It is contraindicated during pregnancy. HSG poorly defines the external uterine contour and can delineate only patent cavities. Described next, remember that some unicornuate rudimentary horns lack a cavity. Also, outlet obstructions will preclude dye filling. For infertility, hysteroscopy and/or laparoscopy plus chromotubation may help confirm or treat uterine cavity or tubal pathologies. These also screen for endometriosis, which often coexists with both infertility and müllerian anomalies (American Society for Reproductive Medicine, 2015). In pregnancy, laparoscopy is rarely used to diagnose müllerian defects, and hysteroscopy is contraindicated.

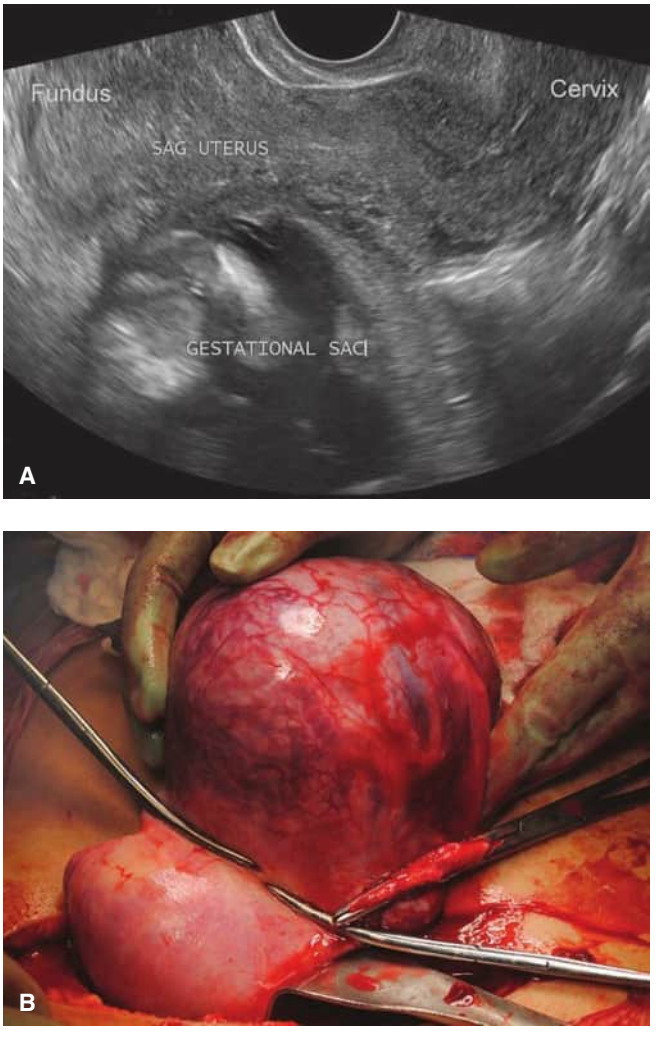

FIGURE 3-6 A. Sagittal transvaginal sonogram shows a gestational sac surrounded by myometrium. The gestational sac is not contiguous with the endocervical canal or with the main horn's endometrium. **B.** Here, two Pean clamps are placed across the vascular tissue bridge that separates the rudimentary horn (*above*) from the main uterine horn (*below*). (Reproduced with permission from Dr. Elaine L. Duryea.)

Unicornuate Uterus (Class II)

General population estimates cite an incidence of 1 case in 4000 women (Reichman, 2009). In class II-D forms, only one uterine horn is present (see Fig. 3-5). Instead, an underdeveloped rudimentary horn may be present. The rudiment may or may not communicate with the dominant horn and may or may not contain an endometrium-lined cavity. With noncommunicating types, the rudiment may lie near the uterus or may lie anywhere along the embryological migration path of the paramesonephros. This starts at the back and sweeps forward along the broad ligament.

This anomaly may be detected during fertility evaluation by HSG, but false-negative examinations stem from noncavitary or noncommunicating horns failing to fill with dye. If this anomaly is suspected, 3-D TVS raises diagnostic accuracy, but again MR imaging may be preferred to define endometrium (Fukunaga, 2017). Importantly, 40 percent of affected women will have renal anomalies (Fedele, 1996).

Main Horn. Pregnancies developing in the main horn carry significant obstetrical risks. These include first- and second-trimester miscarriage, malpresentation, fetal-growth restriction, fetal demise, prematurely ruptured membranes, and preterm delivery (Chan, 2011a; Hua, 2011; Reichman, 2009). These risks theoretically stem from abnormal uterine blood flow, cervical insufficiency, and diminished cavity size and muscle mass (Donderwinkel, 1992). The main unicornuate horn is indeed smaller than normal uterine lengths of 7- to 8-cm (Hawkins, 2013). One small study of 140 nulligravidas found a median uterine length of 5 cm (Li, 2019). Those with lengths from the internal os to fundus <4.5 cm prior to pregnancy had higher preterm labor rates during subsequent pregnancy compared with longer hemiuteri. Thus, a heightened awareness of potential complications is prudent. However, specific surveillance for poor fetal growth or preterm labor is mainly guided by prior pregnancy outcomes.

Rudimentary Horn. Ectopic pregnancy, correctly termed a *cornual pregnancy*, can develop within a remnant (Arleo, 2014). This risk includes noncommunicating cavitary rudiments, for which transperitoneal sperm migration permits ovum fertilization and pregnancy (Nahum, 2004). Although less common than other unicornuate pregnancy complications, rupture can create life-threatening hemorrhage. Convergence of uterine and ovarian branches near the pregnancy and the commonly associated placenta accreta spectrum (PAS) explain this risk.

In a report of 70 such pregnancies, Rolen and associates (1966) found that most rudimentary uterine horn pregnancies ruptured prior to 20 weeks' gestation. Nahum (2002) reviewed the literature from 1900 to 1999 and identified 588 rudimentary horn pregnancies. Half had uterine rupture, and 80 percent did so before the third trimester. Of the total 588, the neonatal survival rate was only 6 percent.

First-trimester sonography allows an earlier diagnosis and rudiment excision before rupture. The main horn shows an empty endometrium continuous with the cervical canal, and the interstitial portion of a fallopian tube is seen only on one side. The rudimentary horn pregnancy displays: (1) no continuity between the cervical canal and gestational sac, (2) myometrium surrounding the gestation, (3) PAS-associated hypervascularity surrounding the gestational sac, and (4) a vascular pedicle connecting the main horn and the sac's surrounding myometrium (Mavrelos, 2007; Tsafrir, 2005). If necessary, 3-D TVS is an appropriate adjunct (Tolani, 2018). As seen in Figure 3-6, the connecting pedicle can be broad and vascular.

Treatment is surgical and removes the rudimentary horn and in situ pregnancy. The ipsilateral fallopian tube is also excised to avert future ectopic pregnancies (Dove, 2017; Worley, 2008). Steps include sequential division of the uteroovarian ligament, mesosalpinx, round ligament, and pedicle to the main horn. Ideally, the ovary is spared, but large pregnancies with a short uteroovarian ligament may prompt adnexectomy. Surgical route is dictated by pregnancy size and laparoscopic capabilities.

In nonpregnant women, most unicornuate uteri are asymptomatic. Those with a noncommunicating cavitary rudiment may present with outlet obstruction symptoms at puberty. In this instance, comorbid endometriosis can club fimbria and obstruct tubal egress of blood. In all cases, prophylactic excision of a cavitary rudiment is recommended to avoid pregnancy in an inadequately sized horn (Fedele, 2005; Rackow, 2007; Schneiderman, 2018). Data regarding subsequent pregnancy after excision are scarce. In one series of eight women, all had a preterm cesarean delivery (Pados, 2014).

Uterine Didelphys (Class III)

This anomaly arises from incomplete fusion that results in two entirely separate hemiuteri, two cervices, and usually two vaginas or a longitudinal vaginal septum (see Fig. 3-5). Uterine didelphys may be isolated or part of a rare triad with an obstructed hemivagina and ipsilateral renal agenesis (OHVIRA), also known as Herlyn-Werner-Wunderlich syndrome (Tong, 2014). Rarely diagnosed antenatally, it is considered in a fetus with renal agenesis and a cystic pelvic mass, which reflects hydrometrocolpos (p. 40) (Tuna, 2019). Fetal MR imaging aids diagnosis.

Uterine didelphys is suspected on pelvic examination by identification of a longitudinal vaginal septum and two cervices. During HSG for fertility evaluation, contrast shows two separate endocervical canals. These open into separate noncommunicating fusiform endometrial cavities that each ends with a solitary fallopian tube. In women without fertility issues, 2- or 3-D TVS is a logical initial imaging tool, and separate divergent uterine horns with a large intervening fundal cleft are seen. Endometrial cavities and two cervices are uniformly separate. MR imaging can clarify cases lacking classic findings.

Adverse obstetrical outcomes associated with uterine didelphys are similar to but less frequent than those seen with unicornuate uterus. Increased risks include miscarriage, preterm birth, and malpresentation (Chan, 2011a; Hua, 2011).

Metroplasty for either uterine didelphys or bicornuate uterus involves resection of intervening myometrium and fundal recombination (Alborzi, 2015). These rarely performed surgeries are chosen for highly selected patients with otherwise unexplained recurrent miscarriage at later gestational ages. After metroplasty, scheduled delivery prior to labor is prudent to avoid uterine rupture (Ayhan, 1992).

Bicornuate Uterus (Class IV)

This fusion anomaly results in two hemiuteri. As shown in Figure 3-5, the central myometrium runs either partially or completely to the cervix. A complete bicornuate uterus may extend to the internal cervical os and have a single cervix (bicornuate unicollis) or reach the external os (bicornuate bicollis). As with uterine didelphys, a coexistent longitudinal vaginal septum is common.

Radiological discrimination of a bicornuate uterus from a septate uterus can be challenging, and defining criteria vary. This distinction, however, is important because septate uterus can be treated with hysteroscopic septal resection. HSG or 2-D TVS may initially suggest an anomaly, but further distinction is provided by 3-D TVS or MR imaging. With these, the intercornual angle, fundal contour, and a straight line drawn between the imaged tubal ostia serve as defining thresholds (Fig. 3-7).

Bicornuate uterus carries increased risks for miscarriage, preterm birth, and malpresentation (Chan, 2011a; Mastrolia, 2017). As discussed in the prior section, rare surgical correction by metroplasty is reserved for highly selected cases.

Septate Uterus (Class V)

With this anomaly, a resorption defect leads to a persistent complete or partial longitudinal uterine septum (see Fig. 3-5).

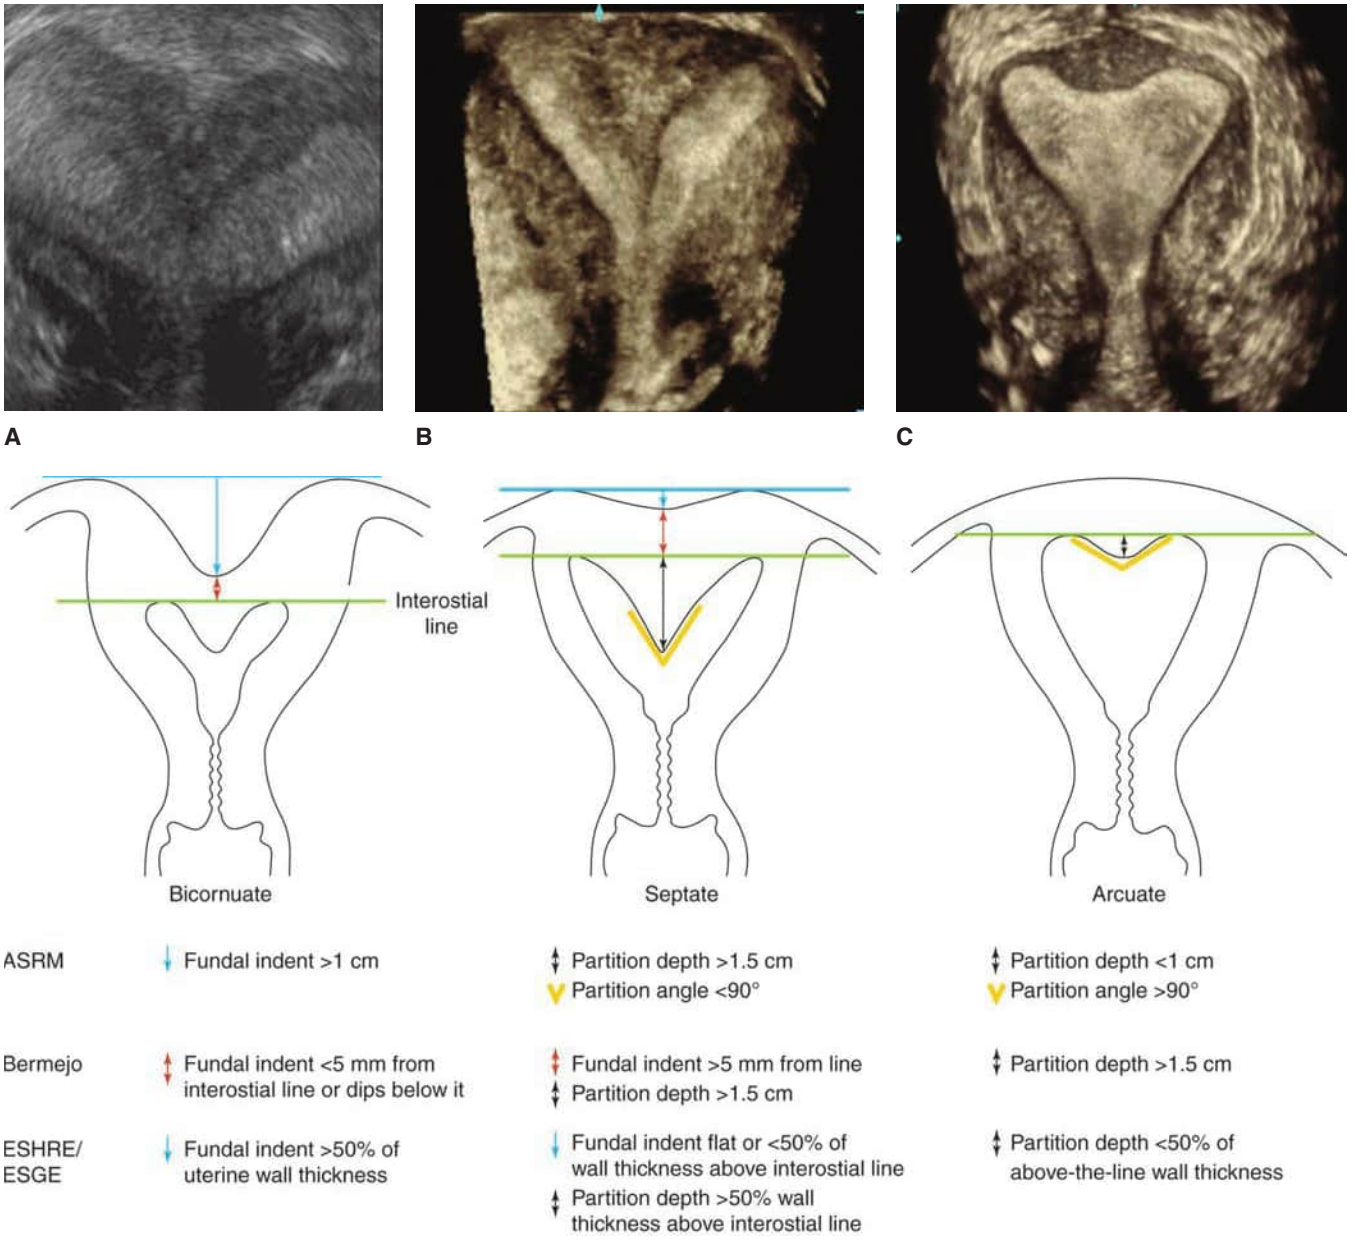

FIGURE 3-7 Three-dimensional transvaginal sonography (3-D TVS) images of müllerian uterine anomalies in the coronal plane. Below each are corresponding diagrammatic uteri and differing organizational definitions. **A.** Bicornuate uterus. This 3-D TVS rendered image demonstrates a concave external fundal contour that dips to a point near or below the interostial line (*green line*). (Reproduced with permission from Dr. Elysia Moschos.) **B.** Septate uterus. This sonogram depicts the narrow angle between the two small endometrial cavities, which is characteristic of a septate) uterus. The external contour here is flat but may show minor fundal indentation. **C.** Arcuate uterus. This image illustrates the normal external uterine contour and obtuse angle of the endometrial cleft that is characteristic of an arcuate uterus. Organizations vary among their use of the terms intercornual, interostial, or interstitial line. ASRM = American Society for Reproductive Medicine; ESHRE/ESGE = European Society of Human Reproduction and Embryology/European Society for Gynaecological Endoscopy. (Data from American Society for Reproductive Medicine, 2016, Bermejo, 2010, Grimbizis, 2013, 2016.)

In the rare Robert uterus, an asymmetric longitudinal septum creates a sequestered noncommunicating hemicavity that acts similar to a rudimentary horn (Ludwin, 2018a).

Many septate uteri are identified during evaluation of infertility or recurrent pregnancy loss. Although an abnormality may be identified with HSG or 2-D TVS, typically 3-D TVS or MR imaging is required to differentiate septate and bicornuate uteri. Experts still debate diagnostic criteria (see Fig. 3-7).

Septate anomalies can be associated with increased risks for adverse pregnancy outcomes that include miscarriage, preterm delivery, and malpresentation (Chan, 2011a; Ghi, 2012). In those with recurrent pregnancy loss, hysteroscopic septal resection may improve birth rates (American Society for Reproductive Medicine, 2016; Corroenne, 2018; Valle, 2013). During a subsequent labor, those with prior septal resection, especially if complicated by uterine perforation, carry a small risk for uterine rupture (Homer, 2000; Sentilhes, 2005).

Arcuate Uterus (Class VI)

This malformation is a mild deviation from the normally developed uterus (see Fig. 3-7). Most consider this anomaly benign, but some have found excessive second-trimester losses, preterm labor, and malpresentation (Chan, 2011a; Mucowski, 2010; Prior, 2018; Woelfer, 2001).

Cesarean Delivery

As noted in the above sections, cesarean delivery rates are increased with müllerian uterine anomalies. Data regarding subsequent trial of labor after cesarean (TOLAC) are few and show evidence both for and against its success and safety (Erez, 2007; Ravasia, 1999). Failed TOLAC attempts or the risk of rupture may stem from smaller than normal cavity size, abnormal propagation of myometrial action potentials, and a weaker cesarean scar due to congenitally altered vascular anatomy (Altwerger, 2015). Other factors that support or disfavor TOLAC are similar to those for women with normal-shaped uteri and are outlined in Chapter 31.

In those without prior cesarean delivery, external cephalic version (ECV) is reasonable to avoid primary cesarean delivery for malpresentation. A smaller uterine cavity or an obstructing midline partition may limit fetal turning. These are added to the traditional list of factors that should be reviewed when assessing a potential ECV candidate (Chap. 28, p. 528).

At times, a müllerian anomaly may not be diagnosed until cesarean delivery, and additional information should be methodically sought. Prior to hysterotomy closure, the cavity is manually explored to define the length of any cavity partition. If a rudimentary horn is found, the main cavity is also digitally explored for a communication. However, this may be missed due to its narrow caliber.

After closure, the fundus is examined. The external contour is delineated to differentiate bicornuate from didelphys types. If only one adnexum is found, a unicornuate uterus is suspected. In this case, if an obvious rudiment is not attached to the main horn, the surgeon should trace the embryological migratory path of the paramesonephric duct starting at the patient's back and sweeping forward. If found, the rudiment may be removed or at minimum its accompanying fallopian tube should be ligated to prevent later ectopic pregnancy.

With any müllerian anomaly, both renal fossae are examined intraoperatively to confirm kidneys. Postoperative radiologic assessment of the urinary collecting anatomy is reasonable.

Treatment with Cerclage

Uterine anomalies are one risk for cervical insufficiency (Althuisius, 2001; Berghella, 1999; Mastrolia, 2018). Some women with uterine anomalies and repetitive pregnancy loss after the first trimester may benefit from cervical cerclage (Golan, 1992; Yassaee, 2011). Others with partial cervical atresia or hypoplasia also may benefit (Ludmir, 1991; Song, 2015). For women with a uterine anomaly, candidacy for cervical length sonographic screening or for cerclage placement is determined by the same criteria used for women without a uterine defect (American College of Obstetricians and Gynecologists, 2021; Society for Maternal–Fetal Medicine, 2016). These topics are discussed in Chapters 45 (p. 794) and 11 (p. 205), respectively.

■ Diethylstilbestrol-related Abnormalities (Class VII)

In the 1960s, a synthetic nonsteroidal estrogen—diethylstilbestrol (DES)—was used to treat threatened abortion, preterm labor, preeclampsia, and diabetes. It was remarkably ineffective. Moreover, women exposed as fetuses carry increased risks for vaginal clear cell adenocarcinoma, cervical intraepithelial neoplasia, and vaginal adenosis (Hatch, 2001; Herbst, 1971; Robboy, 1984). Women exposed in utero can also show a cervix or vagina with a transverse septum, circumferential ridge, or cervical collar. Uteri are potentially smaller or have a T-shaped cavity (see Fig. 3-5) (Kaufman, 1984). Women exposed as fetuses are now postreproductive, but they did suffer risks for infertility and adverse pregnancy outcome (Kaufman, 2000; Palmer, 2001).

■ Fallopian Tube Abnormalities

The fallopian tubes develop from the unpaired distal ends of the müllerian ducts. Congenital anomalies include accessory ostia, complete or segmental tubal agenesis, and several embryonic cystic remnants. The most common is a small, benign cyst attached by a pedicle to the distal end of the fallopian tube—the hydatid of Morgagni. In other cases, benign paratubal cysts may be of mesonephric or mesothelial origin. Last, in utero exposure to DES is associated with various tubal abnormalities (DeCherney, 1981).

UTERINE FLEXION

Moderate flexion of the pregnant uterus is typically inconsequential, but exaggerated flexion may pose unique complications. *Anteflexion* describes forward angling of the uterine fundus in the sagittal plane relative to the cervix. In extreme cases, the fundus later in pregnancy falls forward to lie below the lower margin of the symphysis. Abdominal wall laxity is contributory. This uterine position can prevent proper transmission of labor contractions but is usually corrected by repositioning and application of an abdominal binder.

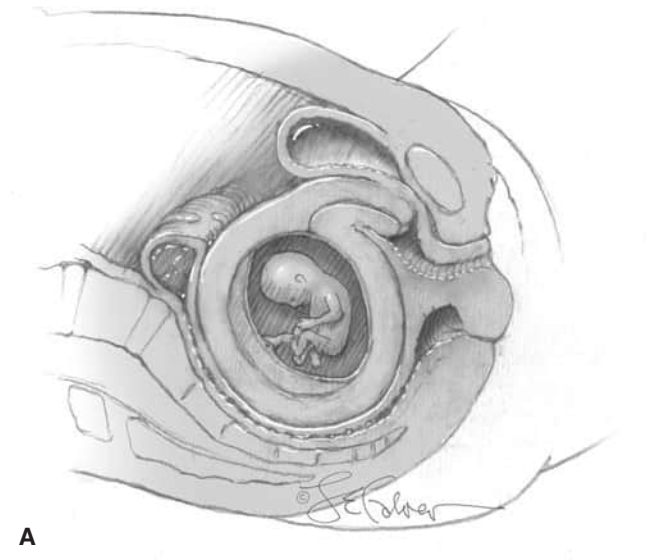

FIGURE 3-8 A. With uterine incarceration, the uterus is wedged between the sacral promontory and symphysis pubis. Resulting pressure against the urethra and rectum can cause urinary retention and constipation, respectively (Reproduced with permission from Corton MM: Anatomy. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.) **B.** Sagittal transvaginal sonogram shows a first-trimester fetus and incarcerated uterine fundus. The marked retroflexion brings the fundus to lie beneath the cervix. (Reproduced with permission from Dr. Angela Seasley.)

Retroflexion describes uterine fundal angling posteriorly in the sagittal plane. A growing retroflexed uterus fundus will occasionally become trapped in the hollow of the sacrum (Fig. 3-8). Symptoms include pelvic pressure or pain plus voiding dysfunction or retention. During bimanual pelvic examination, the cervix will be anterior and behind the symphysis pubis, whereas the uterus is wedged in the deep pelvis. Sonography or MR imaging can aid diagnosis (Gardner, 2013; Grossenburg, 2011).

With continued uterine growth, the incarcerated uterus can spontaneously resolve over 1 to 2 weeks. A knee-chest position assumed by the patient several times daily may assist resolution (Hooker, 2009). An indwelling urinary catheter or intermittent self-catheterization resolves retention. Persistent cases require manual repositioning. For this, after bladder catheterization, the uterus can usually be pushed out of the pelvis when the woman is placed in a knee-chest position. Often, this is best accomplished by digital pressure applied through the rectum or vagina. Intravenous sedation or spinal analgesia aids comfort and allows sufficient dislodging forces (Hire, 2019). Afterward, insertion of a soft, space-filling pessary for a few weeks usually prevents recurrence (Gibbons, 1969).

For rare resistant cases, advancing a colonoscope or colonoscopic insufflation can dislodge the fundus (Newell, 2014; Seubert, 1999). Upward round ligament traction during laparoscopy also has been described (Lettieri, 1994).

Rarely, *sacculation* may form as an extensive lower uterine segment dilation due to persistent uterine entrapment. Clinically, the elongated vagina extends above the level of the deeply descended fetal head. The Foley catheter is frequently palpated above the level of the umbilicus! In these extreme cases, sonography and MR imaging help define anatomy (Gottschalk, 2008; Lee, 2008). To avoid uterine rupture, cesarean delivery is necessary when sacculation is marked. Spearing (1978) recommended extending the abdominal incision above the umbilicus and delivering the entire uterus from the abdomen before hysterotomy. Correct anatomical relationships are ideally restored to help prevent inadvertent incisions into and through the vagina and bladder (Fig. 3-9). (Singh, 2007; Uma, 2002).

Uterine torsion is another rare acquired anomaly. During pregnancy, the uterus commonly rotates gently to the maternal right. Rotation exceeding 180 degrees creates torsion, and most cases stem from uterine leiomyomas, müllerian anomalies, fetal malpresentation, pelvic adhesions, or laxity of the abdominal wall or uterine ligaments. In one review of 212 cases, associated symptoms were obstructed labor, intestinal or urinary complaints,

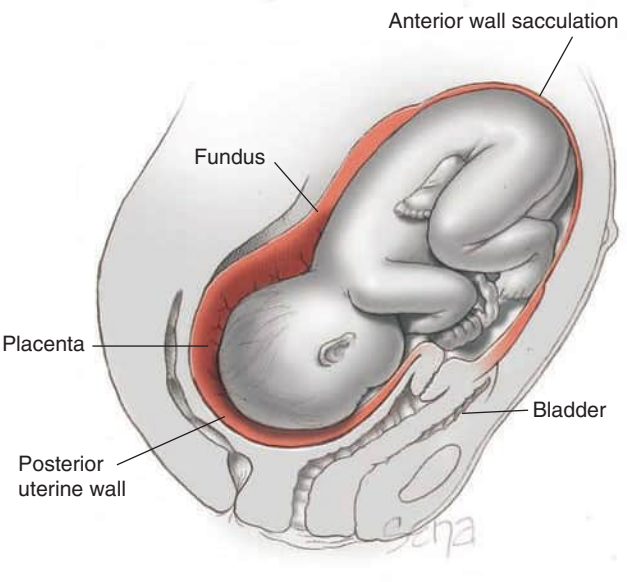

FIGURE 3-9 With anterior sacculation, note the markedly attenuated anterior uterine wall and atypical location of the true uterine fundus.

abdominal pain, uterine hypertonus, vaginal bleeding, or hypotension (Jensen, 1992).

In some women, torsion can be confirmed preoperatively with MR imaging, which shows a twisted vagina that appears X-shaped rather than its normal H-shape (Nicholson, 1995). Flipped placenta location and abnormal umbilical Doppler findings have been described sonographically (Rood, 2014). However, uterine torsion is usually found at the time of cesarean delivery, and the severely rotated uterus should be repositioned anatomically before hysterotomy. In some cases, an inability to reposition or a failure to recognize the torsion may lead to a posterior hysterotomy incision (Albayrak, 2011; Karavani, 2017). Rotation of 90 degrees risks uterine vessel laceration (Berger, 2020).

CHAPTER 4

Maternal Physiology

The anatomical, physiological, and biochemical adaptations of pregnancy are profound. Many gestational changes begin soon after fertilization and continue throughout pregnancy. Equally astounding is the almost complete return to the prepregnancy state after delivery and lactation. Most pregnancy-related changes are prompted by stimuli provided by the fetus and placenta. Virtually every organ system undergoes alterations, and these can appreciably modify criteria for disease diagnosis and treatment. Thus, an understanding of pregnancy adaptations is essential to avoid misinterpretation. Moreover, some normal physiological changes can unmask or worsen preexisting disease.

REPRODUCTIVE TRACT

Uterus

In the nonpregnant woman, the uterus weighs approximately 70 g and is almost solid, except for a cavity of 10 mL or less. During pregnancy, the uterus is transformed into a thin-walled muscular organ of sufficient capacity to accommodate the fetus, placenta, and amnionic fluid. The total volume of the contents at term averages 5 L but may be 20 L or more! Thus, by the end of pregnancy, the uterus has achieved a capacity that is 500 to 1000 times greater than the nonpregnant state. The corresponding increase in uterine weight is such that, by term, the organ weighs nearly 1100 g.

Uterine hypertrophy early in pregnancy is probably stimulated by the action of estrogen and perhaps progesterone. Thus, similar uterine changes can be observed with ectopic pregnancy. But after approximately 12 weeks' gestation, uterine growth is related predominantly to pressure exerted by the expanding products of conception.

Within the uterus, enlargement is most marked in the fundus. The extent of uterine hypertrophy is also influenced by the position of the placenta. Namely, the myometrium surrounding the placental site grows more rapidly than does the rest.

During pregnancy, uterine enlargement involves stretching and marked hypertrophy of muscle cells, whereas the production of new myocytes is limited. Fibrous tissue also accumulates, particularly in the external muscle layer, together with a considerable rise in elastic tissue content. The walls of the corpus considerably thicken and strengthen during the first few months of pregnancy but then gradually thin. By term, the myometrium is only 1 to 2 cm thick, and the fetus usually can be palpated through the soft, readily indentable uterine walls.

The uterine musculature during pregnancy is arranged in three strata. The first is an outer hoodlike layer, which arches over the fundus and extends into the various ligaments. The middle layer is a dense network of muscle fibers perforated in all directions by blood vessels. Last is an internal layer, with sphincter-like fibers around the fallopian tube orifices and internal cervical os. Most of the uterine wall is formed by the middle layer. Here, each myocyte has a double curve so that the interlacing of any two cells forms a figure eight. This crucial arrangement permits myocytes to contract after delivery and constrict penetrating blood vessels to halt bleeding.

Uterine Shape and Position

For the first few weeks, the uterus maintains its original piriform or pear shape. But, as pregnancy advances, the corpus and fundus become globular and almost spherical by 12 weeks' gestation. Subsequently, the organ grows more rapidly in length than in width and becomes ovoid. By the end of 12 weeks, the enlarged uterus extends out of the pelvis. With growth, it contacts the anterior abdominal wall, displaces the intestines laterally and superiorly, and ultimately reaches almost to the liver. As it ascends, the uterus usually rotates to the right, and this dextrorotation likely is caused by the rectosigmoid on the left side of the pelvis. As the uterus rises, tension is exerted on the broad and round ligaments.

With the pregnant woman standing, the longitudinal axis of the uterus corresponds to an extension of the pelvic inlet axis. The abdominal wall supports the uterus and maintains this axis, unless the wall is lax. When the pregnant woman lies supine, the uterus falls back to rest on the vertebral column and the adjacent great vessels.

Uterine Contractility

Beginning in early pregnancy, the uterus contracts irregularly, and these may be perceived as mild cramps. During the second trimester, these contractions can be detected by bimanual examination. In 1872, J. Braxton Hicks first brought attention to these contractions, which now bear his name. These appear unpredictably and sporadically. Their intensity varies between 5 and 25 mm Hg (Alvarez, 1950). Until near term, these *Braxton Hicks contractions* are infrequent, but their number rises during the last week or two. At this time, the uterus may contract as often as every 10 to 20 minutes and with some degree of rhythmicity. Correspondingly, uterine electrical activity is low and uncoordinated early in gestation but becomes progressively more intense and synchronized by term (Rabotti, 2015). This synchrony develops twice as fast in multiparas compared with nulliparas (Govindan, 2015). Late in pregnancy, these contractions may cause some discomfort and account for so-called false labor (Chap 21, p. 401).

Uteroplacental Blood Flow

The delivery of most substances essential for fetal and placental growth, metabolism, and waste removal requires the placental intervillous space to be adequately perfused (Chap. 5, p. 86). Placental perfusion depends on total uterine blood flow, but simultaneous measurement of uterine, ovarian, and collateral vessels is not yet possible, even using magnetic resonance (MR) angiography (Pates, 2010). For this measurement, early results using four-dimensional flow MR imaging in the primate are promising (MacDonald, 2019).

Doppler ultrasound interrogation of the uterine arteries shows a progressive increase in uteroplacental blood flow during pregnancy. Flow rates rise from approximately 450 mL/min in the midtrimester to nearly 500 to 750 mL/min at 36 weeks' gestation (Flo, 2014; Wilson, 2007). These measures are similar to flow estimates ascertained indirectly using clearance rates of androstenedione and xenon-133 (Edman, 1981; Kauppila, 1980). These values also mirror older ones—500 to 750 mL/min—obtained with invasive methods (Assali, 1953; Metcalfe, 1955). Logically, such massively increased uteroplacental blood flow requires adaptation of the uterine veins as well. The resulting increased venous caliber and distensibility can result in uterine vein varices that rarely may rupture (Lim, 2014).

As noted first from animal studies, uterine contractions, either spontaneous or induced, lower uterine blood flow proportionally to contraction intensity (Assali, 1968). A tetanic contraction yields a precipitous fall in uterine blood flow. In humans, three-dimensional power Doppler angiography has also demonstrated reduced uterine blood flow during contractions (Jones, 2009). Using a similar technique, resistance to blood flow in both maternal and fetal vessels was found to be greater during the second stage of labor compared with the first (Baron, 2015). Given that baseline uterine blood flow is diminished in pregnancies complicated by fetal-growth restriction, these fetuses often tolerate spontaneous labor less effectively (Simeone, 2017).

Uteroplacental Blood Flow Regulation

The vessels that supply the uterine corpus widen and elongate yet preserve their contractile function (Mandala, 2012). As an exception, the spiral arteries, which directly supply the placenta, vasodilate but completely lose contractility. This presumably stems from endovascular trophoblast invasion, which destroys the intramural muscular elements (Chap. 5, p. 92). This vasodilation allows maternal–placental blood flow to progressively rise during gestation. Given that blood flow increases proportionally to the fourth power of the radius of the vessel, small widening of a vessel diameter results in tremendous augmentation of flow. In one study, the uterine artery diameter grew from only 3.3 mm to 3.7 mm between 22 and 29 weeks' gestation, but mean blood flow velocity increased 50 percent, from 29 to 43 cm/sec (Flo, 2010).

The downstream fall in vascular resistance is another key factor that accelerates flow and shear stress in upstream vessels. In turn, shear stress leads to circumferential vessel growth. Nitric oxide—a potent vasodilator—appears to play a central role in regulating this process and is discussed later (p. 65). Endothelial nitric oxide synthase (eNOS) and nitric oxide production are augmented by endothelial shear stress and several hormones and growth factors (Osol, 2019; Zhang, 2017). Factors include estrogen, progesterone, activin, placental growth factor (PlGF), and vascular endothelial growth factor (VEGF), which is a promoter of angiogenesis. As an important aside, VEGF and PlGF signaling is attenuated in response to excess placental secretion of their soluble receptor—*soluble FMS-like tyrosine kinase 1*

(sFlt-1). An elevated maternal sFlt-1 level inactivates and lowers circulating PlGF and VEGF concentrations and is important in preeclampsia pathogenesis (Chap. 40, p. 694).

Normal pregnancy is also characterized by vascular refractoriness to the pressor effects of infused angiotensin II, and this raises uteroplacental blood flow (Rosenfeld, 2012). Other factors that augment uteroplacental blood flow include relaxin and certain adipocytokines (Vodstrcil, 2012). *Chemerin* is an adipocytokine secreted by several tissues, including the placenta (Kasher-Meron, 2014). Its concentration rises as gestation advances and serves to increase human umbilical eNOS activity (Wang, 2015). Another adipocytokine—*visfatin*—raises VEGF secretion and VEGF receptor 2 expression in epithelial cells derived from the placental amnion (Astern, 2013). Other adipocytokines include *leptin*, *resistin,* and *adiponectin,* which all enhance umbilical vein endothelial cell proliferation (Połeć, 2014).

Last, certain microRNA species mediate vascular remodeling and uterine blood flow early in placentation (Santa, 2015). In particular, members of the miR-17–92 cluster and miR-34 are important in spiral artery remodeling and invasion. MicroRNA dysfunction has been reported in preeclampsia, fetal-growth restriction, and gestational diabetes.

Cervix

As early as 1 month after conception, the cervix begins to soften and gain bluish tones. These changes result from increased vascularity and edema of the entire cervix, from alterations in the collagen network, and from hypertrophy and hyperplasia of the cervical glands (Peralta, 2015). Although the cervix contains a small amount of smooth muscle, its major component is connective tissue. Rearrangement of this collagen-rich tissue aids the cervix in retention of the pregnancy until term, in dilation to aid delivery, and in postpartum repair and reconstitution to permit a subsequent successful pregnancy (Myers, 2015). As detailed in Chapter 21 (p. 405), cervical ripening involves connective tissue remodeling that lowers collagen and proteoglycan concentrations and raises water content compared with the nonpregnant cervix.

Cervical glands undergo marked proliferation, and by the end of pregnancy, they occupy up to one half of the entire cervical mass. This normal pregnancy-induced change prompts an extension, or *eversion*, of the proliferating columnar endocervical glands onto the ectocervical portio (Fig. 4-1). This tissue appears red and velvety and bleeds even with minor trauma, such as with Pap smear testing.

The endocervical mucosal cells produce copious amounts of tenacious mucus that obstructs the cervical canal soon after conception (Bastholm, 2017). This mucus is rich in immunoglobulins and cytokines and may act as an immunological barrier to protect the uterine contents against infection (Hansen, 2014). At labor onset, if not before, this *mucus plug* is expelled, resulting in a *bloody show.* Moreover, the cervical mucus consistency changes during pregnancy. Specifically, in most pregnant women, as a result of progesterone, when cervical mucus is spread and dried on a glass slide, it shows poor crystallization, termed *beading*. In some gravidas, as a result of amnionic fluid leakage, an arborization of ice-like crystals, called *fern*ing, is seen microscopically.

FIGURE 4-1 Cervical eversion of pregnancy as viewed through a colposcope. The eversion represents columnar epithelium on the portio of the cervix. (Reproduced with permission from Dr. Claudia Werner.)

Histologically, basal cells near the squamocolumnar junction can be prominent in size, shape, and staining quality in pregnancy. These changes are considered to be estrogen induced. In addition, pregnancy is associated with both endocervical gland hyperplasia and hypersecretory appearance—the *Arias-Stella reaction*. This cytologic change can make differentiating these from truly atypical glandular cells during Pap test evaluation particularly difficult (Rosai, 2015).

Ovaries

Ovulation ceases during pregnancy, and maturation of new follicles is suspended. The single corpus luteum functions maximally during the first 6 to 7 weeks of pregnancy—4 to 5 weeks postovulation. Thereafter, it contributes relatively little to progesterone production. As discussed in Chapter 66 (p. 1170), surgical removal of the corpus luteum before 7 weeks' gestation prompts a rapid fall in maternal serum progesterone levels and spontaneous abortion (Csapo, 1973). In these cases, exogenous progesterone is necessary for pregnancy maintenance until placental function is sufficient. After 7 weeks, however, corpus luteum excision ordinarily does not cause abortion.

An extrauterine *decidual reaction* on and just beneath the ovarian surface is common in pregnancy and is usually observed at cesarean delivery. These appear as slightly elevated clear or red blisters or patches that bleed easily and may, on first glance, resemble freshly torn adhesions. Similar decidual reactions are seen on the uterine serosa and other pelvic, or even extrapelvic, abdominal organs (Bloom, 2010). These areas arise from subcoelomic mesenchyme or endometriotic lesions that have been stimulated by progesterone. They histologically appear similar to progestin-stimulated intrauterine endometrial stroma (Kim, 2015).

The enormous caliber of the ovarian veins viewed at cesarean delivery is startling. Hodgkinson (1953) found that the diameter of the ovarian vascular pedicle increased during pregnancy from 0.9 cm to approximately 2.6 cm at term. Again, recall

that flow in a tubular structure increases exponentially as the diameter enlarges.

Relaxin

This protein hormone is secreted by the corpus luteum, the decidua, and the placenta in a pattern similar to that of human chorionic gonadotropin (hCG) (Chap. 5, p. 97). Relaxin is also expressed in brain, heart, and kidney. It is mentioned here because its secretion by the corpus luteum appears to aid many maternal physiological adaptations, such as remodeling of reproductive-tract connective tissue to accommodate labor (Vrachnis, 2015). Relaxin also appears important in initiating augmented renal hemodynamics, lowering serum osmolality, and increasing arterial compliance, which are all associated with normal pregnancy (Conrad, 2015). Despite its name, serum relaxin levels do not contribute to greater peripheral joint laxity or pelvic girdle pain during pregnancy (Aldabe, 2012; Marnach, 2003).

Theca-Lutein Cysts

These benign ovarian lesions reflect exaggerated physiological follicle stimulation, which is termed *hyperreactio luteinalis.* The resulting bilateral cystic ovaries are variably enlarged. The reaction is usually linked to markedly elevated serum hCG levels. Logically, theca-lutein cysts are found frequently with gestational trophoblastic disease (Fig. 13-3, p. 238). They may also develop with the placentomegaly that can accompany diabetes, anti-D alloimmunization, and multifetal gestation. Hyperreactio luteinalis is associated with preeclampsia and hyperthyroidism, which may contribute to elevated risks for fetal-growth restriction and preterm birth (Lynn, 2013; Malinowski, 2015). These cysts are also encountered in women with otherwise uncomplicated pregnancies. In these cases, an exaggerated response of the ovaries to normal levels of circulating hCG is suspected (Sarmento Gonçalves, 2015).

Although usually asymptomatic, hemorrhage into the cysts can cause acute abdominal pain (Amoah, 2011). Maternal virilization may be seen in up to 30 percent of women, however, virilization of the fetus has only rarely been reported. Maternal findings that include temporal balding, hirsutism, and clitoromegaly are associated with massively elevated levels of androstenedione and testosterone. The diagnosis typically is based on sonographic findings of bilateral enlarged ovaries containing multiple cysts in the appropriate clinical settings. The condition is self-limited and resolves following delivery. Its management was reviewed by Malinowski (2015) and discussed further in Chapter 66 (p. 1171).

Fallopian Tubes

The fallopian tube musculature, that is, the *myosalpinx*, undergoes little hypertrophy during pregnancy. The epithelium of the *endosalpinx* somewhat flattens. Decidual cells may develop in the stroma of the endosalpinx, but a continuous decidual membrane is not formed. Rarely, a fallopian tube may twist during uterine enlargement, but this torsion is more common with comorbid paratubal or ovarian cysts (Lee, 2015; Macedo, 2017).

Vagina and Perineum

During pregnancy, greater vascularity and hyperemia develop in the skin and muscles of the perineum and vulva, and the underlying abundant connective tissue softens. This augmented vascularity prominently affects the vagina and cervix and results in the violet color characteristic of the *Chadwick sign.*

Within the vagina, the considerably elevated volume of cervical secretions during pregnancy forms a somewhat thick, white discharge. The pH is acidic and varies from 3.5 to 6. This pH results from increased production of lactic acid by *Lactobacillus acidophilus* during metabolism of glycogen energy stores in the vaginal epithelium. Pregnancy is associated with an elevated risk of vulvovaginal candidiasis, particularly during the second and third trimesters. Higher infection rates may stem from immunological and hormonal changes and from greater vaginal glycogen stores (Aguin, 2015).

The vaginal walls undergo striking changes in preparation for the distention that accompanies labor and delivery. These include considerable epithelial thickening, connective tissue loosening, and hypertrophy of smooth muscle cells.

Pelvic Organ Prolapse

Pelvic Organ Prolapse Quantification (POP-Q) scores and sonographic studies show that vaginal support changes across pregnancy. In particular, vaginal lengthening, posterior vaginal wall and hiatal relaxation, increased levator hiatal area, and greater first-trimester vaginal elastase activity are all associated with uncomplicated spontaneous vaginal delivery (Oliphant, 2014). The larger hiatal area persists in women who deliver vaginally compared with women delivering by prelabor or early-labor cesarean delivery. However, all women show greater hiatal distensibility after delivery, which is potentially a factor in later pelvic floor dysfunction (Blomqvist, 2018; Friedman, 2019).

In women with existing apical vaginal prolapse, the cervix, and occasionally a portion of the uterine body, can protrude variably from the vulva during early pregnancy. With further growth, the uterus usually rises above the pelvis and can draw the cervix up with it. If the uterus persists in its prolapsed position, symptoms of incarceration may develop at 10 to 14 weeks' gestation (Chap. 3, p. 46). As a preventive measure, the uterus can be replaced early in pregnancy and held in position with a space-filling pessary.

Attenuation of anterior vaginal wall support can lead to prolapse of the bladder, that is, cystocele. Associated urinary stasis can predispose to infection. Pregnancy may also worsen coexistent *stress urinary incontinence (SUI)*, likely because urethral closing pressures do not rise sufficiently to compensate for altered bladder neck support. Urinary incontinence affects nearly 20 percent of women during the first trimester and nearly 40 percent during the third trimester. Most cases stem from SUI rather than urgency urinary incontinence (Abdullah, 2016; Franco, 2014). In primigravidas, maternal age greater than 30 years, obesity, smoking, constipation, and gestational diabetes mellitus are all risk factors associated with incontinence during pregnancy (Sangsawang, 2014).

Attenuation of posterior vaginal wall support can lead to rectocele, and a large defect may fill with feces. Splinting, in

which a finger is inserted into the vagina, can bolster posterior wall support to aid evacuation. Occasionally, digital rectal disimpaction is needed. Uncommonly during labor, fetal descent is blocked by a cystocele or rectocele. Emptying by catheterization or enema and compressing the bulge with vaginal fingers will resolve the impasse. Rarely, a large enterocele may bulge into the vagina to block descent. Similarly, the hernia sac and its abdominal contents are gently reduced.

BREASTS

In early pregnancy, women often experience breast tenderness and paresthesias. After the second month, the breasts grow in size, and delicate veins are visible just beneath the skin. The nipples become considerably larger, more deeply pigmented, and more erectile. After the first few months, a thick, yellowish fluid—*colostrum*—can often be expressed from the nipples by gentle massage. During the same months, the areolae become broader and more deeply pigmented. Scattered through each areola are several small elevations, the *glands of Montgomery*, which are hypertrophic sebaceous glands. If breasts gain extensive size, skin striae similar to those observed in the abdomen may develop. Rarely, breasts can become pathologically enlarged—referred to as *gigantomastia*—which may require consideration of postpartum bromocriptine and later surgical reduction (Rezai, 2015; Türkan, 2016).

For most, prepregnancy breast size and ultimate volume of breast milk do not correlate. Multiple factors influence milk production and are discussed in Chapter 36 (p. 640).

SKIN

Skin changes are common, and Fernandes and Amaral (2015) described dermatological changes in more than 900 pregnant women. They found at least one physiological cutaneous change in 89 percent of the women examined. Dermatological pathologies during pregnancy are found in Chapter 65.

Abdominal Wall

Beginning after midpregnancy, reddish, slightly depressed streaks commonly develop in the skin. These are called *striae gravidarum* or *stretch marks.* In multiparas, glistening, silvery lines that represent the cicatrices of previous striae frequently coexist. In one study of 800 primiparas, 70 percent developed striae gravidarum on their abdomen; 33 percent on their breasts; and 41 percent on their hips and thighs (Picard, 2015). The strongest associated risk factors included younger maternal age, family history, and prepregnancy weight and weight gain during pregnancy. The etiology of striae gravidarum is unknown, but aloe vera gel and almond oil decrease itching and may help to prevent progression (Hajhashemi, 2018).

Occasionally, the muscles of the abdominal walls do not withstand the tension of the expanding pregnancy. As a result, rectus muscles separate in the midline, creating *diastasis recti* of varying extent. If severe, a considerable portion of the anterior uterine wall is covered by only a layer of skin, attenuated fascia, and peritoneum to form a ventral hernia.

Hyperpigmentation

This develops in up to 90 percent of women and is usually more accentuated in those with darker complexion (Bieber, 2017). Of specific sites, the pigmented skin line in the midline of the anterior abdominal wall—the *linea alba*—takes on dark brown-black pigmentation to form the *linea nigra.* Occasionally, irregular brownish patches of varying size appear on the face and neck, giving rise to *chloasma* or *melasma gravidarum*—the *mask of pregnancy*. Pigmentation of the areolae and genital skin also may be accentuated. After delivery, these pigmentary changes usually disappear or at least regress considerably. Oral contraceptives may cause similar alterations (Handel, 2014).

The etiology of these pigmentary changes is incompletely understood, however, hormonal and genetic factors are implicated. Levels of melanocyte-stimulating hormone, a polypeptide similar to corticotropin, are elevated remarkably throughout pregnancy, and estrogen and progesterone also are reported to have melanocyte-stimulating effects.

Vascular Changes

Angiomas, called *vascular spiders*, are particularly common on the face, neck, upper chest, and arms. These are minute, red skin papules with radicles branching out from a central lesion. The condition is often designated as nevus, angioma, or telangiectasis. *Palmar erythema* is encountered during pregnancy. Both conditions lack clinical significance and disappear in most gravidas shortly after pregnancy. They are likely the consequence of hyperestrogenemia. In addition to these discrete lesions, increased cutaneous blood flow in pregnancy serves to dissipate excess heat generated by augmented metabolism.

Hair Changes

Throughout life, the human hair follicle undergoes a pattern of cyclic activity that includes periods of hair growth (anagen phase), apoptosis-driven involution (catagen phase), and a resting period (telogen phase). Based on a study of 116 healthy pregnant women, the anagen phase lengthens during pregnancy and the telogen rate increases postpartum (Gizlenti, 2014). Neither is exaggerated in most gravidas, but excessive hair loss in the puerperium is termed *telogen effluvium* (Stoehr, 2019).

METABOLIC CHANGES

In response to the greater demands of the rapidly growing fetus and placenta, the pregnant woman undergoes numerous metabolic changes. By the third trimester, maternal basal metabolic rate rises by 20 percent compared with that of the nonpregnant state (Berggren, 2015). This rate grows by an additional 10 percent in women with a twin gestation (Shinagawa, 2005). This is stratified as 85, 285, and 475 kcal/d during the first, second, and third trimesters, respectively (Table 4-1) (World Health Organization, 2004). Of note, Abeysekera and coworkers (2016) reported that women accrue fat mass during pregnancy despite the increased total energy expenditure and without significant change in energy intake. This suggests more efficient energy storage.

TABLE 4-1. Additional Energy Demands During Normal Pregnancy[a]

	Rates of Tissue Deposition			
	1st Trimester g/d	2nd Trimester g/d	3rd Trimester g/d	Total Deposition g/280 d
Weight gain	17	60	54	12,000
Protein deposition	0	1.3	5.1	597
Fat deposition	5.2	18.9	16.9	3741

Energy Cost of Pregnancy Estimated from Basal Metabolic Rate and Energy Deposition					
	1st Trimester kJ/d	2nd Trimester kJ/d	3rd Trimester kJ/d	Total Energy Cost	
				MJ	Kcal
Protein deposition	0	30	121	14.1	3370
Fat deposition	202	732	654	144.8	34,600
Efficiency of energy utilization[b]	20	76	77	15.9	3800
Basal metabolic rate	199	397	993	147.8	35,130
Total energy cost of pregnancy	**421**	**1235**	**1845**	**322.6**	**77,100**

[a]Assumes an average gestational weight gain of 12 kg.
[b]Efficiency of food energy utilization for protein and fat deposition estimated as 0.90.

Most of the normal weight gain in pregnancy is attributable to the uterus and its contents, the breasts, and expanded blood and extravascular extracellular fluid volumes. A smaller fraction results from metabolic alterations that promote accumulation of cellular water, fat, and protein, which are so-called maternal reserves. The average weight gain during pregnancy approximates 12.5 kg or 27.5 lb, and this value has remained consistent across studies and over time (Hytten, 1991; Jebeile, 2016). Weight gain is detailed in Table 4-2 and in Chapter 10 (p. 183) (Hytten, 1991).

Water Metabolism

In pregnancy, greater water retention is normal and mediated in part by a drop in plasma osmolality of 10 mOsm/kg. As shown in Figure 4-2, this decline develops in early pregnancy and is induced by a reset of osmotic thresholds for thirst and vasopressin secretion (Lindheimer, 2001). Relaxin and other hormones are thought to play a role (Conrad, 2013).

TABLE 4-2. Weight Gain Based on Pregnancy-Related Components

	Cumulative Increase in Weight (g)			
Tissues and Fluids	10 Weeks	20 Weeks	30 Weeks	40 Weeks
Fetus	5	300	1500	3400
Placenta	20	170	430	650
Amnionic fluid	30	350	750	800
Uterus	140	320	600	970
Breasts	45	180	360	405
Blood	100	600	1300	1450
Extravascular fluid	0	30	80	1480
Maternal stores (fat)	310	2050	3480	3345
Total	**650**	**4000**	**8500**	**12,500**

Maternal serum osmolality is significantly lower than umbilical arterial osmolality to favor water transport to the fetus (Moen, 2018). At term, the water content of the fetus, placenta, and amnionic fluid approximates 3.5 L. Another 3.0 L accumulates from expanded maternal blood volume and from uterus and breast growth. Thus, the minimum amount of extra water that the average woman accrues during normal pregnancy approximates 6.5 L. This corresponds to almost 15 lb.

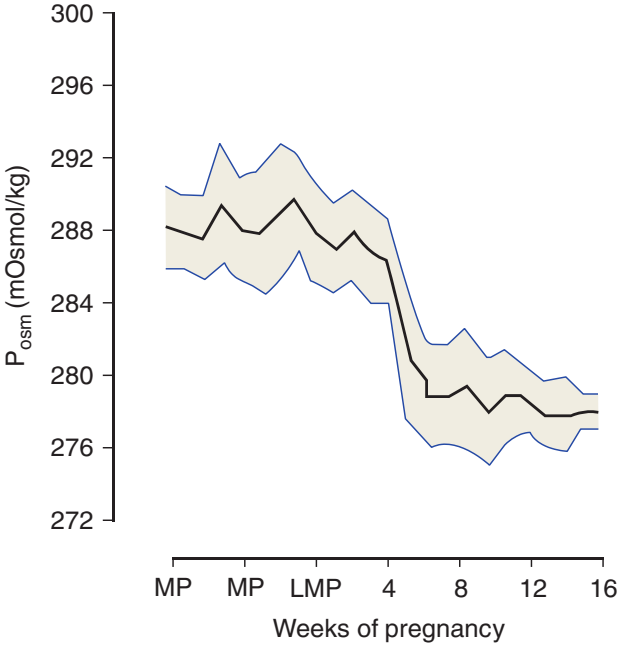

FIGURE 4-2 Mean values (*black line*) ± standard deviations (*blue lines*) for plasma osmolality (P_{osm}) measured at weekly intervals in nine women from preconception to 16 weeks. LMP = last menstrual period; MP = menstrual period. (Redrawn from Davison JM, Dunlop W. Renal hemodynamics and tubular function normal human pregnancy, Kidney Int 1980 Aug;18(2):152–161.)

Demonstrable pitting edema of the ankles and legs is seen in most gravidas, especially at the day's end. This fluid accumulation may amount to a liter or so. It results from greater venous pressure below the level of the uterus as a consequence of partial vena cava occlusion. A decline in interstitial colloid osmotic pressure induced by normal pregnancy also favors edema late in pregnancy (Øian, 1985).

Longitudinal studies of body composition show a progressive accumulation of total body water and fat mass during pregnancy. These two components as well as initial maternal weight and weight gained during pregnancy are highly associated with neonatal birthweight (Lederman, 1999). As discussed in Chapter 51 (p. 905), "overnourished" women are more likely to deliver oversized neonates, even when glucose tolerant.

Protein Metabolism

The products of conception, the uterus, and maternal blood are relatively rich in protein rather than fat or carbohydrate. At term, the normally grown fetus and placenta together weigh about 4 kg and contain approximately 500 g of protein, or about half of the total pregnancy increase. The remaining 500 g is added to the uterus as contractile protein, to the breasts primarily in the glands, and to maternal blood as hemoglobin and plasma proteins.

Amino acid concentrations are higher in the fetal than in the maternal compartment and generally result from facilitated transport across the placenta (Panitchob, 2015). This greater concentration is largely regulated by the placenta through an incompletely understood process (Chap. 7, p. 136). In particular, placental transport is variable for individuals and for different amino acids. For example, tyrosine is a conditionally essential amino acid in the preterm neonate but not in the fetus (Van den Akker, 2011). The placenta concentrates amino acids into the fetal circulation and is also involved in protein synthesis, oxidation, and transamination of some nonessential amino acids (Galan, 2009).

Maternal protein intake does not appear to be a critical determinant for birthweight among well-nourished women (Chong, 2015). Still, recent data suggest that current recommendations for protein intake may be too low. These guidelines are extrapolated from nonpregnant adults and may underestimate actual needs. Stephens and colleagues (2015) prospectively analyzed maternal protein intake and metabolism. They estimated average requirements of 1.22 g/kg/d of protein for early pregnancy and 1.52 g/kg/d for late pregnancy. These levels are higher than the current recommendation of 0.88 g/kg/d. Dietary protein intake is discussed in Chapter 10 (p. 185).

Carbohydrate Metabolism

Normal pregnancy is characterized by mild fasting hypoglycemia, postprandial hyperglycemia, and hyperinsulinemia (Fig. 4-3) (Phelps, 1981). This elevated basal level of plasma insulin in normal pregnancy is associated with several unique responses to glucose ingestion. Specifically, after an oral

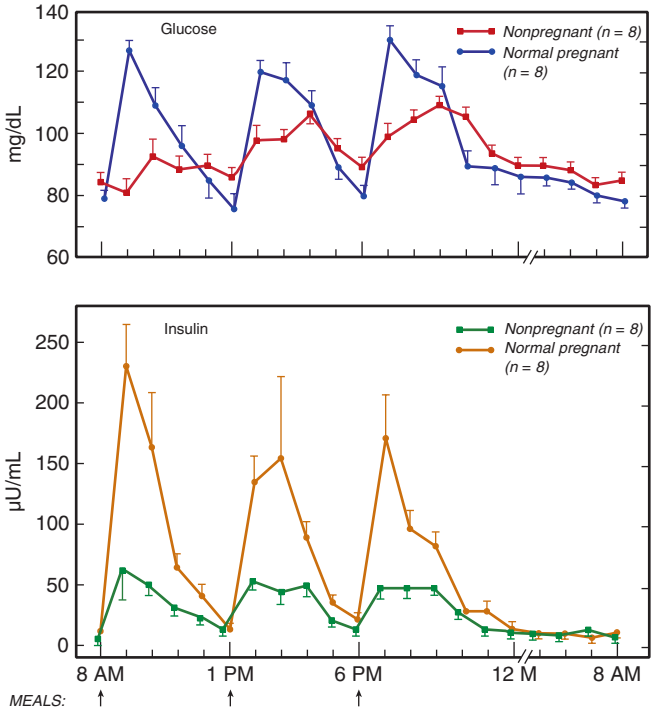

FIGURE 4-3 Diurnal changes in plasma glucose and insulin in normal late pregnancy.

glucose meal, gravidas demonstrate prolonged hyperglycemia and hyperinsulinemia and a greater suppression of glucagon. This cannot be explained by an increased metabolism of insulin because its half-life during pregnancy is not changed appreciably (Lind, 1977). Instead, this response reflects a pregnancy-induced state of peripheral insulin resistance, which ensures a sustained postprandial supply of glucose to the fetus. Indeed, insulin sensitivity in late normal pregnancy is 30 to 70 percent lower than that of nonpregnant women (Lowe, 2014).

The mechanisms responsible for this reduced insulin sensitivity include numerous endocrine and inflammatory factors (Angueira, 2015). In particular, pregnancy-related hormones such as progesterone, placentally derived growth hormone, prolactin, and cortisol; cytokines such as tumor necrosis factor; and hormones derived from central adiposity, particularly leptin and its interplay with prolactin, all have a role in the insulin resistance of pregnancy. Even so, insulin resistance is not the only factor to elevate postprandial glucose values. Hepatic gluconeogenesis is augmented during both diabetic and nondiabetic pregnancies, particularly in the third trimester (Angueira, 2015).

When fasting overnight, the pregnant woman changes from a postprandial state characterized by elevated and sustained glucose levels to a fasting state characterized by lower levels of plasma glucose and some amino acids. Instead, plasma concentrations of free fatty acids, triglycerides, and cholesterol are higher in the fasting state. This pregnancy-induced switch in fuels from glucose to lipids has been called *accelerated starvation.* Certainly, when fasting is prolonged in the pregnant woman, these alterations are exaggerated and ketonemia rapidly appears.

Fat Metabolism

The concentrations of lipids, lipoproteins, and apolipoproteins in plasma rise appreciably during pregnancy (Appendix, p. 1231). Increased insulin resistance and estrogen stimulation during pregnancy are responsible for maternal hyperlipidemia. Augmented lipid synthesis and food intake contribute to maternal fat accumulation during the first two trimesters. Overweight women who have excessive gestational weight gain accrue fat mass (Berggren, 2016). In the third trimester, however, fat storage declines or ceases. This is a consequence of enhanced lipolytic activity, and decreased lipoprotein lipase activity reduces circulating triglyceride uptake into adipose tissue. This transition to a catabolic state favors maternal use of lipids as an energy source and spares glucose and amino acids for the fetus.

Maternal hyperlipidemia is one of the most consistent and striking changes of lipid metabolism during late pregnancy. Triacylglycerol and cholesterol levels in very-low-density lipoproteins (VLDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs) are increased during the third trimester compared with those in nonpregnant women (Table 4-3). After delivery, the concentrations of these lipids, lipoproteins, and apolipoproteins decline. Breastfeeding drops maternal triglyceride levels but increases those of HDL cholesterol (HDL-C). The effects on total cholesterol and LDL cholesterol levels are unclear (Gunderson, 2014).

Hyperlipidemia is theoretically a concern because it is associated with endothelial dysfunction. That said, endothelium-dependent vasodilation responses actually improve across pregnancy (Saarelainen, 2006). This is partly because increased HDL-C concentrations likely inhibit LDL oxidation and thus protect the endothelium. These findings suggest that the increased cardiovascular disease risk in multiparas may be related to factors other than maternal hypercholesterolemia.

Leptin

This peptide hormone is primarily secreted by adipose tissue in nonpregnant humans. It plays a key role in body fat and energy expenditure regulation and in reproduction. For example, leptin is important for implantation, cell proliferation, and angiogenesis (Vazquez, 2015). Leptin deficiency is associated with anovulation and infertility, whereas certain leptin mutations cause extreme obesity (Tsai, 2015).

Among normal-weight gravidas, serum leptin levels rise and peak during the second trimester and plateau until term in concentrations two to four times higher than those in nonpregnant women. Among obese women, leptin levels correlate with adiposity (Tsai, 2015). In all cases, leptin levels fall after delivery, reflecting the significant amounts produced by the placenta (Vazquez, 2015).

Leptin participates in regulating energy metabolism during pregnancy. Despite the rise in leptin concentrations during pregnancy, reduced leptin sensitivity to food intake during pregnancy has been described (Chehab, 2014). This "leptin resistance" may serve to promote energy storage during pregnancy and for later lactation.

Higher leptin levels during pregnancy may be disadvantageous under certain situations, such as maternal obesity. Leptin functions as a proinflammatory cytokine in white adipose tissue, which may dysregulate the inflammatory cascade and lead to placental dysfunction in obese women (Vazquez, 2015). In addition, abnormally elevated leptin levels have been associated with preeclampsia, gestational diabetes, and fetal distress (Rabiepoor, 2019; Taylor, 2015).

Fetal leptin is important for the development of several organs that include the pancreas, kidney, heart, and brain. Fetal levels correlate with maternal body mass index and birthweight (Özdemir, 2020). Lower levels are linked to fetal-growth restriction (Briffa, 2015).

TABLE 4-3. Plasma Concentrations of Lipids

Lipid	Nonpregnant	Third Trimester[a,b]
Total cholesterol	<200 mg/dL	267 ± 30 mg/dL
LDL	<100 mg/dL	136 ± 33 mg/dL
HDL	40–60 mg/dL	81 ± 17 mg/dL
Triglycerides	<150 mg/dL	245 ± 73 mg/dL

[a]Values from the Appendix (p. 1231).
[b]Values expressed as mean ± standard deviation.
HDL = high-density lipoprotein; LDL = low-density lipoprotein.

Other Adipocytokines

Dozens of hormones with metabolic and/or inflammatory functions are produced by adipose tissue. *Adiponectin* is a peptide produced primarily in maternal fat but not in the placenta (Haghiac, 2014). It may play a role in early pregnancy to assure a source of glycogen for fetal energy (Duval, 2018). Adiponectin levels inversely correlate with adiposity, and it acts as a potent insulin sensitizer. Despite reduced adiponectin levels in women with gestational diabetes, directed assays are not useful for predicting diabetes development (Hauguel-de Mouzon, 2013).

Ghrelin is a peptide secreted mainly by the stomach in response to hunger. It cooperates with other neuroendocrine factors, such as leptin, in energy homeostasis. Ghrelin is also expressed in the placenta and likely has a role in fetal growth and cell proliferation (González-Domínguez, 2016).

Visfatin is a peptide that was first identified as a growth factor for B lymphocytes but is mainly produced within adipose tissue. Mumtaz and associates (2015) propose that elevated levels of visfatin and leptin impair uterine contractility. Such findings may provide a physiological basis for the observation that maternal obesity raises the risk for dysfunctional labor.

Electrolyte and Mineral Metabolism

During normal pregnancy, nearly 1000 mEq of *sodium* and 300 mEq of *potassium* are retained (Lindheimer, 1987). The glomerular filtration rate of sodium and potassium is increased, but the excretion of these electrolytes is unchanged during pregnancy as a result of enhanced tubular resorption (Brown, 1988). Although total accumulations of sodium and potassium are elevated, their serum concentrations are diminished slightly (Appendix, p. 1229). Several mechanisms may explain these

lower levels (Odutayo, 2012). In the case of potassium, it possibly involves the expanded plasma volume of pregnancy. With respect to sodium, osmoregulation is altered, and the threshold for arginine vasopressin release is lowered. This promotes free water retention and diminished sodium levels.

Total serum *calcium* levels, which include both ionized and nonionized calcium, decrease during pregnancy. This reduction follows lowered plasma albumin concentrations and in turn a consequent decline in the amount of circulating protein-bound nonionized calcium. Serum ionized calcium levels, however, remain unchanged (Olausson, 2012).

The developing fetus imposes a significant demand on maternal calcium homeostasis. For example, the fetal skeleton accrues approximately 30 g of calcium by term, 80 percent of which is deposited during the third trimester. This demand is largely met by a doubling of maternal intestinal calcium absorption mediated partly by 1,25-dihydroxyvitamin D_3, the serum levels of which also are doubled. These higher levels of vitamin D are possibly stimulated by a twofold rise in parathyroid hormone (PTH)-related peptide levels produced by several tissues including the placenta (Olausson, 2012). To help compensate, dietary intake of sufficient calcium is necessary to prevent excess depletion from the mother. A list of all recommended daily allowances is found in Table 10-5 (p. 184). This is especially important for pregnant adolescents, in whom bones are still developing (Cullers, 2019). Unfortunately, a lack of robust data prevents drawing firm conclusions regarding the utility of calcium and vitamin D supplements during pregnancy (Bi, 2018; Hofmeyr, 2018).

Serum *magnesium* levels also decline during pregnancy. Compared with nonpregnant women, both total and ionized magnesium concentrations are significantly lower during normal pregnancy (Rylander, 2014).

Serum *phosphate* levels lie within the nonpregnant range (Larsson, 2008). Although calcitonin is an important regulator of serum calcium and phosphate, the importance of calcitonin as it relates to pregnancy is poorly understood (Olausson, 2012).

Iodine requirements increase during normal pregnancy for several reasons (Moleti, 2014). First, maternal thyroxine (T4) production rises to maintain maternal euthyroidism and to transfer thyroid hormone to the fetus prior to fetal thyroid functioning. Second, fetal thyroid hormone production increases during the second half of pregnancy. This contributes to greater maternal iodine requirements because iodine readily crosses the placenta. Third, the primary route of iodine excretion is the kidney. Beginning in early pregnancy, the iodine glomerular filtration rate increases by 30 to 50 percent. In sum, because of greater thyroid hormone production, fetal iodine requirements, and augmented renal clearance, dietary iodine needs are higher during normal gestation (Velasco, 2018).

Although the placenta has the ability to store iodine, whether this organ functions to protect the fetus from inadequate maternal dietary iodine is currently unknown. Iodine deficiency is discussed later in this chapter (p. 72) and in Chapter 61 (p. 1097). Extremely low or high maternal iodine intake may affect childhood neurodevelopment (Zhou, 2019). At the extreme, maternal supplements containing excessive iodine have been associated with congenital hypothyroidism. This stems from autoregulation in the thyroid gland—known as the *Wolff-Chaikoff effect*—to curb T4 production in response to iodine overconsumption.

The serum levels of many of these minerals are listed in the Appendix (p. 1229). With respect to most other minerals, pregnancy induces little change in their metabolism other than their retention in amounts equivalent to those needed for growth. An important exception is the considerably greater requirement for *iron*, which is discussed subsequently (Georgieff, 2021).

HEMATOLOGICAL CHANGES

Blood Volume

The well-known hypervolemia associated with normal pregnancy averages 40 to 45 percent above the nonpregnant blood volume after 32 to 34 weeks' gestation (Pritchard, 1965; Zeeman, 2009). In some, accumulated volume rises only modestly, whereas in others blood volume nearly doubles. A fetus is not essential, as augmented blood volume develops in some with hydatidiform mole. The stimulus is not known, but it likely is related to renin and prorenin with its effects on sodium and water retention (Fu, 2018). Simultaneously, vascular plasticity accommodates the larger blood volume (Osol, 2019).

Pregnancy-induced hypervolemia serves several functions. First, it meets the metabolic demands of the enlarged uterus and its greatly hypertrophied vascular system. It also provides abundant nutrients and elements to support the rapidly growing placenta and fetus. The expanded intravascular volume protects the mother, and in turn the fetus, against the deleterious effects of impaired venous return in the supine and erect positions. Last, it safeguards the mother against the adverse effects of parturition-associated blood loss.

Maternal blood volume begins to accrue during the first trimester. By 12 menstrual weeks, plasma volume expands by approximately 15 percent compared with that prior to pregnancy (Bernstein, 2001). Maternal blood volume grows most rapidly during the midtrimester, rises at a much slower rate during the third trimester, and reaches a plateau during the last several weeks of pregnancy (Fig. 4-4) (Thomsen, 1994). Blood volume accrues even more dramatically in twin gestations.

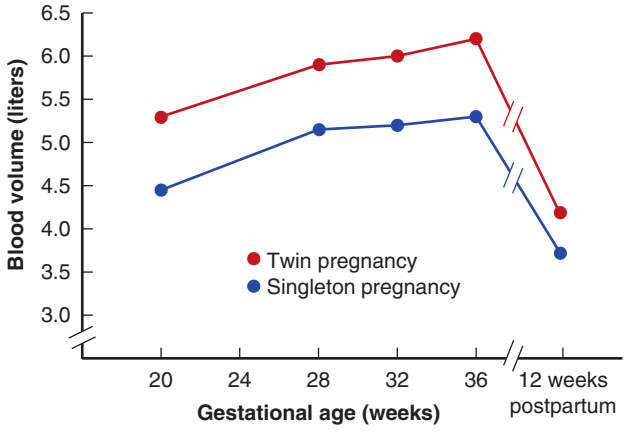

FIGURE 4-4 Blood volume expansion during pregnancy in twins (n = 10) and singletons (n = 40). Data shown as medians.

During blood volume expansion, plasma volume and erythrocyte mass increase. Although more plasma than erythrocytes is usually added to the maternal circulation, the increase in erythrocyte volume is considerable and averages 450 mL (Pritchard, 1960). Moderate erythroid hyperplasia develops in the bone marrow, and the reticulocyte count is elevated slightly during normal pregnancy. These changes are almost certainly related to the rise in maternal plasma erythropoietin levels (Appendix, p. 1227).

Because of great plasma augmentation, both hemoglobin concentration and hematocrit decline slightly during pregnancy. As a result, whole blood viscosity decreases (Huisman, 1987). Hemoglobin concentration at term averages 12.5 g/dL, and in approximately 5 percent of women it is below 11.0 g/dL. Thus, a concentration <11.0 g/dL, especially late in pregnancy, is considered abnormal and usually due to iron-deficiency anemia rather than pregnancy hypervolemia (Chap. 59, p. 1049).

Iron Metabolism

The total iron content of normal adult women ranges from 2.0 to 2.5 g, or approximately half that found normally in men. Most of this is incorporated in hemoglobin or myoglobin, and thus iron stores of normal young women approximate only 300 mg (Pritchard, 1964). Although the lower iron levels in women may be partly due to menstrual blood loss, other factors have a role. One is *hepcidin*—a peptide hormone that functions as a homeostatic regulator of systemic iron metabolism (Fisher, 2017). As shown in Figure 4-5, hepcidin levels drop early in pregnancy (Hedengran, 2016a,b). Lower hepcidin levels are associated with greater absorption of iron via ferroportin in enterocytes (Camaschella, 2015). Lower hepcidin levels also augment iron transport into the fetus via ferroportin in syncytiotrophoblast. Hepcidin levels rise with inflammation, but drop with iron deficiency and increased amount of several hormones, including testosterone, estrogen, vitamin D, and possibly prolactin (Liu, 2016).

Of the approximate 1000 mg of iron required for normal pregnancy, about 300 mg is actively transferred to the fetus and placenta, and another 200 mg is lost through various normal excretion routes, primarily the gastrointestinal tract. These are obligatory losses and accrue even when the mother is iron deficient. The average increase in the total circulating erythrocyte volume—about 450 mL—requires another 500 mg. Recall that each 1 mL of erythrocytes contains 1.1 mg of iron.

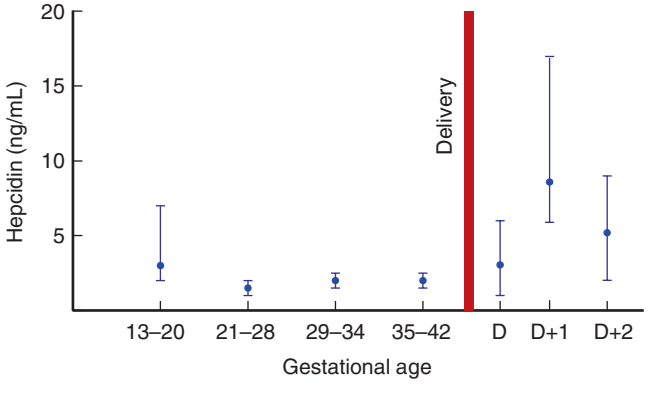

FIGURE 4-5 Hepcidin levels during pregnancy. Blue data points are median values and crossbars are the 25th and 75th percentiles. D is delivery and D + 1 and D + 2 are postpartum days 1 and 2.

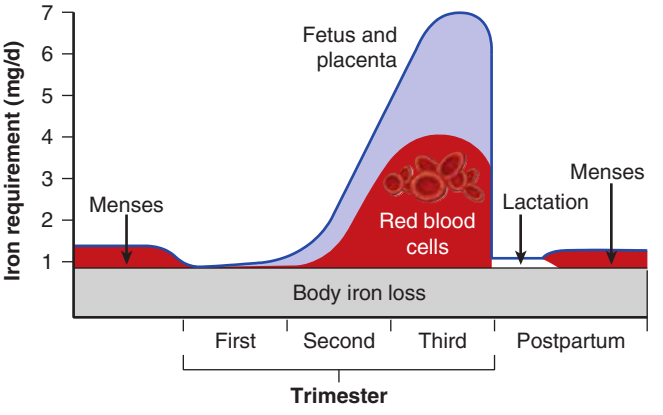

FIGURE 4-6 Estimated daily iron requirements during pregnancy in a 55-kg woman.

As shown in Figure 4-6, most iron is used during the latter half of pregnancy (Koenig, 2014). Thus, the iron requirement becomes large after midpregnancy and averages 6 to 7 mg/d (Pritchard, 1970). In most women, this amount is usually not available from iron stores or diet. If the nonanemic pregnant woman is not given supplemental iron, serum iron and ferritin concentrations decline after midpregnancy. Moreover, the optimal rise in maternal erythrocyte volume will not develop, and the hemoglobin concentration and hematocrit will fall appreciably as plasma volume rises. At the same time, fetal red cell production is not impaired because the placenta transfers iron even if the mother has marked iron-deficiency anemia. In severe cases, we have documented maternal hemoglobin values of 3 g/dL, and at the same time, fetuses had hemoglobin concentrations of 16 g/dL. The mechanisms of placental iron transport and regulation are complex (Koenig, 2014; McArdle, 2014).

With normal vaginal delivery, at least 500 to 600 mL of blood is typically lost, and thus not all the maternal iron added in the form of hemoglobin is spent. The excess hemoglobin iron postpartum becomes stored iron.

Immunological Functions

Pregnancy is associated with suppression of various humoral and cell-mediated immunological functions (Chap. 5, p. 93). This permits accommodation of the "foreign" semiallogeneic fetal graft that contains antigens of both maternal and paternal origin (Redman, 2015). The tolerance that exists at the maternal-fetal interface remains a great unsolved medical mystery. This tolerance is complex and involves certain immune system adaptations and crosstalk among the maternal microbiome, uterine decidua, and trophoblast. In particular, areas of the uterus that were previously considered sterile are colonized with bacteria. In most cases, these microbes are believed to be commensal and play a tolerizing and protective role. Indeed, commensal organisms may inhibit the proliferation of certain pathogens. Several reviewers have described these relationships (Mor, 2015; Racicot, 2014; Sisti, 2016).

One immune adaptation that promotes tolerance and protection at the maternal-fetal interface involves the expression of special major histocompatibility complex (MHC) molecules on the trophoblast. Another immune adaptation that promotes tolerance stems from important changes in CD4 T lymphocyte subpopulations in pregnancy. Specifically, immunity mediated by T-helper (Th) 1 cells shifts to Th2-mediated immunity. An important antiinflammatory component of pregnancy involves suppression of Th1 and T-cytotoxic (Tc) 1 cells, which lower secretion of interleukin 2 (IL-2), interferon α, and tumor necrosis factor (TNF).

In cervical mucus, peak levels of immunoglobulins A and G (IgA and IgG) are significantly higher during pregnancy, and the immunoglobulin-rich cervical mucus plug creates a barrier to ascending infection (Hansen, 2014; Wang, 2014). Similarly, IgG is transferred to the developing fetus in the third trimester as a form of passive immunity, ostensibly in anticipation of birth. Immunoglobulins secreted into breast milk during lactation augment neonatal defenses against infection (Chap. 36, p. 640).

Leukocytes and Lymphocytes

Normal leukocyte counts during pregnancy can be higher than nonpregnant values, and upper values approach 15,000/μL (Appendix, p. 1227). During labor and the early puerperium, values may markedly rise to attain levels ≥25,000/μL (Gat, 2019). The cause is unknown, but the same response occurs during and after strenuous exercise. The leukocytosis possibly represents the reappearance of leukocytes previously shunted out of active circulation.

The distribution of lymphocyte cell types also is altered during pregnancy. Specifically, B lymphocytes numbers are unchanged, but the absolute numbers of T lymphocytes rise and create a relative increase. Concurrently, the ratio of CD4 to CD8 T lymphocytes does not change (Kühnert, 1998).

Inflammatory Markers

Many tests performed to diagnose inflammation cannot be used reliably during pregnancy. For example, *leukocyte alkaline phosphatase* levels—used to evaluate myeloproliferative disorders—are elevated beginning early in pregnancy. The concentration of *C-reactive protein,* an acute-phase serum reactant, rises rapidly in response to tissue trauma or inflammation. Median C-reactive protein levels in pregnancy and labor are higher than for nonpregnant women (Anderson, 2013). Of nonlaboring gravidas, 95 percent had levels measuring ≤1.5 mg/dL, and gestational age did not affect serum levels.

Another marker of inflammation, the *erythrocyte sedimentation rate (ESR)*, is increased in normal pregnancy because of elevated plasma globulin and fibrinogen concentrations. *Complement factors C3* and *C4* levels also significantly rise during the second and third trimesters (Richani, 2005). Concentrations of *procalcitonin*, a normal precursor of calcitonin, are low to undetectable in midpregnancy but increase at the end of the third trimester and through the first few postpartum days (Bilinski, 2018). Procalcitonin levels rise with severe bacterial infections but remain low in viral infections and nonspecific inflammatory disease. However, measured levels poorly predict development of overt or subclinical chorioamnionitis after premature rupture of membranes (Thornburg, 2016; Tujula, 2018).

Coagulation and Fibrinolysis

During normal pregnancy, both coagulation and fibrinolysis are augmented but remain balanced to maintain hemostasis (Kenny, 2015). Evidence of activation includes increased concentrations of all clotting factors except factors XI and XIII (Table 4-4) (Cunningham, 2015).

Of procoagulants, the level and rate of thrombin generation throughout gestation progressively increase (McLean, 2012). In normal nonpregnant women, plasma fibrinogen (factor I) averages 300 mg/dL and ranges from 200 to 400 mg/dL. During normal pregnancy, the fibrinogen concentration rises approximately 50 percent. In late pregnancy, it averages 450 mg/dL, with a range from 300 to 600 mg/dL. As discussed, this contributes greatly to the striking elevation in the erythrocyte sedimentation rate. Also, levels of factor XIII—*fibrin stabilizing factor*—significantly drop as normal pregnancy advances (Sharief, 2014). Few studies describe thromboelastographic changes in normal pregnancy (Murray, 2018).

The end product of the coagulation cascade is fibrin formation, and the main function of the fibrinolytic system is to remove excess fibrin. Tissue plasminogen activator (tPA) converts plasminogen into plasmin, which is the enzyme that promotes fibrinolysis. It yields fibrin-degradation products such as D-dimers, and levels of these are increased in pregnancy (Hedengran, 2016b). Although somewhat conflicting, most evidence suggests that fibrinolytic activity is reduced in normal pregnancy (Kenny, 2015). As reviewed by Cunningham and

TABLE 4-4. Coagulation Factor Normal Values Across Pregnancy

Factor	Nonpregnant	Trimester		
		1st	2nd	3rd
Fibrinogen (mg/dL)	233–496	244–510	291–538	373–6.19
D-dimer (μg/mL)	0.22–0.74	0.05–0.95	0.32–1.29	0.13–1.7
Factor (% activity)				
V	50–150	75–95	72–96	60–88
VII	50–150	100–146	95–153	149–211
VIII	50–150	90–110	97–312	143–353
Protein C, functional (%)	70–130	78–121	83–133	67–135
Protein S, functional (%)	65–140	57–95	42–68	16–42

Nelson (2015), these changes favor fibrin formation. Although this is countered by increased levels of plasminogen, the net result is that pregnancy is a procoagulant state. Amnionic fluid is a potent activation of coagulation (Oda, 2018). Such changes serve to ensure hemostatic control during pregnancy, particularly during delivery when a certain amount of blood loss is expected.

Regulatory Proteins

Several proteins are natural inhibitors of coagulation, including proteins C and S and antithrombin. Inherited or acquired deficiencies of these and other natural regulatory proteins—collectively referred to as *thrombophilias*—account for many thromboembolic episodes during pregnancy. They are discussed in Chapter 55 (p. 976).

Activated protein C, along with the cofactors protein S and factor V, functions as an anticoagulant by neutralizing the procoagulants factor Va and factor VIIIa. During pregnancy, resistance to activated protein C grows progressively and is related to a concomitant drop in free protein S levels and greater factor VIII concentrations. Between the first and third trimesters, activated protein C levels decline from 2.4 to 1.9 U/mL, and free protein S concentrations diminish from 0.4 to 0.16 U/mL (Cunningham, 2015; Walker, 1997). Antithrombin levels drop by 13 percent between midpregnancy and term and fall 30 percent from this baseline until 12 hours after delivery. By 72 hours after delivery, there is a return to baseline (James, 2014).

Platelets

In a study of more than 7000 women, and as shown in Figure 4-7, the average platelet count declined across pregnancy and returned to normal nonpregnant values by 4 to 12 weeks postpartum (Reese, 2018). The platelet counts were lower for twin pregnancies. Lower platelet concentrations are partially due to hemodilution. In addition, platelet consumption is likely augmented and creates a greater proportion of younger and therefore larger platelets (Han, 2014). Further, clinically insignificant levels of several markers of platelet activation rise with gestational age but drop postpartum (Blomqvist, 2018). Because of splenic enlargement, an element of "hypersplenism," may sequester and prematurely destroy platelets (Kenny, 2015).

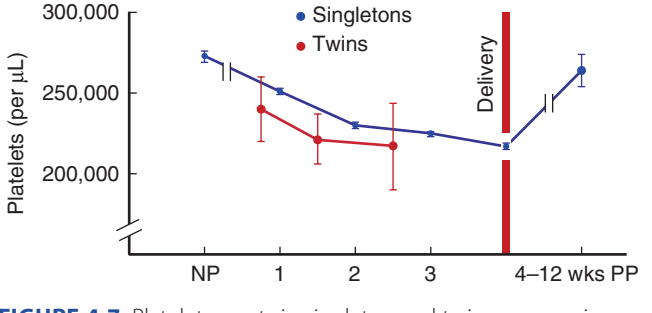

FIGURE 4-7 Platelet counts in singleton and twin pregnancies determined during 1st, 2nd, and 3rd trimester, at delivery, and then at 4–12 weeks postpartum. NP = nonpregnant. Values are means and 95% confidence intervals.

Spleen

By the end of normal pregnancy, the spleen enlarges up to 50 percent compared with that in the first trimester (Maymon, 2007). Moreover, Gayer and coworkers (2012) found that splenic size was 68-percent greater compared with that of nonpregnant controls. The cause of this splenomegaly is unknown, but it might follow the increased blood volume and/or the hemodynamic changes of pregnancy.

CARDIOVASCULAR SYSTEM

Changes in cardiac function become apparent during the first 8 weeks of pregnancy (Hibbard, 2015). Cardiac output is increased as early as the fifth week and reflects a reduced systemic vascular resistance and an increased heart rate. Compared with prepregnancy measurements, brachial systolic blood pressure, diastolic blood pressure, and central systolic blood pressure are all significantly lower 6 to 7 weeks from the last menstrual period (Mahendru, 2012). The resting pulse rate rises approximately 10 beats/min during pregnancy. Nelson and associates (2015) found that for both normal and overweight women, heart rate rose significantly between 12 and 16 weeks' and between 32 and 36 weeks' gestation. Between weeks 10 and 20, plasma volume expansion begins, and preload rises. This augmented preload results in a significantly larger left atrial volume and ejection fraction (Cong, 2015).

Ventricular performance during pregnancy is influenced by both the decline in systemic vascular resistance and changes in pulsatile arterial flow. Multiple factors contribute to this overall altered hemodynamic function, which allows the physiological demands of the fetus to be met while maintaining maternal cardiovascular integrity (Hibbard, 2015). These changes in stroke volume during the last half of pregnancy and the effects of maternal posture are summarized in Figure 4-8 (Nelson, 2015). Bijl and colleagues (2019) offer a detailed review of methods to measure cardiac function in gravidas.

Heart

As the diaphragm becomes progressively elevated, the heart is displaced to the left and upward and is rotated on its long

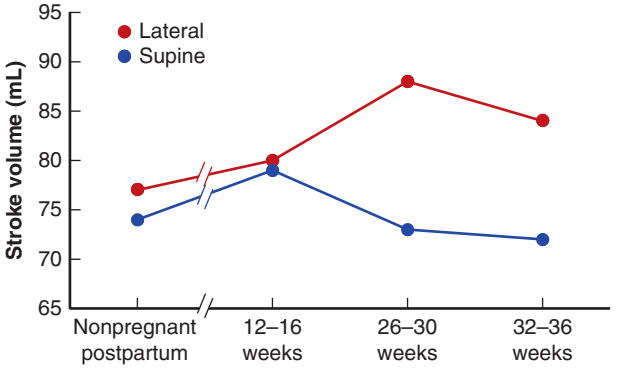

FIGURE 4-8 Left ventricular stroke volume across pregnancy compared with 12-week postpartum (nonpregnant) values for normal-weight women in the supine and lateral positions.

axis. As a result, the apex is moved somewhat laterally from its usual position and produces a larger cardiac silhouette in chest radiographs. Furthermore, gravidas normally have some degree of benign pericardial effusion, which may enlarge the cardiac silhouette (Enein, 1987). These factors make it difficult to precisely identify moderate degrees of cardiomegaly by simple radiographic studies.

Normal pregnancy induces some characteristic electrocardiographic (ECG) changes, and the most common is slight left-axis deviation due to the altered heart position. Q waves in leads II, III, and avF and flat or inverted T waves in leads III and V1–V3 also may be seen (Sunitha, 2014).

During pregnancy, many of the normal *cardiac sounds* are modified. These include: (1) an exaggerated splitting of the first heart sound and increased loudness of both components, (2) no definite changes in the aortic and pulmonary elements of the second sound, and (3) a loud, easily heard third sound (Cutforth, 1966). In most gravidas, a systolic murmur is intensified during inspiration in some or with expiration in others. Less often, a soft diastolic murmur can be noted transiently, and continuous murmurs arising from the breast vasculature may be heard (Fig. 52-1, p. 917).

Structurally, the expanding plasma volume seen during normal pregnancy is reflected by enlarging cardiac end-systolic and end-diastolic dimensions. Concurrently, however, septal thickness or ejection fraction does not change. This is because these dimensional changes are accompanied by substantive ventricular remodeling, which is characterized by left-ventricular mass expansion of 30 to 35 percent near term. In the nonpregnant state, the heart is capable of remodeling in response to stimuli such as hypertension and exercise. Such cardiac *plasticity* likely is a continuum that encompasses physiological growth as with exercise, and pathological hypertrophy as with hypertension (Hill, 2008; Osol, 2019).

Stewart and colleagues (2016) used cardiac MR imaging to prospectively evaluate cardiac remodeling during pregnancy. Compared with the first trimester, left ventricular mass significantly grew beginning at 26 to 30 weeks' gestation, and this continued until delivery (Fig. 4-9) (Stewart, 2016). This remodeling is concentric and proportional to maternal size for both normal and overweight women and resolved within 3 months of delivery. Certainly for clinical purposes,

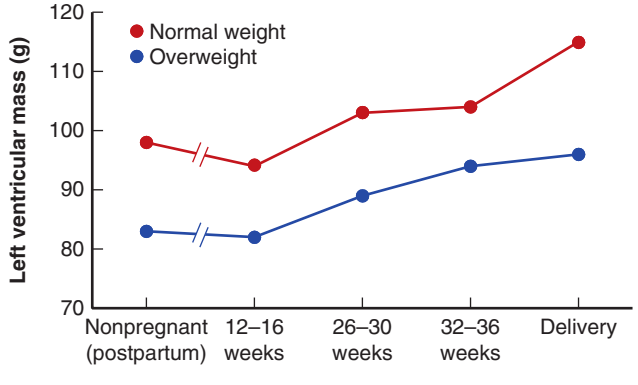

FIGURE 4-9 Left ventricular mass of normal-weight and overweight women across pregnancy compared with 12-week postpartum (nonpregnant) values.

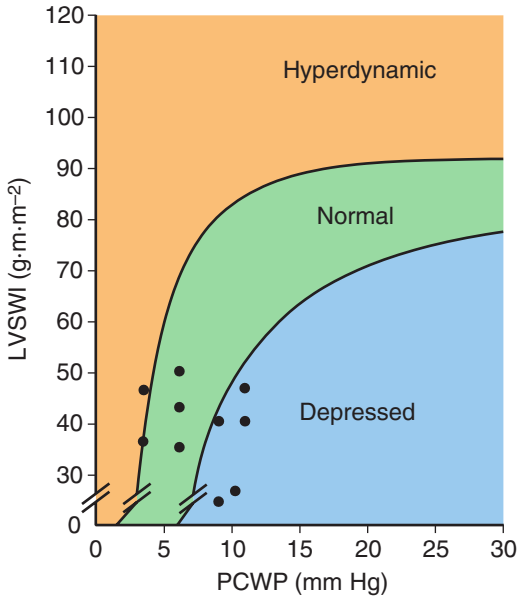

FIGURE 4-10 Relationship between left ventricular stroke work index (LVSWI), cardiac output, and pulmonary capillary wedge pressure (PCWP) in 10 normal pregnant women in the third trimester.

ventricular function during pregnancy is normal, as estimated by the *Braunwald ventricular function* graph (Fig. 4-10) (Clark, 1989). For the given filling pressures, cardiac output is appropriate and thus cardiac function during pregnancy is eudynamic. Of the metabolic changes that occur in the heart during pregnancy, the efficiency of cardiac work—which is the product of cardiac output × mean arterial pressure—is estimated to rise by approximately 25 percent. The associated increase in oxygen consumption is primarily accomplished via increased coronary blood flow rather than increased extraction (Liu, 2014).

Cardiac Output

When measured in the lateral recumbent position at rest, cardiac output increases significantly beginning in early pregnancy. It continues to rise and remains elevated during the remainder. In a supine woman, a large uterus consistently compresses veins and diminishes venous return from the lower body. It may also compress the aorta. In response, cardiac filling is limited, and cardiac output lessened. Specifically, cardiac MR imaging shows that a woman rolling from her back onto her left side raises her cardiac output at 26 to 30 weeks' gestation by approximately 20 percent and at 32 to 34 weeks by 10 percent (see Fig. 4-7). Consistent with this, Simpson and James (2005) found that fetal oxygen saturation is approximately 10 percent higher if a laboring woman lies in a lateral recumbent position compared with supine. Upon standing, cardiac output falls to the same degree as in the nonpregnant woman (Easterling, 1988).

In multifetal pregnancies, compared with singletons, maternal cardiac output is augmented further by almost another 20 percent. Ghi and coworkers (2015) used transthoracic echocardiography to show that first-trimester cardiac output with twins (mean 5.5 L/min) was more than 20 percent greater than postpartum values. Cardiac output values in the second (6.3 L/min)

and third (6.3 L/min) trimesters rose an additional 15 percent compared with first-trimester output. Due to augmented preload, left atrial and left ventricular end-diastolic diameters also grow with twins (Orabona, 2021). The augmented heart rate and inotropic contractility imply that cardiovascular reserve is reduced in multifetal gestations (Orabona, 2019).

During first-stage labor, cardiac output rises moderately. During the second stage, with vigorous expulsive efforts, it is appreciably greater. The pregnancy-induced increase is lost after delivery, at times dependent on blood loss.

Hemodynamic Function in Late Pregnancy

Clark and associates (1989) conducted invasive studies to measure hemodynamic function late in pregnancy (Table 4-5). Right heart catheterization was performed in 10 healthy nulliparas at 35 to 38 weeks' gestation, and again at 11 to 13 weeks postpartum. Late pregnancy was associated with the expected increases in heart rate, stroke volume, and cardiac output. Systemic vascular and pulmonary vascular resistance both dropped significantly, as did colloid osmotic pressure. Pulmonary capillary wedge pressure and central venous pressure did not change appreciably. Thus, although cardiac output rises, left ventricular function as measured by stroke work index remains similar to the nonpregnant normal range (see Fig. 4-10). Put another way, normal pregnancy is not a continuous "high-output" state (Herrera, 2018).

Circulation and Blood Pressure

Arterial pressure usually declines to a nadir at 24 to 26 weeks' gestation and rises thereafter. Diastolic pressure decreases more than systolic. Changes in posture affect arterial blood pressure (Fig. 4-11) (Wilson, 1980). Brachial artery pressure when sitting is lower than that when in the lateral recumbent supine position (Bamber, 2003). Additionally, systolic blood pressure is lower in the lateral positions compared with either the flexed sitting or supine positions (Armstrong, 2011). In approximately

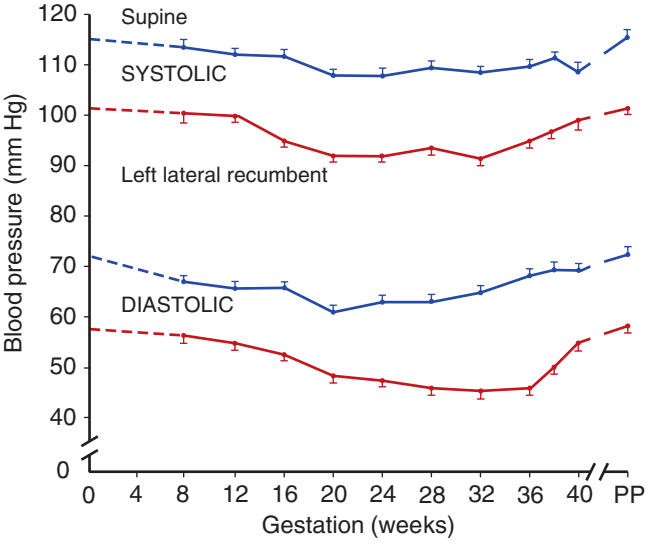

FIGURE 4-11 Sequential changes (± SEM) in blood pressure throughout pregnancy in 69 women in supine (*blue lines*) and left lateral recumbent positions (*red lines*). PP = postpartum.

10 percent of women, supine compression of the great vessels by the uterus causes significant arterial hypotension, sometimes referred to as the supine hypotensive syndrome. Also when supine, uterine arterial pressure—and thus uterine blood flow—is significantly lower than that in the brachial artery. Evidence to support whether this directly affects fetal heart rate patterns in uncomplicated low-risk pregnancies is conflicting (Armstrong, 2011; Ibrahim, 2015). Similar changes can also be seen with hemorrhage or with spinal analgesia.

Studies have assessed vascular compliance before pregnancy, during pregnancy, and postpartum (Morris, 2015; Osman, 2017). Compared with healthy nonpregnant controls, significant declines in mean arterial pressure and arterial stiffness were observed between prepregnant and postpartum time periods. These findings suggest that pregnancy confers a favorable effect on maternal cardiovascular remodeling.

TABLE 4-5. Central Hemodynamic Changes in 10 Normal Nulliparous Women Near Term and Postpartum

	Pregnant[a] (35–38 wk)	Postpartum (11–13 wk)	Change[b]
Mean arterial pressure (mm Hg)	90 ± 6	86 ± 8	NSC
Pulmonary capillary wedge pressure (mm Hg)	8 ± 2	6 ± 2	NSC
Central venous pressure (mm Hg)	4 ± 3	4 ± 3	NSC
Heart rate (beats/min)	83 ± 10	71 ± 10	+17%
Cardiac output (L/min)	6.2 ± 1.0	4.3 ± 0.9	+43%
Systemic vascular resistance (dyn/sec/cm^{-5})	1210 ± 266	1530 ± 520	−21%
Pulmonary vascular resistance (dyn/sec/cm^{-5})	78 ± 22	119 ± 47	−34%
Serum colloid osmotic pressure (mm Hg)	18.0 ± 1.5	20.8 ± 1.0	−14%
COP-PCWP gradient (mm Hg)	10.5 ± 2.7	14.5 ± 2.5	−28%
Left ventricular stroke work index (g/m/m^2)	48 ± 6	41 ± 8	NSC

[a]Measured in lateral recumbent position.
[b]Changes significant unless NSC = no significant change.
COP = colloid osmotic pressure; PCWP = pulmonary capillary wedge pressure.

The venous system is a high-flow, low-resistance circulation during pregnancy (Gyselaers, 2018). While antecubital venous pressure remains unchanged, in the supine position, femoral venous pressure rises steadily, from approximately 8 mm Hg early in pregnancy to 24 mm Hg at term. Venous blood flow in the legs is retarded except when the lateral recumbent position is assumed. This tendency toward blood stagnation in the lower extremities during later pregnancy is attributable to occlusion of the pelvic veins and inferior vena cava by the enlarged uterus. The elevated venous pressure returns to normal when the pregnant woman lies on her side and immediately after delivery. These alterations contribute to the dependent edema frequently experienced and to development of hemorrhoids and varicose veins in the legs and vulva. These changes also predispose to deep-vein thrombosis and pulmonary embolism.

Renin, Angiotensin II, and Plasma Volume

The renin-angiotensin-aldosterone axis is intimately involved in blood pressure control via sodium and water balance. All components of this system show increased levels in normal pregnancy. Renin is produced by both the maternal kidney and the placenta, and greater amounts of renin substrate (angiotensinogen) are produced by both maternal and fetal liver. Elevated angiotensinogen levels result, in part, from augmented estrogen production during normal pregnancy and are important in first-trimester blood pressure maintenance (West, 2016).

Gant and associates (1973) reported that nulliparas who remained normotensive became and stayed refractory to the pressor effects of infused angiotensin II. Conversely, those who ultimately became hypertensive developed, but then lost, this refractoriness. The diminished vascular responsiveness to angiotensin II may be progesterone related. Placental growth factor (PlGF) also blunts this response (Espinoza, 2019). Normally, pregnant women lose their acquired vascular refractoriness to angiotensin II within 15 to 30 minutes after the placenta is delivered. Large amounts of intramuscular progesterone given during late labor delay this diminishing responsiveness.

Cardiac Natriuretic Peptides

At least two species of these—*atrial natriuretic peptide (ANP)* and *brain natriuretic peptide (BNP)*—are secreted by cardiomyocytes in response to chamber-wall stretching. These peptides regulate blood volume by provoking natriuresis, diuresis, and vascular smooth-muscle relaxation. In nonpregnant and pregnant patients, levels of BNP and of amino-terminal pro–brain natriuretic peptide (Nt pro-BNP), as well as newer analytes such as suppressor of tumorigenicity 2 (ST2), may be useful in screening for depressed left ventricular systolic function and determining chronic heart failure prognosis (Cunningham, 2019; Ker, 2018).

During normal pregnancy, plasma ANP and BNP levels are maintained in the nonpregnant range despite greater plasma volume (Yurteri-Kaplan, 2012). In one study, median BNP levels were stable across pregnancy with values <20 pg/mL (Resnik, 2005). BNP levels are elevated in severe preeclampsia, and this may be caused by cardiac strain from increased afterload. It would appear that ANP-induced physiological adaptations participate in extracellular fluid volume expansion and in the elevated plasma aldosterone concentrations characteristic of normal pregnancy.

Prostaglandins

Elevated prostaglandin production during pregnancy is thought to have a central role in control of vascular tone, blood pressure, and sodium balance. Renal medullary prostaglandin E_2 synthesis is markedly elevated during late pregnancy and is presumed to be natriuretic. Levels of prostacyclin (PGI_2), the principal prostaglandin of endothelium, also rise during late pregnancy. PGI_2 regulates blood pressure and platelet function. It helps maintain vasodilation during pregnancy, and its deficiency is associated with pathological vasoconstriction (Shah, 2015). The ratio of PGI_2 to thromboxane in maternal urine and blood may be important indicators of preeclampsia pathogenesis.

Endothelin

Pregnancy generates several endothelins, which are vasoconstricting peptides. Endothelin-1 is a potent vasoconstrictor produced in endothelial and vascular smooth muscle cells and regulates local vasomotor tone (Lankhorst, 2016). Its production is stimulated by angiotensin II, arginine vasopressin, and thrombin. Endothelins, in turn, stimulate secretion of ANP, aldosterone, and catecholamines. Vascular sensitivity to endothelin 1 is not altered during normal pregnancy. Pathologically elevated levels may play a role in preeclampsia (Saleh, 2016).

Nitric Oxide

This potent vasodilator is released by endothelial cells and may modify vascular resistance during pregnancy. As discussed earlier (p. 52), nitric oxide is an important mediator of placental vascular tone and development (West, 2016). Abnormal nitric oxide synthesis has been linked to preeclampsia (Laskowska, 2015; Vignini, 2016).

RESPIRATORY TRACT

Of anatomical changes, the diaphragm rises approximately 4 cm during pregnancy (Fig. 4-12). The subcostal angle widens appreciably as the transverse diameter of the thoracic cage lengthens approximately 2 cm. The thoracic circumference increases about 6 cm, but not sufficiently to prevent reduced residual lung volumes created by the elevated diaphragm. Even so, diaphragmatic excursion is greater in pregnancy. Dyspnea is common (Rudder, 2021).

Pulmonary Function

Of physiological lung changes, *functional residual capacity (FRC)* decreases by approximately 20 to 30 percent or 400 to 700 mL during pregnancy (Fig. 4-13). This capacity is composed of *expiratory reserve volume*—which drops 15 to 20 percent or 200 to 300 mL—and *residual volume*—which decreases 20 to 25 percent or 200 to 400 mL. FRC and residual volume decline

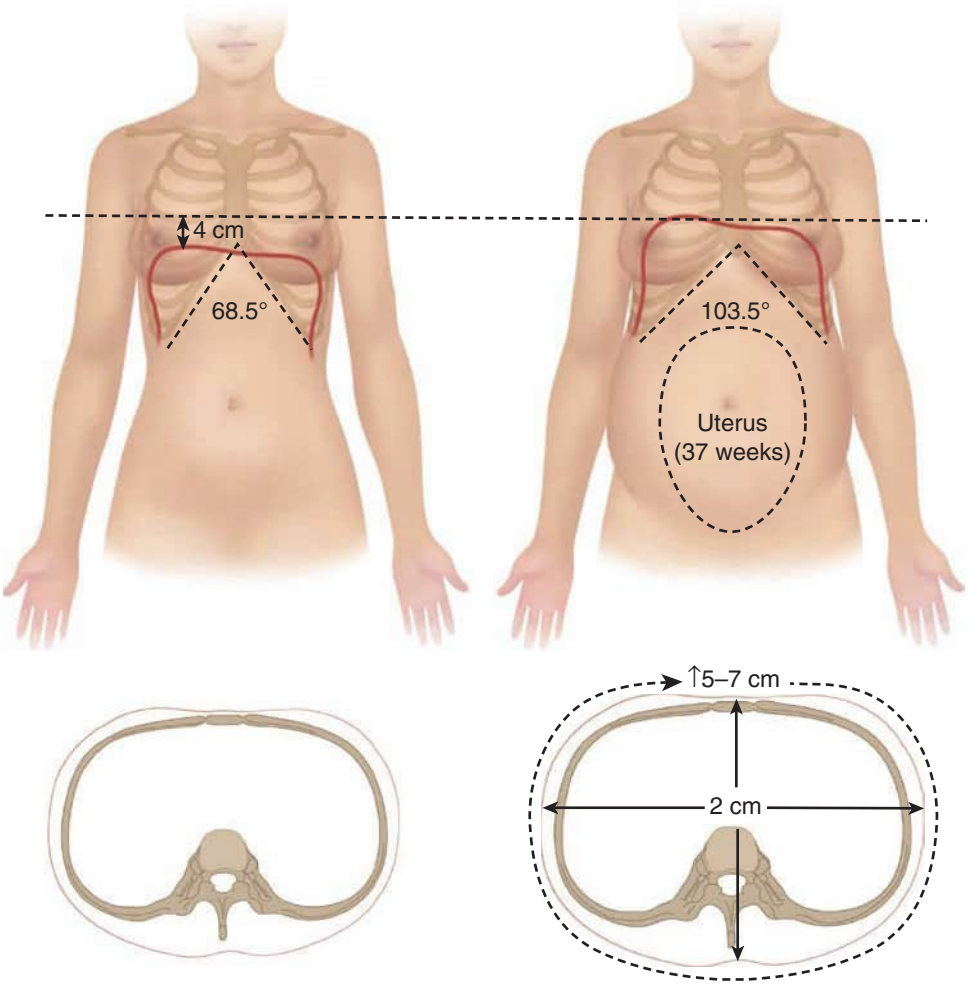

FIGURE 4-12 Chest wall measurements in nonpregnant (*left*) and pregnant women (*right*). The subcostal angle increases, as does the anteroposterior and transverse diameters of the chest wall and chest wall circumference. These changes compensate for the 4-cm elevation of the diaphragm so that total lung capacity is not significantly reduced. (Redrawn from Hegewald MJ, Crapo RO. Respiratory physiology in pregnancy, Clin Chest Med 2011 Mar;32(1):1–13.)

progressively across pregnancy due to diaphragm elevation. Significant reductions are observed by the sixth month. *Inspiratory capacity*, the maximum volume that can be inhaled from FRC, rises by 5 to 10 percent or 200 to 350 mL during pregnancy. *Total lung capacity*—the combination of FRC and inspiratory capacity—is unchanged or declines by <5 percent at term (Hegewald, 2011).

The respiratory rate is essentially unchanged, but *tidal volume* and *resting minute ventilation* increase significantly as pregnancy advances. Kolarzyk and coworkers (2005) reported significantly greater mean tidal volumes—0.66 to 0.8 L/min—and resting minute ventilations—10.7 to 14.1 L/min—compared with those of nonpregnant women. The elevated minute ventilation is caused by several factors. These include enhanced respiratory drive primarily due to the stimulatory action of progesterone, low expiratory reserve volume, and compensated respiratory alkalosis (Heenan, 2003). Also, decreased plasma osmolality can result in less respiratory depression (Moen, 2014).

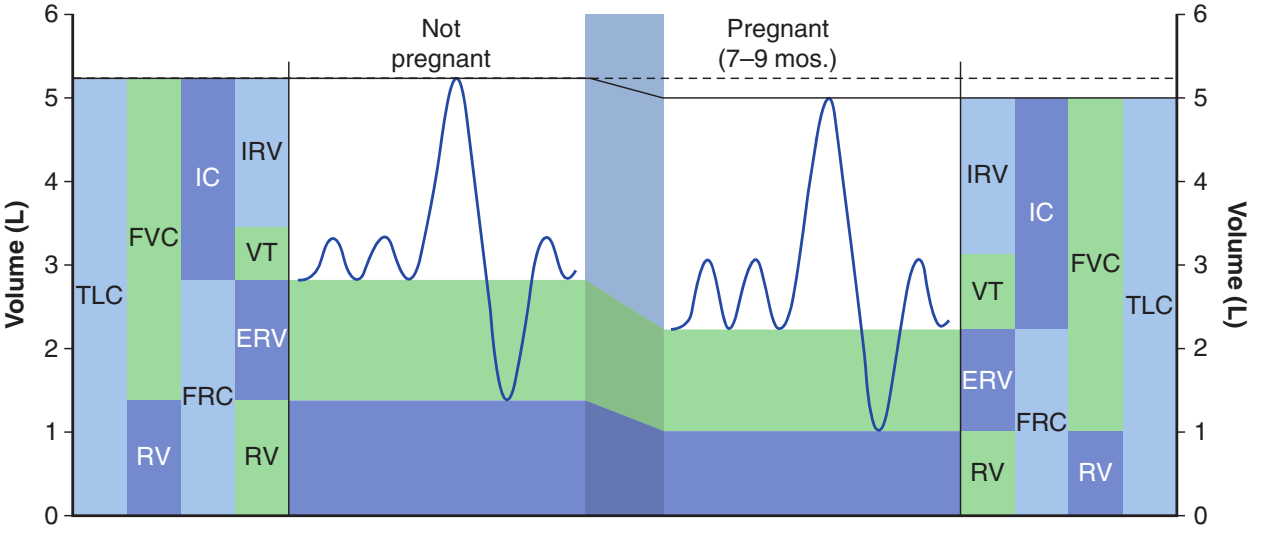

FIGURE 4-13 Changes in lung volumes with pregnancy. The most significant changes are reduction in functional residual capacity (FRC) and its subcomponents, expiratory reserve volume (ERV) and residual volume (RV), as well as increases in inspiratory capacity (IC) and tidal volume (VT). (Reproduced with permission from Hegewald MJ, Crapo RO. Respiratory physiology in pregnancy, Clin Chest Med 2011 Mar;32(1):1–13.)

Regarding pulmonary function, *peak expiratory flow rates* rise progressively as gestation advances (Grindheim, 2012). *Lung compliance* is unaffected by pregnancy. *Airway conductance* is increased and *total pulmonary resistance* reduced, possibly as a result of progesterone. The *maximum breathing capacity* and *forced* or *timed vital capacity* are not altered appreciably. It is unclear whether the critical *closing volume*—the lung volume at which airways in the dependent parts of the lung begin to close during expiration—is higher in pregnancy (Hegewald, 2011). Pulmonary function with a singleton pregnancy does not significantly differ from that with twins (Siddiqui, 2014). Importantly, the greater oxygen requirements and perhaps the increased critical closing volume imposed by pregnancy make respiratory diseases more serious.

Demir and colleagues (2015) studied nasal physiology in 85 pregnant women. Although the minimal cross-sectional area decreased between the first and third trimesters, subjective reports of nasal congestion or total nasal resistance did not significantly differ among trimesters or compared with nonpregnant controls.

Oxygen Delivery

The amount of oxygen delivered into the lungs by the increased tidal volume clearly exceeds oxygen requirements imposed by pregnancy. Moreover, the total hemoglobin mass and, in turn, total oxygen-carrying capacity rise appreciably during normal pregnancy, as does cardiac output. Consequently, the *maternal arteriovenous oxygen* difference is diminished. Oxygen consumption grows approximately 20 percent during pregnancy, and it is approximately 10 percent higher in multifetal gestations (Ajjimaporn, 2014). During labor, oxygen consumption increases 40 to 60 percent (Bobrowski, 2010).

Acid–Base Equilibrium

A greater awareness of a desire to breathe is common even early in pregnancy (Milne, 1978). This may be interpreted as dyspnea, which may suggest pulmonary or cardiac abnormalities when none exist. This physiological dyspnea, which should not interfere with normal physical activity, is thought to result from greater tidal volume that lowers the partial pressure of carbon dioxide (CO_2) in blood ($Paco_2$) slightly and paradoxically causes dyspnea. The increased respiratory effort during pregnancy, and in turn the reduction in the $Paco_2$, is likely induced in large part by progesterone and to a lesser degree by estrogen. Progesterone acts centrally. Here, it lowers the threshold and raises the sensitivity of the chemoreflex response to carbon dioxide (Jensen, 2005).

To compensate for the resulting respiratory alkalosis, plasma bicarbonate levels normally drop from 26 to 22 mmol/L. Although blood pH is increased only minimally, it does shift the oxygen dissociation curve to the left. This shift increases the affinity of maternal hemoglobin for oxygen—the *Bohr effect*—thereby lowering the oxygen-releasing capacity of maternal blood. This is offset because the slight pH rise also stimulates an increase in 2,3-diphosphoglycerate in maternal erythrocytes. This shifts the curve back to the right (Tsai, 1982). Thus, reduced $Paco_2$ from maternal hyperventilation aids CO_2 (waste) transfer from the fetus to the mother while also aiding oxygen release to the fetus.

URINARY SYSTEM

Kidney

The urinary system undergoes several remarkable changes in pregnancy (Table 4-6) (Lindheimer, 2000). *Kidney size* grows

TABLE 4-6. Renal Changes in Normal Pregnancy

Parameter	Alteration	Clinical Relevance
Kidney size	Approximately 1 cm longer on radiograph	Size returns to normal postpartum
Dilatation	Resembles hydronephrosis on sonogram or IVP (more marked on right)	Can be confused with obstructive uropathy; retained urine leads to collection errors; renal infections are more virulent; may be responsible for "distention syndrome"; elective pyelography should be deferred to at least 12 weeks postpartum
Renal function	Glomerular filtration rate and renal plasma flow increase ~50%	Serum creatinine decreases during normal gestation; >0.8 mg/dL (>72 μmol/L) creatinine already borderline; protein, amino acid, and glucose excretion all increase
Maintenance of acid-base	Decreased bicarbonate threshold; progesterone stimulates respiratory center	Serum bicarbonate decreased by 4–5 mEq/L; Pco_2 decreased 10 mm Hg; a Pco_2 of 40 mm Hg already represents CO_2 retention
Plasma osmolality	Osmoregulation altered; osmotic thresholds for AVP release and thirst decrease; hormonal disposal rates increase	Serum osmolality decreases 10 mOsm/L (serum Na^+ ~5 mEq/L) during normal gestation; increased placental metabolism of AVP may cause transient diabetes insipidus during pregnancy

AVP = vasopressin; IVP = intravenous pyelography; Pco_2 = partial pressure carbon dioxide.

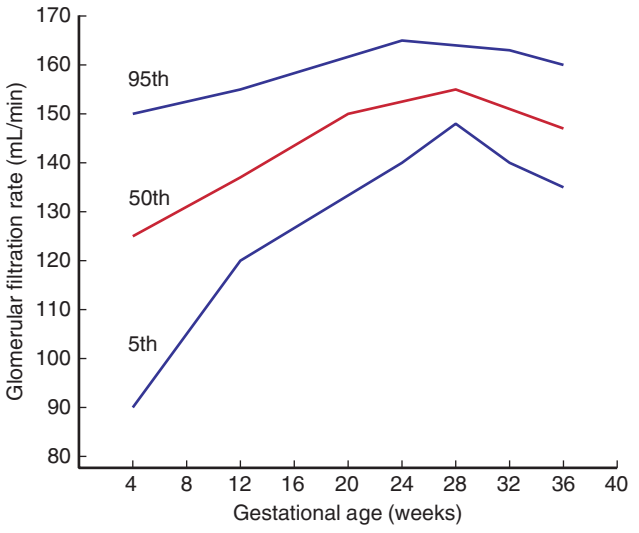

FIGURE 4-14 Glomerular filtration rate across pregnancy as measured by inulin clearance. The solid line is the 50th percentile and the dashed lines are the 5th and 95th percentiles.

approximately 1.0 cm (Cietak, 1985). Both the *glomerular filtration rate (GFR)* and *renal plasma flow* increase early in pregnancy. The GFR rises as much as 25 percent by the second week after conception and 50 percent by the beginning of the second trimester (Fig. 4-14) (Lopes van Balen, 2019). This hyperfiltration results from two principal factors. First, hypervolemia-induced hemodilution lowers the protein concentration and oncotic pressure of plasma entering the glomerular microcirculation. Second, renal plasma flow rises by approximately 80 percent before the end of the first trimester (Conrad, 2015; Lopes van Balen, 2019). Elevated GFR persists until term, even though renal plasma flow declines during late pregnancy. Primarily as a consequence of this elevated GFR, approximately 60 percent of nulliparas during the third trimester experience urinary frequency, and 80 percent experience nocturia (Frederice, 2013).

During the puerperium, a marked GFR persists during the first postpartum day, principally from the reduced glomerular capillary oncotic pressure. The gestational hypervolemia and hemodilution, still evident on the first postpartum day, resolves by the second week postpartum.

Studies suggest that relaxin, discussed earlier (p. 54), may mediate both increased GFR and renal blood flow during pregnancy (Conrad, 2015). Relaxin boosts renal nitric oxide production, which leads to renal vasodilation and lowered renal afferent and efferent arteriolar resistance. This augments renal blood flow and GFR (Bramham, 2016). Relaxin may also increase vascular gelatinase activity during pregnancy, which leads to renal vasodilation, glomerular hyperfiltration, and reduced myogenic reactivity of small renal arteries (Odutayo, 2012).

As with blood pressure, maternal posture may considerably influence several aspects of renal function. Late in pregnancy, the sodium excretion rate in the supine position averages less than half that in the lateral recumbent position. The effects of posture on GFR and renal plasma flow vary.

One unusual feature of the pregnancy-induced changes in renal excretion is the remarkably higher amounts of some nutrients lost in the urine. Amino acids and water-soluble vitamins are excreted in much greater amounts (Shibata, 2013).

Renal Function Tests

The mean nonpregnancy serum creatinine level of 0.7 mg/dL declines during normal pregnancy to 0.5 mg/dL. *Values ≥0.9 mg/dL suggest underlying renal disease and prompt further evaluation.* Creatinine clearance in pregnancy averages 30 percent higher than the 100 to 115 mL/min in nonpregnant women. This is a useful test to estimate renal function, provided that complete urine collection is made during an accurately timed period. If this is not done precisely, results are misleading (Lindheimer, 2010). During the day, pregnant women tend to accumulate water as dependent edema. When recumbent at night, they mobilize this fluid with diuresis. This reversal of the usual nonpregnant diurnal pattern of urinary flow causes nocturia, and urine is more dilute than in nonpregnant women. Failure of a pregnant woman to excrete concentrated urine after withholding fluids for approximately 18 hours does not necessarily signify renal damage. In fact, the kidneys in these circumstances function perfectly normally by excreting mobilized extracellular fluid of relatively low osmolality.

Urinalysis

Glucosuria during pregnancy may not be abnormal. The appreciably increased GFR, together with impaired tubular reabsorptive capacity for filtered glucose, accounts for most cases of glucosuria. Chesley (1963) calculated that approximately one sixth of gravidas will spill glucose in the urine. As discussed in Chapter 56 (p. 994), although the sensitivity is low, glucosuria may be an indicator of gestational diabetes mellitus. For women with glucosuria, no guidelines in the United States direct practice, but in the United Kingdom, early oral glucose testing is considered for those with an isolated 2+ or repetitive 1+ urine dipstick readings (National Institute for Health And Clinical Excellence, 2015).

Hematuria most often suggests urinary tract disease or infection. Evaluation of this finding is outlined in Chapter 56 (p. 995). Hematuria is common after difficult labor and delivery because of trauma to the bladder and urethra.

Proteinuria is typically defined in nonpregnant subjects as a protein excretion rate of more than 150 mg/d. Because of the aforementioned hyperfiltration and possible reduction of tubular reabsorption, proteinuria during pregnancy is usually considered significant once a protein excretion threshold of at least 300 mg/d is reached (Odutayo, 2012). Higby and coworkers (1994) measured protein excretion in 270 normal women throughout pregnancy (Fig. 4-15). Mean 24-hour excretion for all three trimesters was 115 mg, and the upper 95-percent confidence limit was 260 mg/d without significant differences by trimester. They showed that albumin excretion is minimal and ranges from 5 to 30 mg/d. Proteinuria increases with gestational age, which corresponds with the peak in GFR (Benzing, 2021).

Measuring Urine Protein

The three most commonly employed approaches for assessing proteinuria are the qualitative classic dipstick, the quantitative

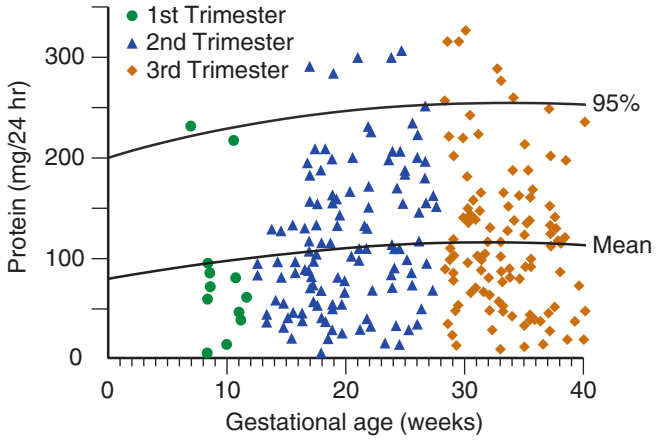

FIGURE 4-15 Scatter plot of women showing 24-hour urinary total protein excretion by gestational age. Mean and 95-percent confidence limits are outlined. (Modified with permission from Higby K, Suiter CR, Phelps JY, et al: Normal values of urinary albumin and total protein excretion during pregnancy, Am J Obstet Gynecol 1994 Oct;171(4):984–989.)

24-hour collection, and the albumin/creatinine or protein/creatinine ratio of a single voided urine specimen. The pitfalls of each approach have been reviewed (Bramham, 2016; Conrad, 2015).

With dipstick assessment, the principal problem is its failure to account for renal concentration or dilution of urine. For example, with polyuria and extremely dilute urine, a negative or trace dipstick could actually be associated with excessive protein excretion.

The 24-hour urine collection is affected by urinary tract dilation, discussed in the next section. The dilated tract may lead to errors related both to retention—hundreds of milliliters of urine remaining in the dilated tract—and to timing—the remaining urine may have formed hours before the collection. To minimize these pitfalls, the patient is first hydrated and positioned in lateral recumbency—the definitive nonobstructive posture—for 45 to 60 minutes. After this, she is asked to void, and this specimen is discarded. Immediately following this void, her 24-hour collection begins. During the final hour of collection, the patient is again placed in the lateral recumbent position. But, at the end of this hour, the final collected urine is incorporated into the total collected volume (Lindheimer, 2010).

Last, the protein:creatinine ratio is a promising approach because data can be obtained quickly and collection errors are avoided. Disadvantageously, the amount of protein per unit of creatinine excreted during a 24-hour period is not constant, and the thresholds to define abnormal vary. Nomograms for urinary microalbumin and creatinine ratios during uncomplicated pregnancies have been developed. The ratio is unreliable postpartum (Aziz, 2018).

■ Ureters

After the uterus completely rises out of the pelvis, it rests on the ureters. This laterally displaces and compresses them at the pelvic brim. Above this level, elevated intraureteral tonus results, and ureteral dilation (hydroureter) and hydronephrosis is impressive. It is greater on the right side as shown in Figure 4-16

FIGURE 4-16 Hydronephrosis. Plain film from the 15-minute image of an intravenous pyelogram (IVP). Moderate hydronephrosis on the right (*arrows*) and mild hydronephrosis on the left (*arrowheads*) are both normal for this 35-week gestation.

(Wadasinghe, 2016). It is right sided in 86 percent of women. This unequal dilation may result from cushioning provided to the left ureter by the sigmoid colon and perhaps from greater right ureteral compression exerted by the dextrorotated uterus. The right ovarian vein complex, which is remarkably dilated during pregnancy, lies obliquely over the right ureter and may also contribute to ureteral compression and proximal dilation.

Progesterone likely has some additional effect. Van Wagenen and Jenkins (1939) described continued ureteral dilation after removal of the monkey fetus but with the placenta left in situ. The relatively abrupt onset of dilation in women at midpregnancy, however, seems more consistent with ureteral compression.

Ureteral elongation accompanies distention, and the ureter is frequently thrown into curves of varying size, and smaller curves may be sharply angulated. These so-called kinks are poorly named, because the term connotes obstruction. They are usually single or double curves that, when viewed in a radiograph taken in the same plane as the curve, may appear as acute angulations. Another exposure at right angles nearly always identifies them to be gentle curves. Despite these anatomical changes, complication rates associated with ureteroscopy in pregnant and nonpregnant patients do not differ significantly (Semins, 2014).

■ Bladder

The bladder shows few significant anatomical changes before 12 weeks' gestation. Subsequently, however, increased uterine size, the hyperemia that affects all pelvic organs, and hyperplasia

of bladder muscle and connective tissues together elevate the trigone and thicken its intraureteric margin. Continuation of this process to term produces marked deepening and widening of the trigone. The bladder mucosa is unchanged other than an increase in the size and tortuosity of its blood vessels.

Bladder pressure in primigravidas rises from 8 cm H_2O early in pregnancy to 20 cm H_2O at term (Iosif, 1980). To compensate for reduced bladder capacity, absolute and functional urethral lengths increase by 6.7 and 4.8 mm, respectively. Concurrently, maximal intraurethral pressure rises from 70 to 93 cm H_2O, and thus continence is maintained. Still, at least half of women experience some degree of urinary incontinence by the third trimester (Abeysekera, 2016). Indeed, this is always considered in the differential diagnosis of ruptured membranes. Near term—particularly in nulliparas, in whom the presenting part often engages before labor—the entire base of the bladder is pushed ventral and cephalad. This converts the normally convex surface into a concavity. As a result, diagnostic and therapeutic procedures are more difficult. Moreover, pressure from the presenting part impairs blood and lymph drainage from the bladder base, often rendering the area edematous, easily traumatized, and possibly more susceptible to infection.

GASTROINTESTINAL TRACT

As pregnancy progresses, the stomach and intestines are displaced cephalad by the enlarging uterus. Consequently, the physical findings in certain diseases are altered. The appendix, for instance, is usually displaced upward and somewhat laterally. At times, it may reach the right flank.

Pyrosis (heartburn) is common during pregnancy and is most likely caused by reflux of acidic secretions into the lower esophagus. Although the altered stomach position probably contributes to its frequency, lower esophageal sphincter tone also is diminished. In addition, intraesophageal pressures are lower and intragastric pressures higher in pregnant women. Concurrently, esophageal peristalsis has lower wave speed and lower amplitude (Ulmsten, 1978).

Gastric emptying time is essentially unchanged across pregnancy in gravidas compared with nonpregnant women. In fasting women at term, gastric volume is not different than that in nonpregnant controls (Van de Putte, 2019). At term, during labor, and especially after administration of analgesics, however, gastric emptying time may be appreciably prolonged (Barboni, 2016). As a result, one danger of general anesthesia for delivery is regurgitation and aspiration of either food-laden or highly acidic gastric contents.

Some reports describe maternal gut microbiome changes during pregnancy (Smid, 2018). Currently, however, the vaginal and gut microbiome profiles and their influence on pregnancy are unclear (Taddei, 2018).

Hemorrhoids are common during pregnancy (Shin, 2015). They are caused in large measure by constipation and elevated pressure in rectal veins below the level of the enlarged uterus.

Liver

Liver size does not enlarge during human pregnancy. Hepatic arterial and portal venous blood flow, however, rise substantively (Clapp, 2000). Liver stiffness increases from the second to third trimester and returns to baseline postpartum (Ammon, 2018).

Some laboratory test results of hepatic function are altered in normal pregnancy (Appendix, p. 1229). Total alkaline phosphatase activity almost doubles, but much of the rise is attributable to heat-stable placental alkaline phosphatase isozymes. Serum aspartate transaminase (AST), alanine transaminase (ALT), γ-glutamyl transpeptidase (GGT), and bilirubin levels are slightly lower compared with nonpregnant values (Cattozzo, 2013).

The serum albumin concentration declines during pregnancy. By late pregnancy, albumin levels may be near 3.0 g/dL compared with approximately 4.3 g/dL in nonpregnant women (Mendenhall, 1970). Total body albumin levels rise, however, because of pregnancy-associated expansion of plasma volume. Serum globulin levels also are slightly higher.

Leucine aminopeptidase is a proteolytic liver enzyme whose serum levels may be elevated with liver disease. Its activity is markedly higher in pregnant women. The rise, however, results from a pregnancy-specific enzyme(s) with distinct substrate specificities (Song, 1968). Pregnancy-induced aminopeptidase has oxytocinase and vasopressinase activity that occasionally causes transient diabetes insipidus (Chap. 61, p. 1104).

Gallbladder

During normal pregnancy, gallbladder volume expands by approximately 50 percent, contractility declines, and both lead to greater residual volume (Braverman, 1980). Progesterone potentially impairs gallbladder contraction by inhibiting cholecystokinin-mediated smooth muscle stimulation, which is the primary regulator of gallbladder contraction. Impaired emptying, subsequent stasis, and the greater cholesterol saturation of bile in pregnancy contribute to the increased prevalence of cholesterol gallstones in multiparas. In one study, approximately 8 percent of women had gallbladder sludge or stones (Ko, 2014).

The pregnancy effects on maternal serum bile acid concentrations are still incompletely characterized. This is despite the long-acknowledged propensity for pregnancy to cause intrahepatic cholestasis from retained bile salts. Cholestasis of pregnancy is described in Chapter 58 (p. 1032).

ENDOCRINE SYSTEM

Pituitary Gland

During normal pregnancy, the pituitary gland enlarges by approximately 135 percent (Woodmansee, 2019). This expansion may sufficiently compress the optic chiasma to reduce visual fields. Impaired vision from this is rare and usually due to macroadenomas (Lee, 2014). Pituitary enlargement is primarily caused by estrogen-stimulated hypertrophy and hyperplasia of the lactotrophs (Feldt-Rasmussen, 2011). As discussed subsequently, maternal serum prolactin levels parallel this growth. Gonadotroph number decline, and corticotroph and thyrotroph populations remain constant. Somatotroph function is generally suppressed due to negative feedback by the placental production of growth hormone.

Peak pituitary size may reach 12 mm in MR images in the first days postpartum. The gland involutes rapidly and reaches normal size by 6 months postpartum (Woodmansee, 2019). The incidence of pituitary prolactinomas is not increased during pregnancy. When these tumors are large before pregnancy, such as with macroadenomas that by definition measure ≥10 mm, then growth during pregnancy is more likely (Chap. 61, p. 1103).

The maternal pituitary gland is not essential for pregnancy maintenance. Many women have undergone hypophysectomy, completed pregnancy successfully, and entered spontaneous labor while receiving compensatory glucocorticoids, thyroid hormone, and vasopressin.

Of pituitary gland hormones, *growth hormone* during the first trimester is secreted predominantly from the maternal pituitary gland, and concentrations in serum and amnionic fluid lie within the nonpregnant range. As early as 6 weeks' gestation, growth hormone secreted from the placenta becomes detectable, and by approximately 20 weeks, the placenta is the principal source of growth hormone secretion (Woodmansee, 2019). During this time, maternal serum values rise slowly from approximately 3.5 ng/mL at 10 weeks to plateau at about 14 ng/mL after 28 weeks' gestation. Growth hormone in amnionic fluid peaks at 14 to 15 weeks' gestation and slowly declines thereafter to reach baseline values after 36 weeks.

Placental growth hormone—which differs from pituitary growth hormone by 13 amino acid residues—is secreted by syncytiotrophoblast (Newbern, 2011). Its regulation and physiological effects are incompletely understood, but it influences fetal growth via upregulation of insulin-like growth factor 1 (IGF-1). That said, fetal growth still progresses in the complete absence of this hormone. Although not absolutely essential, the hormone may act in concert with placental lactogen to regulate fetal growth (Newbern, 2011).

Prolactin levels rise markedly in maternal plasma during normal pregnancy. Concentrations are usually tenfold greater at term—approximately 150 ng/mL—compared with those of nonpregnant women. Paradoxically, plasma levels drop after delivery even in women who are breastfeeding. During early lactation, pulsatile bursts of prolactin secretion are a response to suckling.

The principal function of maternal prolactin is to ensure lactation. Early in pregnancy, prolactin acts to initiate DNA synthesis and mitosis of glandular epithelial cells and presecretory alveolar cells of the breast. Prolactin also augments the number of estrogen and prolactin receptors in these cells. Last, prolactin promotes mammary alveolar cell RNA synthesis, galactopoiesis, and production of casein, lactalbumin, lactose, and lipids (Andersen, 1982). A woman with isolated prolactin deficiency failed to lactate after two pregnancies (Kauppila, 1987). This establishes prolactin as a requisite for lactation but not for pregnancy.

Grattan (2015) has reviewed the numerous physiological roles of prolactin to aid maternal adaptations to pregnancy. The prolactin receptor in the maternal pancreas indicates that prolactin may function to mediate pancreatic adaptations to pregnancy (Nteeba, 2019). A possible role is proposed for a prolactin fragment in the genesis of peripartum cardiomyopathy (Chap. 52, p. 933) (Cunningham, 2019; Koenig, 2018).

Prolactin is present in amnionic fluid in high concentrations. Levels of up to 10,000 ng/mL are found at 20 to 26 weeks' gestation. Thereafter, levels decline and reach a nadir after 34 weeks. Uterine decidua is the synthesis site of amnionic fluid prolactin. The exact function of this hormone is unknown, but water transfer from the fetus into the maternal compartment to prevent fetal dehydration is one suggestion.

Oxytocin and *antidiuretic hormone* are hormones secreted from the posterior pituitary gland. The roles of oxytocin in parturition and lactation are discussed in Chapters 21 (p. 413) and 36 (p. 640), respectively. Brown and colleagues (2013) have reviewed the complex mechanisms that promote quiescence of oxytocin systems during pregnancy. Levels of antidiuretic hormone, also called vasopressin, do not change during pregnancy. As discussed earlier (p. 56), osmolality is slightly higher in maternal compared with fetal blood, and the gradient favors water transport to the fetus (Moen, 2018).

Thyroid Gland

The maternal and fetal thyroid glands are intricately interrelated. On the maternal side, *thyrotropin-releasing hormone (TRH)* is secreted by the hypothalamus and stimulates thyrotrope cells of the anterior pituitary to release *thyroid-stimulating hormone (TSH),* also called *thyrotropin*. TRH levels do not rise during normal pregnancy. However, TRH does cross the placenta and may serve to stimulate the fetal pituitary to secrete TSH.

Serum TSH and hCG levels vary with gestational age (Fig. 4-17) (Burrow, 1994). As discussed in Chapter 5 (p. 96), the α-subunits of the two glycoproteins are identical, whereas the β-subunits, although similar, differ in their amino acid sequence. As a result of this structural similarity, hCG has intrinsic thyrotropic activity, and thus, high serum hCG levels cause thyroid stimulation. Indeed, TSH levels in the first trimester decline in more than 80 percent of pregnant women, however, they still remain in the normal range for nonpregnant women.

The thyroid gland boosts production of thyroid hormones by 40 to 100 percent to meet maternal and fetal needs (Korevaar, 2017). To accomplish this, the thyroid gland undergoes moderate enlargement during pregnancy caused by glandular hyperplasia and greater vascularity. Mean thyroid volume expands from 12 mL in the first trimester to 15 mL at term (Glinoer, 1990). That said, normal pregnancy does not typically cause significant thyromegaly, and thus any goiter warrants evaluation.

Early in the first trimester, levels of the principal carrier protein—*thyroid-binding globulin (TBG)*—rise. They reach their zenith at about 20 weeks' gestation. Concentrations stabilize at approximately double baseline values for the remainder of pregnancy (see Fig. 4-17). The greater TBG concentrations result from both higher hepatic synthesis rates—due to estrogen stimulation—and lower metabolism rates due to increased TBG sialylation and glycosylation. These elevated TBG levels increase total serum T_4 and triiodothyronine (T_3) concentrations, but do not affect the physiologically important serum *free* T_4 and *free* T_3 levels. Specifically, total serum T_4 levels rise sharply beginning between 6 and 9 weeks' gestation and reach a plateau at 18 weeks. Serum free T_4 levels rise only slightly and peak along with hCG levels, and then they return to normal.

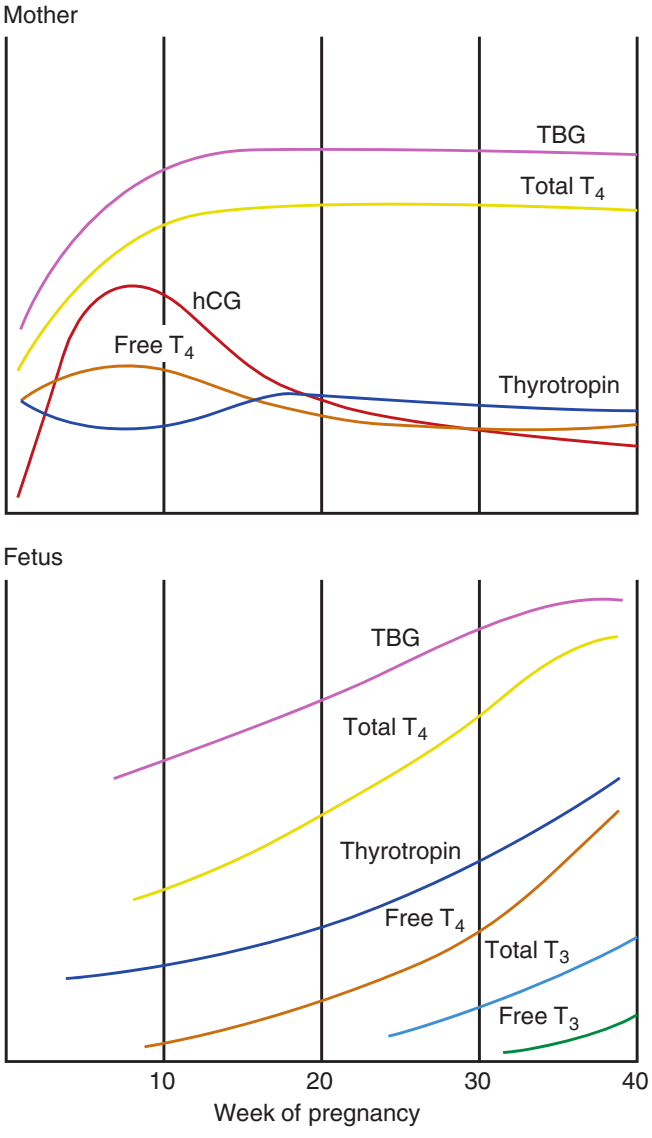

FIGURE 4-17 Relative changes in maternal and fetal thyroid function across pregnancy. Maternal changes include a marked and early increase in hepatic production of thyroxine-binding globulin (TBG) and placental production of human chorionic gonadotropin (hCG). Elevated TBG increases serum thyroxine (T_4) concentrations. hCG has thyrotropin-like activity and stimulates maternal free T_4 secretion. This transient hCG-induced increase in serum T_4 levels inhibits maternal secretion of thyrotropin. Except for minimally increased free T_4 levels when hCG peaks, these levels are essentially unchanged. Fetal levels of all serum thyroid analytes increase incrementally across pregnancy. Fetal triiodothyronine (T_3) does not increase until late pregnancy.

Interestingly, T_4 and T_3 secretion is not similar for all pregnant women. Approximately a third of women experience relative hypothyroxinemia, preferential T_3 secretion, and higher, albeit normal, serum TSH levels (Korevaar, 2017). Thus, thyroidal adjustments during normal pregnancy may vary considerably.

The fetus relies on maternal T_4, which crosses the placenta in small quantities to maintain normal fetal thyroid function (Chap. 61, p. 1089). Recall that the fetal thyroid does not begin to concentrate iodine until 10 to 12 weeks' gestation. The synthesis and secretion of thyroid hormone by fetal pituitary TSH

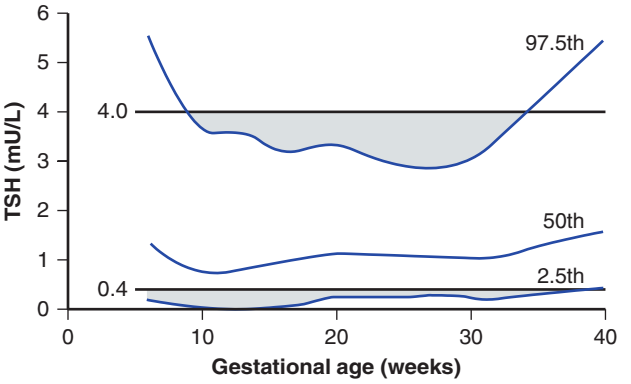

FIGURE 4-18 Gestational age-specific thyroid-stimulating hormone (TSH) nomogram derived from 13,599 singleton pregnancies. The nonpregnant reference values of 4.0 and 0.4 mU/L are represented as solid black lines. Upper shaded area represents the 28 percent of singleton pregnancies with TSH values above the 97.5th percentile threshold that would not have been identified as abnormal based on the assay reference value of 4.0 mU/L. Lower shaded area represents singleton pregnancies that would have been (falsely) identified as having TSH suppression based on the assay reference value of 0.4 mU/L.

ensues at approximately 20 weeks. At birth, approximately 30 percent of the T_4 in umbilical cord blood is of maternal origin (Leung, 2012).

Thyroid Function Tests

As detailed in Chapter 61 (p. 1095), a substantial proportion of otherwise normal pregnancies are found to have subclinical hypothyroidism or isolated hypothyroxinemia. The effects of thyroxine replacement in these women is currently controversial (Korevaar, 2017). Normal suppression of TSH during pregnancy may lead to a misdiagnosis of subclinical hyperthyroidism. Of greater concern is the potential failure to identify women with early hypothyroidism because of suppressed TSH concentrations. To mitigate the likelihood of such misdiagnoses, Dashe and coworkers (2005), and others, have developed gestational-age-specific TSH normal curves for both singleton and twin pregnancies (Fig. 4-18).

These complex alterations of thyroid regulation do not appear to alter maternal thyroid status as measured by metabolic studies. Although basal metabolic rate rises progressively by as much as 25 percent during normal pregnancy, most of this greater oxygen consumption can be attributed to fetal metabolic activity. If fetal body surface area is considered along with that of the mother, the predicted and observed basal metabolic rates are similar to those in nonpregnant women.

Iodine Status

As discussed earlier (p. 59), iodine requirements increase during normal pregnancy (Chap. 61, p. 1097). In women with low or marginal intake, deficiency may manifest as low T_4 and higher TSH levels. Importantly, more than one third of the world population lives in areas where iodine intake is marginal. Even in modernized countries, iodine deficiency is commonplace (Snart, 2019). For the fetus, early exposure to thyroid hormone is essential for the nervous system. Yet, despite public health programs

to supplement iodine, severe deficiency that results in cretinism affects more than 2 million people globally (Syed, 2015).

Parathyroid Glands

During pregnancy, levels of calcitriol, which is the bioactive form of vitamin D, increase twofold and enhance intestinal calcium absorption (Khan, 2019). In an earlier longitudinal investigation of 20 women, all markers of bone turnover rose during normal pregnancy and failed to reach baseline levels by 12 months postpartum (More, 2003). Investigators concluded that the calcium needed for fetal growth and lactation may be drawn at least in part from the maternal skeleton. The factors affecting bone turnover create a net yield that favors fetal skeletal formation at the expense of the mother. As a result, pregnancy is a vulnerable period for osteoporosis (Sanz-Salvador, 2015).

Parathyroid hormone (PTH) release is stimulated by acute or chronic declines in plasma calcium or acute drops in magnesium levels. Conversely, greater calcium and magnesium levels suppress PTH levels. The action of this hormone on bone resorption, intestinal absorption, and kidney reabsorption is to raise extracellular fluid calcium concentrations and lower phosphate levels.

As discussed earlier (p. 59), fetal skeleton mineralization requires approximately 30 g of calcium, primarily during the third trimester. Although this amounts to only 3 percent of the total calcium held within the maternal skeleton, calcium demands still challenge the mother (Degennaro, 2021). Augmented maternal calcium absorption provides the additional calcium. During pregnancy, the amount of calcium absorbed rises gradually and reaches approximately 400 mg/d in the third trimester. Greater calcium absorption appears to be mediated by elevated maternal 1,25-dihydroxyvitamin D concentrations. This occurs despite decreased PTH levels during early pregnancy, which is the normal stimulus for active vitamin D production within the kidney. Indeed, PTH plasma levels decline during the first trimester and then rise progressively throughout the remainder of pregnancy (Pitkin, 1979).

The increased production of active vitamin D is likely due to placental production of either PTH or a PTH-related protein (PTH-rP). Outside pregnancy and lactation, PTH-rP is usually detectable only in serum of women with hypercalcemia due to malignancy. During pregnancy, however, PTH-rP concentrations rise significantly. This protein is synthesized in both fetal tissues and maternal breasts.

Calcitonin is secreted by C cells that are located predominantly in the perifollicular areas of the thyroid gland. Calcitonin opposes actions of PTH and vitamin D and protects the maternal skeleton during times of calcium stress. As discussed, pregnancy and lactation cause profound maternal calcium stress. Indeed, fetal calcitonin levels are at least twofold higher than maternal levels (Ohata, 2016). Although maternal calcitonin levels fall during pregnancy, they generally rise postpartum.

Calcium and magnesium promote the biosynthesis and secretion of calcitonin. Various gastric hormones—gastrin, pentagastrin, glucagon, and pancreozymin—and food ingestion also promote calcitonin plasma levels.

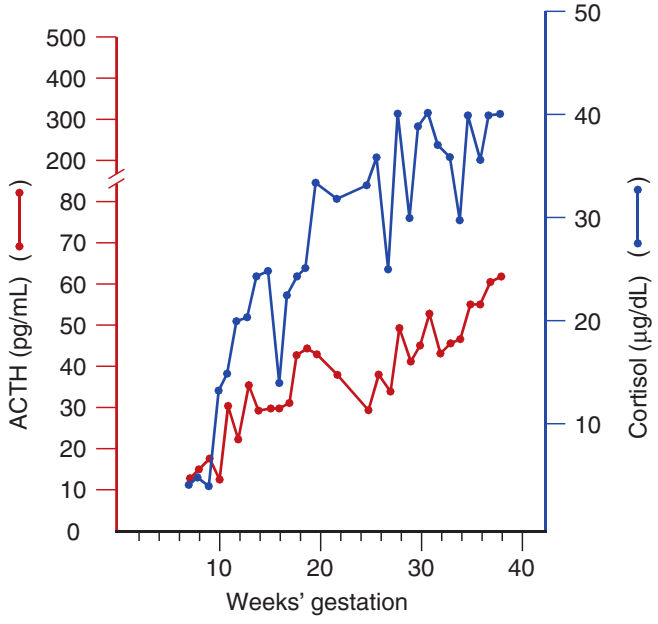

FIGURE 4-19 Serial increases in serum cortisol (*blue line*) and adrenocorticotropic hormone (ACTH) (*red line*) across normal pregnancy.

Adrenal Glands

Cortisol

In normal pregnancy, unlike their fetal counterparts, the maternal adrenal glands undergo little, if any, morphological change. The serum concentration of circulating cortisol rises, but much of it is bound by *transcortin*, the cortisol-binding globulin. The adrenal secretion rate of this principal glucocorticoid is not elevated, and it is probably lower than in the nonpregnant state. The metabolic clearance rate of cortisol, however, is diminished during pregnancy because its half-life is nearly doubled compared with that for nonpregnant women (Migeon, 1957). Administration of estrogen, including most oral contraceptives, causes changes in serum cortisol levels and transcortin similar to those of pregnancy (Jung, 2011).

During early pregnancy, the levels of circulating *adrenocorticotropic hormone* (*ACTH*), also known as *corticotropin*, are dramatically reduced. As pregnancy progresses, ACTH and free cortisol levels rise equally and strikingly (Fig. 4-19) (Carr, 1981). This apparent paradox is not understood completely. Some suggest that greater free cortisol levels in pregnancy result from a "resetting" of the maternal feedback mechanism to higher thresholds (Nolten, 1981). This might result from *tissue refractoriness* to cortisol. Others assert that these incongruities stem from an antagonistic action of progesterone on mineralocorticoids (Keller-Wood, 2001). Thus, in response to elevated progesterone levels during pregnancy, an elevated free cortisol is needed to maintain homeostasis. Other theories include possible roles for higher free cortisol in preparation for the stress of pregnancy, delivery, and lactation.

Aldosterone

As early as 15 weeks' gestation, the maternal adrenal glands secrete considerably higher amounts of aldosterone, the principal mineralocorticoid. By the third trimester, approximately 1 mg/d is

released. If sodium intake is restricted, aldosterone secretion is even further elevated. Concurrently, levels of renin and angiotensin II substrate normally rise, especially during the latter half of pregnancy. This scenario promotes greater plasma levels of angiotensin II, which acts on the zona glomerulosa of the maternal adrenal glands and accounts for the markedly elevated aldosterone secretion. Some suggest the increased aldosterone secretion during normal pregnancy affords protection against the natriuretic effect of progesterone and atrial natriuretic peptide. Gennari-Moser and colleagues (2011) provide evidence that aldosterone and cortisol may modulate trophoblast growth and placental size.

Deoxycorticosterone

Maternal plasma levels of this potent mineralocorticosteroid progressively increase during pregnancy. Indeed, plasma levels of deoxycorticosterone rise to near 1500 pg/mL by term, a more than 15-fold increase (Parker, 1980). This marked elevation does not derive from adrenal secretion but instead represents augmented kidney production resulting from estrogen stimulation. The levels of deoxycorticosterone and its sulfate in fetal blood are appreciably higher than those in maternal blood, which suggests transfer of fetal deoxycorticosterone into the maternal compartment.

Androgens

In balance, androgenic activity rises during pregnancy, and both maternal plasma levels of *androstenedione* and *testosterone* are increased. This finding is not totally explained by alterations in their metabolic clearance. Both androgens are converted to estradiol in the placenta, which increases their clearance rates. Conversely, greater plasma sex hormone–binding globulin levels in gravidas retard testosterone clearance. Thus, the production rates of maternal testosterone and androstenedione during human pregnancy are increased. The source of this higher C_{19}-steroid production is unknown, but it likely originates in the ovary. Interestingly, little or no testosterone in maternal plasma enters the fetal circulation as testosterone. Even when massive testosterone levels are found in the circulation of pregnant women, as with androgen-secreting tumors, testosterone concentrations in umbilical cord blood are likely to be undetectable. This results from the near complete trophoblastic conversion of testosterone to 17β-estradiol.

Maternal serum and urine levels of *dehydroepiandrosterone sulfate* are lower during normal pregnancy. This stems from a greater metabolic clearance through extensive maternal hepatic 16α-hydroxylation and placental conversion to estrogen (Chap. 5, p. 101).

MUSCULOSKELETAL SYSTEM

Progressive lordosis is characteristic of pregnancy. Compensating for the anterior position of the enlarging uterus, lordosis shifts the center of gravity dorsally and over the lower extremities. The sacroiliac, sacrococcygeal, and pubic joints have greater mobility during pregnancy. However, as discussed earlier, increased joint laxity and associated discomfort during pregnancy do not correlate with increased maternal serum levels of estradiol, progesterone, or relaxin. Most relaxation takes place in the first half of pregnancy. It may contribute to maternal posture alterations and in turn create lower back discomfort. As discussed in Chapter 36 (p. 644), although some symphyseal separation likely accompanies many deliveries, those greater than 1 cm may cause significant pain (Shnaekel, 2015).

Aching, numbness, and weakness also occasionally are experienced in the upper extremities. This may result from the marked lordosis and associated anterior neck flexion and shoulder girdle slumping. These can produce traction on the ulnar and median nerves. The latter may give rise to symptoms mistaken for the *carpal tunnel syndrome* (Chap. 63, p. 1137). Joint strengthening begins immediately following delivery and is usually complete within 3 to 5 months. Pelvic dimensions measured by MR imaging up to 3 months postpartum are not significantly different from prepregnancy values (Huerta-Enochian, 2006).

CENTRAL NERVOUS SYSTEM

Changes to the central nervous system during pregnancy are relatively few and mostly subtle. Zeeman and coworkers (2003) used MR imaging to measure cerebral blood flow across pregnancy. They found that mean blood flow in the middle and posterior cerebral arteries declined progressively from 147 and 56 mL/min when nonpregnant to 118 and 44 mL/min late in pregnancy, respectively. Others have found similar middle cerebral artery blood flow changes with ultrasound (Batur Caglayan, 2019). Mechanisms and significance of the decline are unknown. It appears that pregnancy does not affect cerebrovascular autoregulation (Cipolla, 2015).

Memory

Women often report problems with attention, concentration, and memory throughout pregnancy and the early puerperium. Systematic studies of memory in pregnancy, however, are limited and often anecdotal. In a metaanalysis, Davies and coworkers (2018) reported pregnancy-related memory decline was worst in the third trimester. This decline was not attributable to depression, anxiety, sleep deprivation, or other physical changes associated with pregnancy. It was transient and quickly resolved following delivery. In follow up studies, preeclampsia and eclampsia were found to lead to both short- and long-term cognitive disability (Aukes, 2007; Dayan, 2018).

Eyes

Intraocular pressure declines during pregnancy and is attributed partly to greater vitreous outflow. Corneal sensitivity is decreased, and the greatest changes are late in gestation. Most pregnant women demonstrate a measurable but slight increase in corneal thickness, thought to be due to edema. Consequently, they may have difficulty with previously comfortable contact lenses. Brownish-red opacities on the posterior surface of the cornea—*Krukenberg spindles*—are observed with a higher than expected frequency during pregnancy. Hormonal

effects similar to those observed for skin lesions are believed to cause this increased pigmentation. Other than transient loss of accommodation reported during both pregnancy and lactation, visual function is unaffected by pregnancy. These changes during pregnancy and pathological eye aberrations were reviewed by Gilbert and colleagues (2019).

Sleep

Beginning as early as 12 weeks' gestation and extending through the first 2 months postpartum, women have difficulty with falling asleep, frequent awakenings, fewer hours of night sleep, and reduced sleep efficiency. These symptoms are part of the spectrum of sleep-disordered breathing, the most severe of which is obstructive sleep apnea (Ayyar, 2018; Dominguez, 2018). The greatest disruption of sleep is encountered postpartum and may contribute to *postpartum blues* or to frank depression and suicidal ideation (Palagini, 2019).

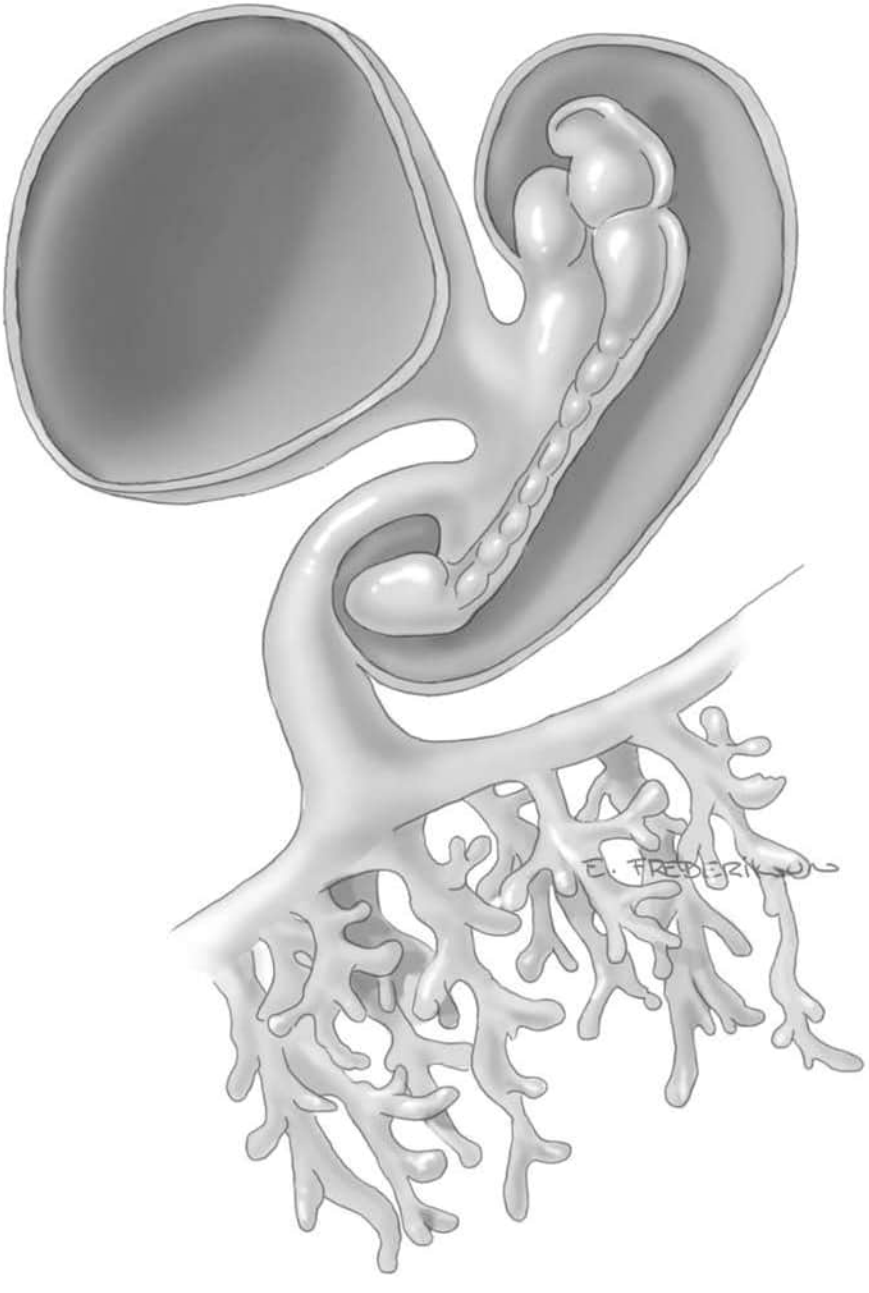
SECTION 3

PLACENTATION, EMBRYOGENESIS, AND FETAL DEVELOPMENT



CHAPTER 5

Implantation and Placental Development

All obstetricians should understand the basic biological steps required for women to achieve pregnancy. Moreover, abnormalities affecting these steps can lead to infertility or pregnancy loss. The biological and molecular changes involved in human zygote implantation and subsequent fetal and placental development are intricate. In the past 50 years, researchers have delineated many of these molecular and physiological events. Yet, much work remains in the continual challenge to improve clinical outcomes.

OVARIAN-ENDOMETRIAL CYCLE

In most women, cyclical ovulation continues during the almost 40 years between menarche and menopause. Thus, without contraception, approximately 400 opportunities for pregnancy exist, and these are tightly regulated by complex interactions of the hypothalamic-pituitary-ovarian axis. Concurrently, endometrium undergoes faithfully reproduced cyclical changes to prepare for pregnancy (Fig. 5-1). Essential contributors in this process include gonadotropin-releasing hormone (GnRH), the gonadotropin hormones follicle-stimulating hormone (FSH) and luteinizing hormone (LH), and the ovarian sex steroid hormones estrogen and progesterone. For a detailed description of menstrual cycle physiology, the reader is referred to Chapter 16 in *Williams Gynecology*, 4th edition (Halvorson, 2020).

Ovulation

This defining event separates the follicular and luteal phases of the menstrual cycle. Following ovulation, the corpus luteum develops from the remains of the graafian follicle in a process referred to as *luteinization*. The basement membrane separating the granulosa-lutein and theca-lutein cells breaks down, and by day 2 postovulation, blood vessels and capillaries invade the granulosa cell layer. During luteinization, these cells undergo hypertrophy and increase their capacity to synthesize hormones. LH is the primary luteotropic factor responsible for corpus luteum maintenance (Vande Wiele, 1970).

The hormone secretion pattern of the corpus luteum differs from that of the follicle. First, the greater capacity of granulosa-lutein cells to produce progesterone results from enhanced access to blood-borne, low-density lipoprotein (LDL)-derived cholesterol, which is a steroidogenic precursor (Carr, 1981). Ovarian progesterone production peaks at 25 to 50 mg/d during the midluteal phase. With pregnancy, the corpus luteum continues progesterone production in response to placental human chorionic gonadotropin (hCG). LH and hCG both act via the same LH-hCG receptor.

The human corpus luteum is a transient endocrine organ. In the absence of pregnancy, it rapidly undergoes apoptosis 9 to 11 days after ovulation (Vaskivuo, 2002). The dramatic drop in

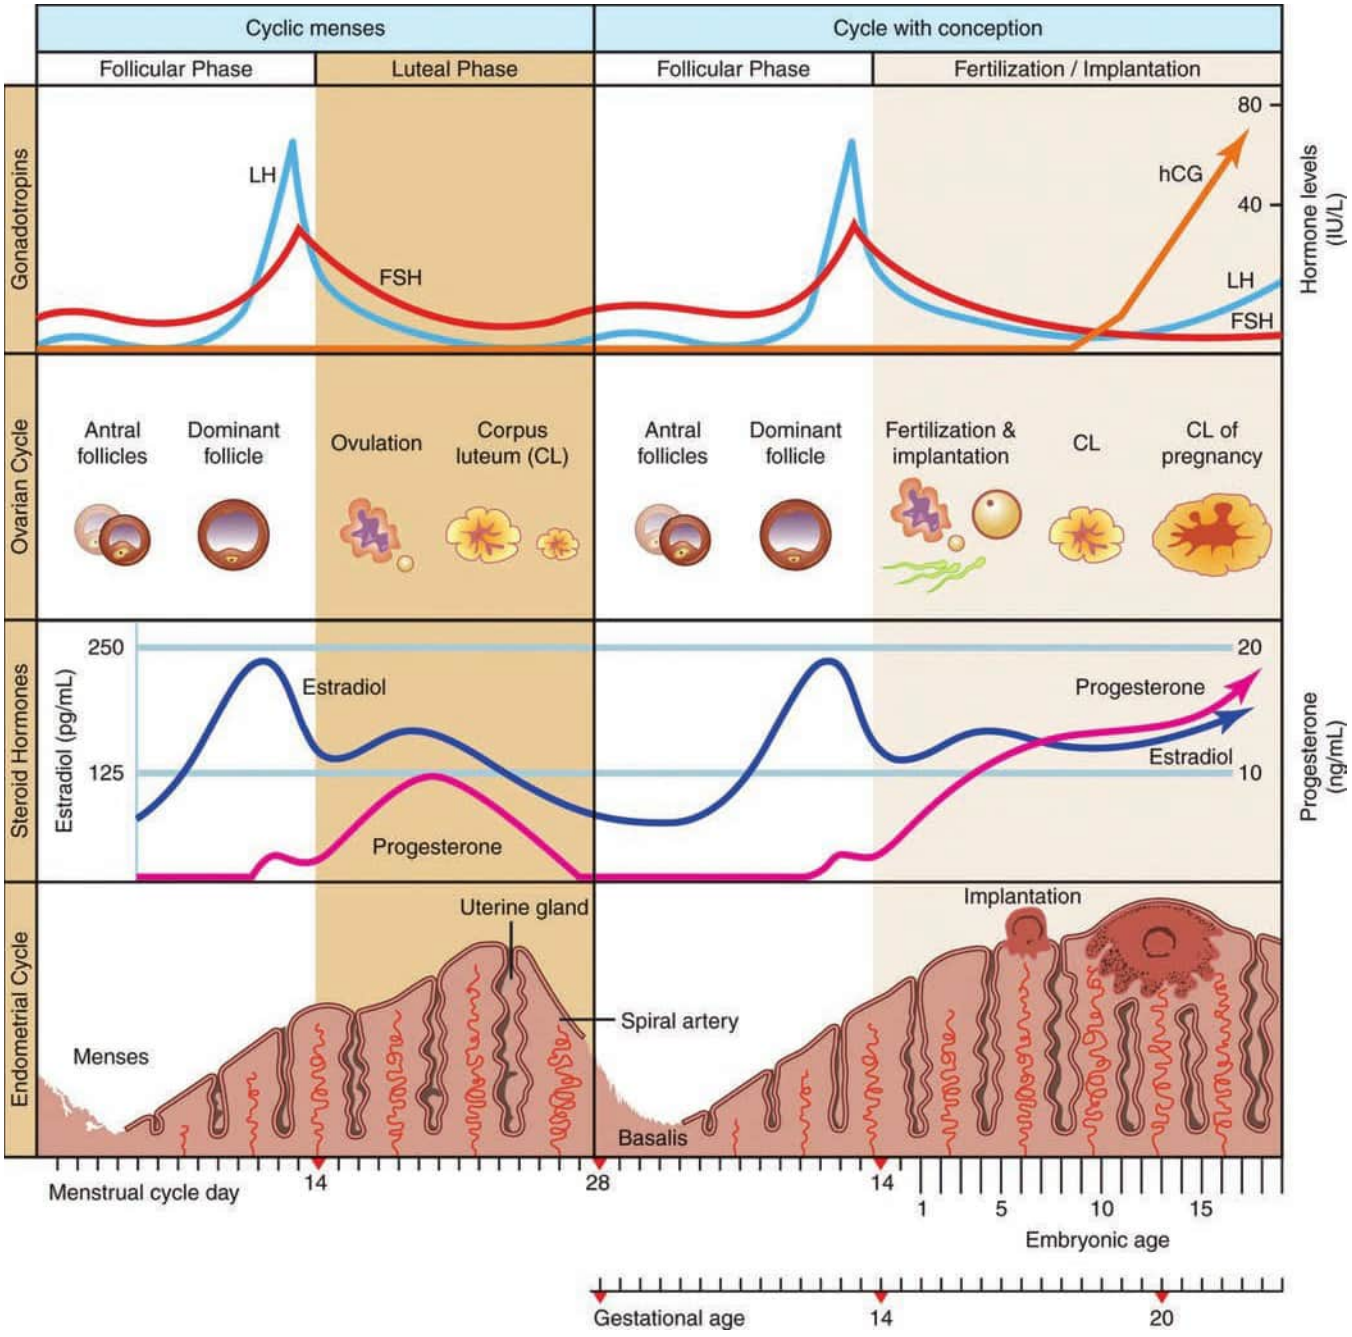


FIGURE 5-1 Gonadotropin control of the ovarian and endometrial cycles. The ovarian-endometrial cycle is structured as a 28-day cycle. The follicular phase (days 1 to 14) is characterized by rising estrogen levels, endometrial thickening, and selection of the dominant "ovulatory" follicle. During the luteal phase (days 14 to 21), the corpus luteum (CL) produces estrogen and progesterone, which prepare the endometrium for implantation. If implantation occurs, the developing blastocyst begins to produce human chorionic gonadotropin (hCG) and rescues the corpus luteum, thus maintaining progesterone production. FSH = follicle-stimulating hormone; LH = luteinizing hormone.

circulating estradiol and progesterone levels initiate molecular events that lead to menstruation.

Between days 22 and 25 after ovulation, the secretory-phase endometrium undergoes striking changes associated with predecidual transformation of the upper two thirds of the functionalis layer. The glands exhibit extensive coiling, and luminal secretions become visible. Changes within the endometrium can also mark the *window of implantation* seen on days 20 to 24. Epithelial surface cells show fewer microvilli and cilia, but luminal protrusions appear on the apical cell surface (Nikas, 2003). These *pinopodes* help prepare for blastocyst implantation. They also coincide with changes in the surface glycocalyx that allow acceptance of a blastocyst (Aplin, 2003).

Another highlight of the secretory phase is the continuing growth and development of the spiral arteries. These vessels arise from the radial arteries, which are myometrial branches of the arcuate and, ultimately, uterine vessels. The morphological and functional properties of the spiral arteries are unique and essential to blood flow changes seen during menstruation or implantation. During endometrial growth, spiral arteries lengthen at

a rate appreciably greater than the rate of endometrial tissue thickening. This growth discordance obliges even greater coiling. Spiral artery development reflects a marked induction of angiogenesis, reflected by widespread vessel sprouting and extension.

At this juncture with hormonal withdrawal, menstruation follows. With blastocyst implantation, however, the endometrium is converted to the decidua.

DECIDUA

This is a specialized, highly modified endometrium of pregnancy. It is essential for *hemochorial placentation*, that is, one in which maternal blood contacts trophoblast. This relationship requires trophoblast invasion, and considerable research has focused on the interaction between decidual cells and invading trophoblasts. *Decidualization* transforms proliferating endometrial stromal cells into specialized secretory cells. This process depends on estrogen, progesterone, androgens, and factors secreted by the implanting blastocyst (Gibson, 2016). The decidua produces factors that regulate endometrial receptivity and that modulate immune and vascular cell functions within the maternal–fetal microenvironment. The special immunomodulatory relationship between the decidua and invading trophoblasts is largely mediated by decidual natural killer (NK) cells and ensures success of the pregnancy semiallograft.

Decidual Structure

The decidua is classified into three parts based on anatomical location. Decidua directly beneath the implanted blastocyst is modified by trophoblast invasion and becomes the *decidua basalis*. The *decidua capsularis* overlies the enlarging blastocyst and initially separates the conceptus from the rest of the uterine cavity (Fig. 5-2). This portion is most prominent during the second month of pregnancy and consists of stromal decidual cells covered by a single layer of flattened epithelial cells. The other side of the capsularis contacts the avascular, extraembryonic fetal membrane—the chorion laeve. The remainder of the uterus is lined by *decidua parietalis*. During early pregnancy, a space lies between the decidua capsularis and parietalis because the gestational sac does not fill the entire uterine cavity. The gestational sac is the *extraembryonic coelom* and also called the chorionic cavity. By 14 to 16 weeks' gestation, the expanding sac has enlarged to completely fill the uterine cavity. The resulting apposition of the decidua capsularis and parietalis creates the *decidua vera*, and the uterine cavity is functionally obliterated.

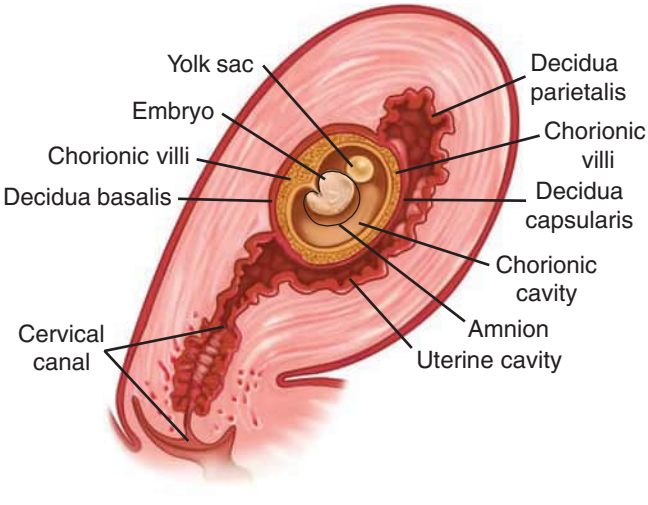

FIGURE 5-2 Three portions of the decidua—the basalis, capsularis, and parietalis—are illustrated.

In early pregnancy, the decidua begins to thicken, eventually attaining a depth of 5 to 10 mm. With magnification, furrows and numerous small openings, representing the mouths of uterine glands, can be detected. Later in pregnancy, the decidua becomes thinner, presumably because of pressure exerted by the expanding uterine contents.

The decidua parietalis and basalis are composed of three layers. There is a surface or compact zone—*zona compacta*; a middle portion or spongy zone—*zona spongiosa*—that has remnants of glands and numerous small blood vessels; and a basal zone—*zona basalis*. The zona compacta and spongiosa together form the *zona functionalis*. The basal zone remains after delivery and gives rise to new endometrium.

The decidual reaction is completed only with blastocyst implantation. Predecidual changes, however, commence first during the midluteal phase in endometrial stromal cells adjacent to the spiral arteries and arterioles. Thereafter, these alterations spread in waves throughout the uterine endometrium. The endometrial stromal cells enlarge to form polygonal or round decidual cells. The nuclei become vesicular, and the cytoplasm becomes clear, slightly basophilic, and surrounded by a translucent membrane.

As the embryo–fetus grows, the blood supply to the decidua capsularis is lost. However, spiral arteries persist to supply the decidua parietalis. These arteries retain smooth muscle and endothelium and thereby remain responsive to vasoactive agents.

In contrast, the spiral arteries that supply the decidua basalis and ultimately the placental intervillous space are altered remarkably. Trophoblastic cells invade the spiral arterioles and arteries and replace their endothelial cells. The vessel wall smooth muscle is destroyed, and the resulting uteroplacental vessels become unresponsive to vasoactive agents. Defective trophoblastic invasion of spiral arteries is thought to be one underlying cause of preeclampsia (Chap. 40, p. 692). Conversely, the fetal chorionic vessels, which transport blood between the placenta and the fetus, contain smooth muscle and thus do respond to vasoactive agents.

Decidual Histology

Early in pregnancy, the decidual zona spongiosa consists of large distended glands, often exhibiting marked hyperplasia and separated by minimal stroma. At first, the glands are lined by typical cylindrical uterine epithelium with abundant secretory activity that contributes to blastocyst nourishment. With advanced pregnancy, the glandular elements largely disappear, and the spongy zone of the decidua basalis consists mainly of arteries and widely dilated veins.

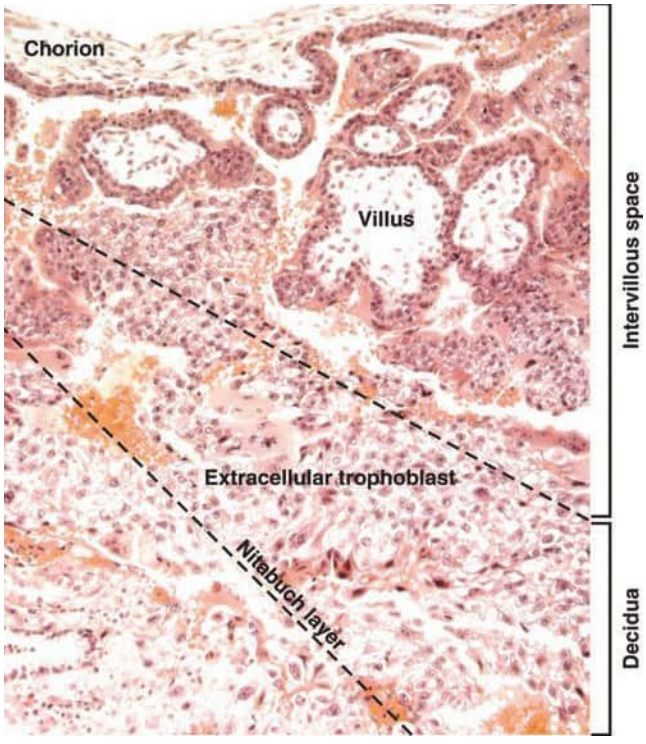

FIGURE 5-3 Section through a junction of chorion, villi, and decidua basalis in early first-trimester pregnancy. (Reproduced with permission from Dr. Kurt Benirschke.)

The decidua basalis contributes to formation of the placental basal plate (Fig. 5-3). As such, it is invaded by many interstitial trophoblasts. The *Nitabuch layer* is a zone of fibrinoid degeneration in which invading trophoblasts meet the decidua basalis. If the decidua is defective, as in placenta accreta, the Nitabuch layer is usually absent (Chap. 43, p. 759). Normally, there is also a more superficial, but inconsistent, deposition of fibrin—*Rohr stria*—at the bottom of the intervillous space and surrounding the anchoring villi. Decidual necrosis is a common phenomenon in the first and probably second trimesters (McCombs, 1964). Thus, necrotic decidua obtained through curettage after spontaneous abortion should not necessarily be interpreted as either a cause or an effect of the pregnancy loss.

Both decidual layers contain numerous cell groups whose composition varies with gestational stage (Loke, 1995). The primary cellular components are the true decidual cells, which differentiated from the endometrial stromal cells, and numerous maternal bone marrow-derived cells. Of the latter, lymphocytes with unique properties accumulate at the maternal–fetal interface and are essential to evoke immune tolerance between mother and fetus. These include regulatory T cells, decidual macrophages, and decidual NK cells. Collectively, these cells not only provide immunotolerance but also play an important role in trophoblast invasion and vasculogenesis (PrabhuDas, 2015).

■ Decidual Prolactin

The decidua produces prolactin, which is present in enormous amounts in amnionic fluid (Golander, 1978; Riddick, 1979). Decidual prolactin is a product of the same gene that encodes for anterior pituitary prolactin, but the exact physiological role of decidual prolactin is unknown. Signaling by prolactin can lead to the production of proangiogenic factors. Prolactin can also be cleaved by proteases to form vasoinhibins (Nakajima, 2015; Triebel, 2015). These compounds have antiangiogenic properties and may contribute to peripartum cardiomyopathy, whose pathogenesis and treatment are discussed in Chapter 52 (p. 933).

Decidual prolactin preferentially enters amnionic fluid and may reach extraordinarily high levels of 10,000 ng/mL at 20 to 24 weeks' gestation (Tyson, 1972). In contrast, maternal serum levels are relatively low at 150 to 200 ng/mL. As discussed in Chapter 4 (p. 57), prolactin inhibits maternal insulin action and results in increased glucose levels for fetal growth.

IMPLANTATION AND EARLY TROPHOBLAST FORMATION

■ Fertilization

With ovulation, the ovary releases the secondary oocyte and surrounding cells of the cumulus–oocyte complex. The oocyte complex is quickly engulfed by the fallopian tube infundibulum. Directional movement of cilia and tubal peristalsis moves the ovum within the tubal lumen. Fertilization takes place in the lumen within a few hours, and no more than a day after ovulation. Because of this narrow window, spermatozoa must be present in the fallopian tube at the time of oocyte arrival. Almost all pregnancies result when intercourse occurs during the 2 days preceding or on the day of ovulation.

Fertilization is highly complex. Molecular mechanisms allow spermatozoa to pass between cumulus cells; through the zona pellucida, which is a thick glycoprotein layer surrounding the oocyte cell membrane; and into the oocyte cytoplasm. Fusion of the two nuclei and intermingling of maternal and paternal chromosomes creates the *zygote*.

Early human development is described by days or weeks postfertilization, that is, postconceptional (Chap. 7, p. 121). By contrast, in most chapters of this book, clinical pregnancy dating is calculated from the first day of the last menstrual period (LMP). Thus, 1 week postfertilization corresponds to approximately 3 weeks from the LMP in women with regular 28-day cycles. This convention is clinically important for dating pregnancies conceived by in vitro fertilization (IVF), in which the gestational age is 14 days greater than the day of fertilization. As an example, 8 weeks' gestation refers to 8 completed weeks following the LMP but corresponds to 6 weeks postfertilization.

After fertilization, the zygote—a diploid cell with 46 chromosomes—undergoes cleavage, and zygote cells produced by this division are *blastomeres* (Fig. 5-4). In the two-cell zygote, the blastomeres and polar body continue to be surrounded by the zona pellucida. The zygote undergoes slow cleavage for 3 days while still in the fallopian tube. As the blastomeres continue to divide, a solid mulberry-like ball of cells—the *morula*—is produced. The morula enters the uterine cavity approximately 3 days after fertilization. Gradual accumulation of fluid between the morula cells leads to formation of the early *blastocyst*.

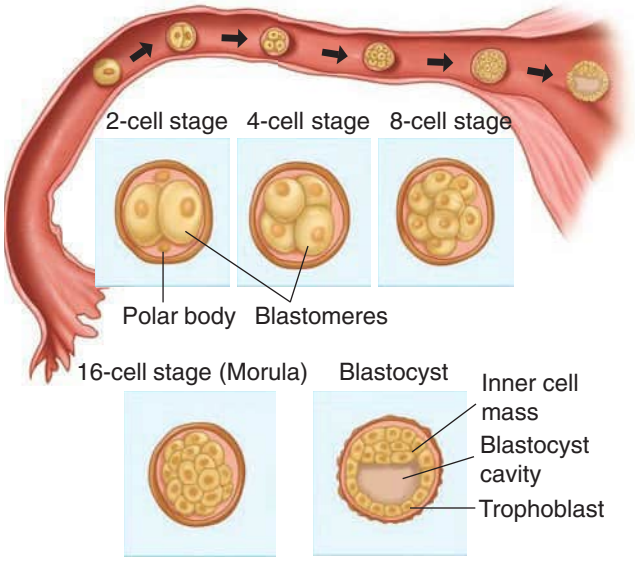

FIGURE 5-4 Zygote cleavage and blastocyst formation. The morula period begins at the 12- to 16-cell stage and ends when the blastocyst forms, which occurs when there are 50 to 60 blastomeres present. The polar bodies, shown in the 2-cell stage, are small nonfunctional cells that degenerate.

Blastocyst

As early as 4 to 5 days after fertilization, the 58-cell blastocyst differentiates into five embryo-producing cells—the *inner cell mass* (see Fig. 5-4). The remaining 53 outer cells, called the *trophectoderm*, are destined to form *trophoblasts* (Hertig, 1962).

In the 107-cell blastocyst, the eight formative, embryo-producing cells are surrounded by 99 trophoblastic cells. The blastocyst is released from the zona pellucida secondary to secretion of specific proteases from the secretory-phase endometrial glands (O'Sullivan, 2002). Release from the zona pellucida allows blastocyst-produced cytokines and hormones to directly influence endometrial receptivity (Lindhard, 2002). The blastocyst secretes interleukin-1α (IL-1α) and IL-1β, which are cytokines that likely directly influence the endometrium. Embryos also secrete hCG, which may influence endometrial receptivity (Licht, 2001; Lobo, 2001).

The receptive endometrium is thought to respond by producing leukemia inhibitory factor (LIF), follistatin, and colony-stimulating factor-1 (CSF-1). LIF and follistatin activate signaling pathways that collectively inhibit proliferation and promote differentiation of the endometrial epithelia and stroma to enable uterine receptivity (Rosario, 2016b). At the maternal–fetal interface, CSF-1 has proposed immunomodulatory and proangiogenic actions that are required for implantation (Rahmati, 2015).

■ Implantation

The blastocyst implants into the uterine wall 6 or 7 days after fertilization. This process can be divided into three phases: (1) *apposition*—initial contact of the blastocyst to the uterine wall; (2) *adhesion*—increased physical contact between the blastocyst and decidua; and (3) *invasion*—penetration and invasion of syncytiotrophoblast and cytotrophoblasts into the decidua, inner third of the myometrium, and uterine vasculature. Successful implantation requires a receptive endometrium appropriately primed with estrogen and progesterone by the corpus luteum. Such uterine receptivity is limited to days 20 to 24 of the endometrial cycle. Adherence is mediated by cell-surface receptors at the implantation site that interact with blastocyst receptors (Carson, 2002; Lessey, 2002). If the blastocyst approaches the endometrium after cycle day 24, the potential for adhesion declines because antiadhesive glycoprotein synthesis prevents receptor interactions (Navot, 1991). A mismatch between uterine receptivity and timing of embryo transfer can lead to repeated implantation failure in some IVF patients. This has stimulated efforts to define receptivity by gene expression profiles to improve clinical outcomes (Ruiz-Alonso, 2013).

At the time of its interaction with the endometrium, the blastocyst is composed of 100 to 250 cells. The blastocyst trophectoderm loosely adheres to the decidua by apposition. This appears to be closely regulated by paracrine interactions between these two tissues and most commonly occurs on the upper posterior uterine wall.

Successful endometrial blastocyst adhesion involves modified expression of cellular adhesion molecules (CAMs). The integrins—one of four families of CAMs—are cell-surface receptors that mediate cell adhesion to extracellular matrix proteins (Lessey, 2002). Endometrial integrins are hormonally regulated, and a specific set of integrins is expressed at implantation (Lessey, 1995). Recognition-site blockade of the integrins needed for binding will prevent blastocyst attachment (Kaneko, 2013).

■ Trophoblast Development

The fetus depends on the placenta for pulmonary, hepatic, and renal functions. These are accomplished through the anatomical relationship of the placenta and its uterine interface. In overview, maternal blood flows from uteroplacental vessels into the placental intervillous space and bathes the syncytiotrophoblast, which surround villi. Here, gases, nutrients, and other substances are exchanged with fetal capillary blood within the core of each placental villus. Thus, fetal and maternal blood do not normally mix in this hemochorial placenta.

Human placental formation begins with the trophectoderm, which gives rise to a trophoblast cell layer encircling the blastocyst. Trophoblast exhibits the most variable structure, function, and developmental pattern of all placental components. Its invasiveness promotes implantation, its nutritional role for the conceptus is reflected in their name, and its endocrine function is essential to maternal physiological adaptations and to pregnancy maintenance.

By the eighth day postfertilization, after initial implantation, the trophoblast has differentiated into an outer multinucleated syncytium—the primitive *syncytiotrophoblast*, and an inner layer of primitive mononuclear cells—*cytotrophoblasts*. The latter are solely germinal cells for the syncytium. As cytotrophoblasts differentiate, they express an endogenous envelope protein called *syncytin*, which aids their cell fusion with the expanding outer layer of syncytiotrophoblast. Each cytotrophoblast has a well-demarcated cell border, a single nucleus, and ability to undergo DNA synthesis and mitosis (Arnholdt, 1991). These are lacking

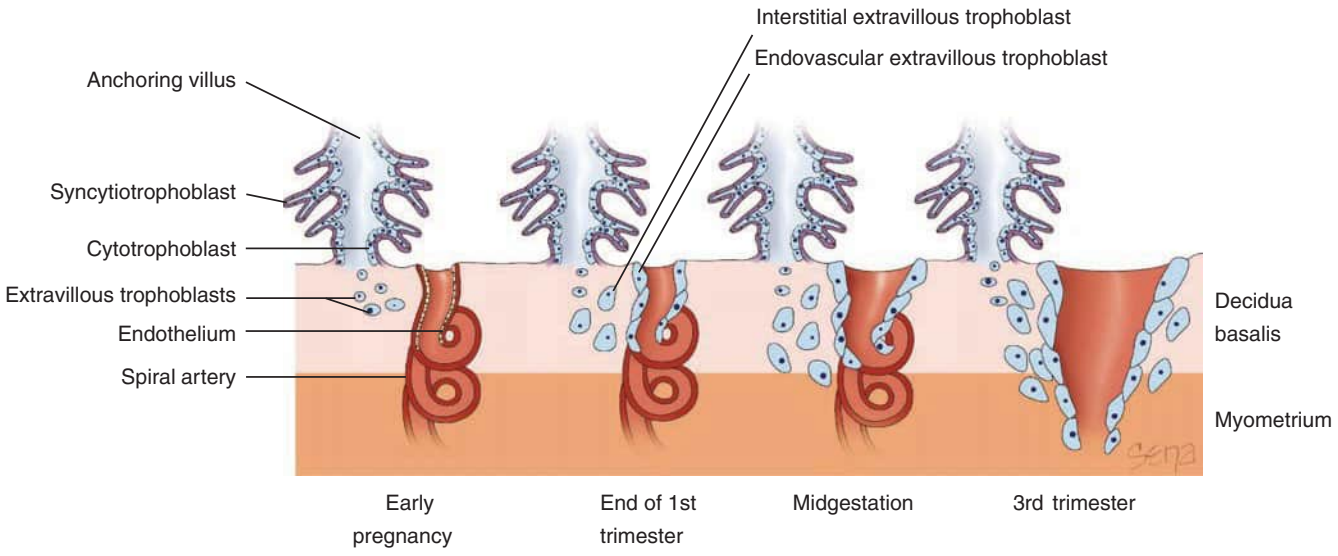

FIGURE 5-5 Endovascular and interstitial extravillous trophoblasts are found outside the villus. Endovascular trophoblasts invade and transform spiral arteries during pregnancy to create low-resistance blood flow that is characteristic of the placenta. Interstitial trophoblasts invade the decidua and surround spiral arteries.

in the syncytiotrophoblast, which provides transport functions of the placenta. It is so named because instead of individual cells, it has an amorphous cytoplasm without cell borders, nuclei that are multiple and diverse in size and shape, and a continuous syncytial lining.

Following implantation, trophoblasts differentiate along two main pathways that give rise to either villous or extravillous trophoblasts. As shown in Figure 5-5, both have distinct functions (Loke, 1995). *Villous trophoblasts* generate chorionic villi, which primarily transport oxygen, nutrients, and other compounds between the fetus and mother. *Extravillous trophoblasts* migrate into the decidua and myometrium (Fig. 5-6). They also penetrate maternal vasculature and thus directly contact various maternal cell types (Pijnenborg, 1994). Extravillous trophoblasts are further classified as *interstitial trophoblasts* and *endovascular trophoblasts*. The interstitial trophoblasts invade the decidua and eventually penetrate the myometrium to form placental-bed giant cells. These trophoblasts also surround spiral arteries. The endovascular trophoblasts penetrate the spiral artery lumens (Pijnenborg, 1983).

Recently, single-cell RNA sequencing technology has enabled inference of trophoblast differentiation lineages (Liu, 2018; Tsang, 2017). This has also yielded insights into the communication between trophoblasts and maternal decidual and immune cell populations (Vento-Tormo, 2018). Furthermore, human trophoblast stem cells, long hypothesized to exist, have been isolated from early gestations (Okae, 2018). Culture of these cells will likely aid greater understanding of early trophoblast differentiation and invasion (Haider, 2018; Turco, 2018).

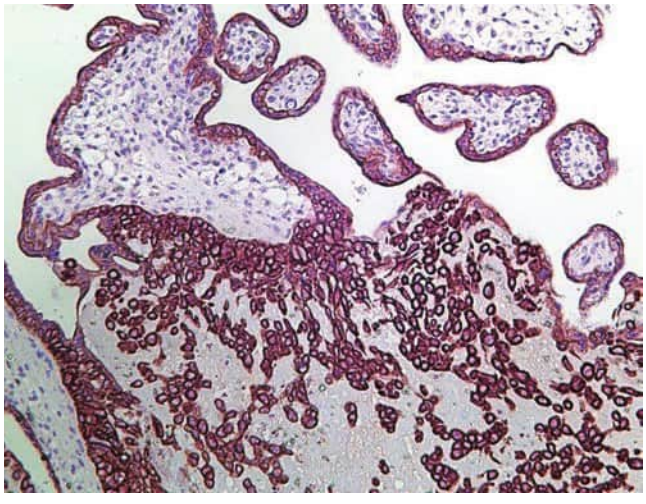

FIGURE 5-6 Photomicrograph of extravillous trophoblast invasion of the decidua basalis.

Early Invasion

After gentle erosion between epithelial cells of the surface endometrium, invading trophoblasts burrow deeper. At 9 days of development, the blastocyst wall facing the uterine lumen is a single layer of flattened cells. By the 10th day, the blastocyst becomes totally encased within the endometrium (Fig. 5-7). The blastocyst wall opposite the uterine lumen is thicker and comprises two zones—the trophoblasts and the embryo-forming inner cell mass. As early as 7.5 days postfertilization, the inner cell mass or embryonic disc differentiates into a thick plate of primitive ectoderm and an underlying layer of endoderm. Some small cells appear between the embryonic disc and the trophoblasts and enclose a space that will become the amnionic cavity.

Extraembryonic mesenchyme first appears as groups of isolated cells within the blastocyst cavity, and later this mesoderm completely lines the cavity. Within this mesoderm, spaces form and then fuse to form the chorionic cavity, that is, the extraembryonic coelom. The *chorion* is composed of trophoblasts and mesenchyme. Some mesenchymal cells eventually will condense to form the *body stalk*. This stalk joins the embryo to the nutrient chorion and later develops into the umbilical cord. The body stalk can be recognized at an early stage at the caudal end of the embryonic disc (Fig. 7-3, p. 123).

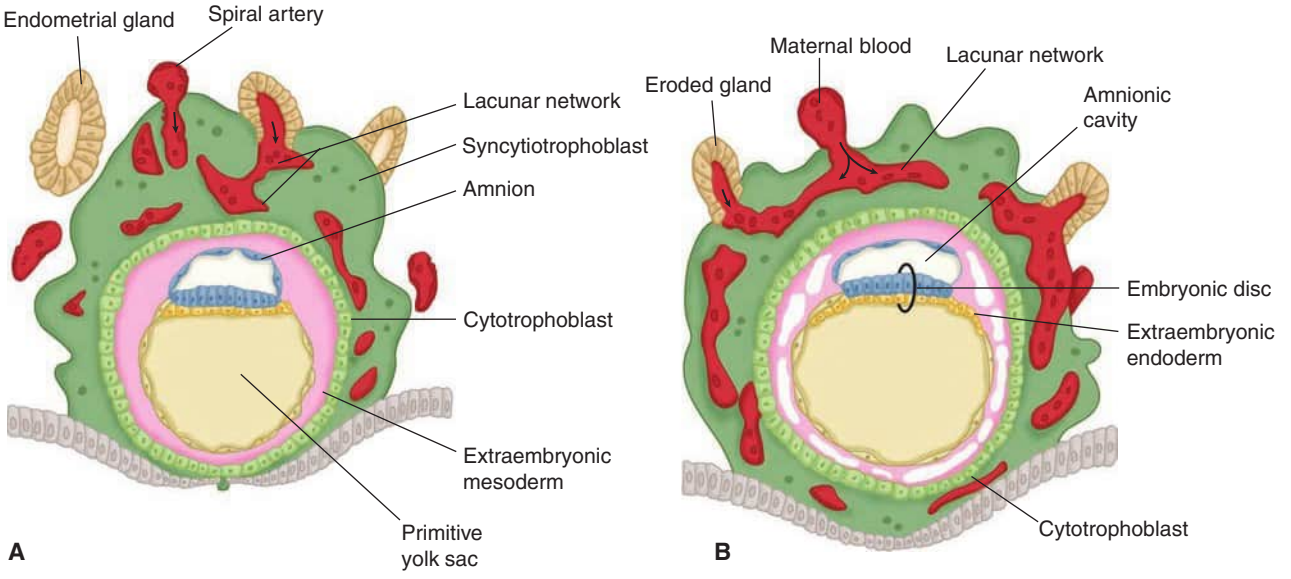

FIGURE 5-7 Drawing of sections through implanted blastocysts. **A.** At 10 days. **B.** At 12 days after fertilization. This stage is characterized by the intercommunication of the lacunae filled with maternal blood. Note in (B) that large cavities have appeared in the extraembryonic mesoderm, forming the beginning of the extraembryonic coelom. Also, extraembryonic endodermal cells have begun to form on the inside of the primitive yolk sac. (Redrawn from Moore KL, Persaud, TV, Torchia, MG (eds): The Developing Human. Clinically Oriented Embryology, 9th ed. Philadelphia, PA: Saunders; 2013.)

As the embryo enlarges, more maternal decidua basalis is invaded by syncytiotrophoblast. Beginning approximately 12 days after conception, the syncytiotrophoblast is permeated by a system of intercommunicating channels called *trophoblastic lacunae*. After invasion of superficial decidual capillary walls, lacunae become filled with maternal blood. At the same time, the decidual reaction, characterized by decidual stromal cell enlargement and glycogen storage, intensifies (p. 84).

Chorionic Villi

With deeper invasion into the decidua, solid primary villi arise from buds of cytotrophoblasts that protrude into the primitive syncytium before 12 days postfertilization. Primary villi are composed of a cytotrophoblast core covered by syncytiotrophoblast. As the lacunae merge, a complicated labyrinth is formed that is partitioned by these solid cytotrophoblastic columns. The trophoblast-lined channels form the *intervillous space*, and the solid cellular columns form the *primary villous stalks*.

Beginning on the 12th day after fertilization, mesenchymal cords derived from extraembryonic mesoderm invade the solid trophoblast columns. These then form *secondary villi*. Once angiogenesis begins in the mesenchymal cords, *tertiary villi* are created. Although maternal venous sinuses are tapped early in implantation, maternal arterial blood does not enter the intervillous space until around day 15. By the 17th day, however, fetal blood vessels are functional, and a placental circulation is established. The fetal–placental circulation is completed when the blood vessels of the embryo are connected with chorionic vessels. In some villi, angiogenesis fails from lack of circulation. The most striking exaggeration of this is seen with hydatidiform mole (Fig. 13-1, p. 236).

Villi are covered by an outer layer of syncytiotrophoblast and an inner layer of cytotrophoblasts. Proliferation of cytotrophoblast at the villous tips produces the trophoblastic cell columns that form *anchoring villi*. They are not invaded by fetal mesenchyme, and they are anchored to the decidua at the *basal plate*, which is the maternal side of the intervillous space. The *chorionic plate* forms the roof of the intervillous space. It consists of the two layers of trophoblasts, which line the intervillous space, and fibrous mesoderm on the opposite side. The final chorionic plate is formed by 8 to 10 weeks as the amnionic and primary chorionic plate mesenchyme fuse together. This formation is accomplished by expansion of the amnionic sac.

Early electron microscopic studies demonstrate prominent microvilli on the syncytial surface (Fig. 5-8) (Wislocki, 1955).

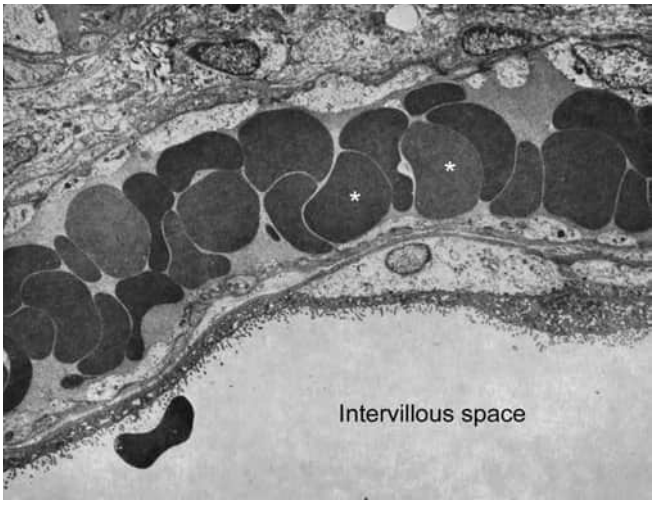

FIGURE 5-8 Electron micrograph of term human placenta villus. A villus capillary filled with fetal red blood cells (*asterisks*) is seen in close proximity to the microvilli border. (Reproduced with permission from Boyd JD, Hamilton WJ: The Human Placenta. Cambridge, Heffer, 1970.)

Associated pinocytotic vacuoles and vesicles are involved in both absorptive and secretory placental functions. Microvilli increase trophoblast surface area in direct contact with maternal blood, the defining characteristic of a hemochorial placenta.

PLACENTA AND CHORION

Chorion Development

In early pregnancy, the villi are distributed over the entire periphery of the chorionic membrane (Fig. 5-9). As the blastocyst with its surrounding trophoblasts grows and expands into the decidua, one pole faces the endometrial cavity. The opposite pole will form the placenta. Here, chorionic villi in contact with the decidua basalis proliferate to form the *chorion frondosum*—or leafy chorion. As growth of embryonic and extraembryonic tissues continues, the blood supply to the chorion facing the endometrial cavity is restricted. Because of this, villi in contact with the decidua capsularis cease to grow and then degenerate. This portion of the chorion becomes the avascular fetal membrane that abuts the decidua parietalis and is called the *chorion laeve*—or smooth chorion. This smooth chorion is composed of cytotrophoblasts and fetal mesodermal mesenchyme. A paracrine system between the decidua and chorion also links mother and fetus. This is an extraordinarily important arrangement for maternal–fetal communication and for maternal immunological acceptance of the conceptus (Guzeloglu-Kayisli, 2009).

Until near the end of the third month, the chorion laeve is separated from the amnion by the exocoelomic cavity. Thereafter, they are in intimate contact to form the avascular amniochorion. These two structures are important sites of molecular transfer and metabolic activity. Moreover, they constitute an important paracrine arm of the fetal–maternal communication system.

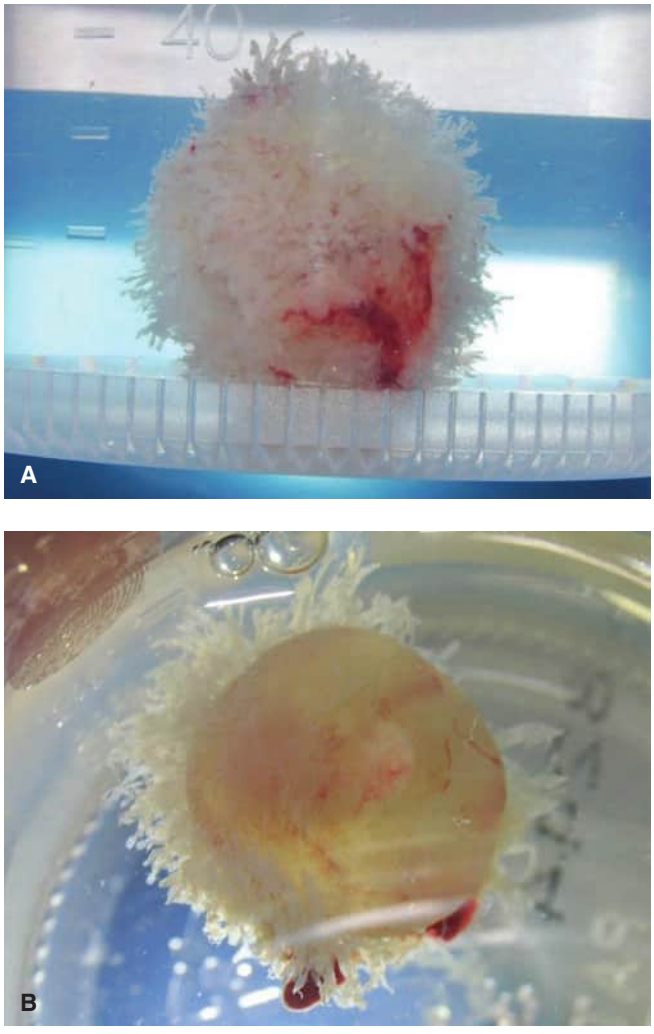

FIGURE 5-9 Complete abortion specimens. **A.** Initially, the entire chorionic sac is covered with villi, and the embryo within is not visible **B.** Stretch and pressure from further growth prompt partial regression of the villi. The remaining villi form the future placenta, whereas the smooth portion is the chorion.

Regulators of Trophoblast Invasion

Implantation and endometrial decidualization activate a unique population of maternal immune cells that play critical functions in trophoblast invasion, angiogenesis, spiral artery remodeling, and maternal tolerance to fetal alloantigens. Decidual natural killer cells (dNK) make up 70 percent of decidual leukocytes in the first trimester and directly contact trophoblasts. In contrast to NK cells in peripheral blood, dNK cells lack cytotoxic functions. They produce specific cytokines and angiogenic factors to regulate trophoblast invasion and spiral artery remodeling (Hanna, 2006). dNK cells promote phagocytosis of cell debris (Faas, 2017). These and other unique properties distinguish dNK cells from circulating NK cells and from NK cells in the endometrium before pregnancy (Fu, 2013; Winger, 2013). dNK cells express both IL-8 and interferon-inducible protein 10, which bind to receptors on invasive trophoblastic cells to promote their decidual invasion toward the spiral arteries. dNK cells also produce proangiogenic factors, including VEGF and placental growth factor (PlGF), which both promote vascular growth in the decidua.

Trophoblasts also secrete specific chemokines that attract the dNK cells to the maternal–fetal interface. Thus, both cell types simultaneously attract each other. Decidual macrophages account for approximately 20 percent of leukocytes in the first trimester and elicit an M2-immunomodulatory phenotype (Williams, 2009). Recall that while M1 macrophages are proinflammatory, M2 macrophages counter proinflammatory responses and promote tissue repair.

Concurrently, T cell subsets aid tolerance toward the allogenic fetus. Regulatory T cells (Tregs) are essential for promoting immune tolerance. Other T cell subsets are present, such as Th1, Th2, and Th17, although their functions are tightly regulated (Ruocco, 2014).

Endometrial Invasion

Extravillous trophoblasts of the first-trimester placenta are highly invasive. This process occurs under low-oxygen conditions, and regulatory factors that are induced under hypoxic conditions are contributory (Soares, 2012). Invasive trophoblasts

secrete numerous proteolytic enzymes that digest extracellular matrix and activate proteinases already present in the decidua. Trophoblasts produce urokinase-type plasminogen activator, which converts plasminogen into the broadly acting serine protease, plasmin. This in turn both degrades matrix proteins and activates MMPs. One member of the MMP family, MMP-9, appears to be critical. The timing and extent of trophoblast invasion is regulated by a balanced interplay between pro- and anti-invasive factors.

Low estradiol levels in the first trimester are critical for trophoblast invasion and spiral artery remodeling. Animal studies suggest that the rise in second-trimester estradiol levels suppresses and limits vessel remodeling by reducing trophoblast expression of VEGF and specific integrin receptors (Bonagura, 2012). Namely, extravillous trophoblasts express integrin receptors that recognize the extracellular matrix proteins collagen IV, laminin, and fibronectin. Binding of these matrix proteins and integrin receptors initiates signals to promote trophoblast cell migration and differentiation. However, as pregnancy advances, rising estradiol levels downregulate VEGF and integrin receptor expression. This represses and controls the extent of uterine vessel transformation.

Spiral Artery Invasion

One of the most remarkable features of human placental development is the extensive modification of maternal vasculature by trophoblasts, which are fetal in origin. These events occur in the first half of pregnancy and are essential to uteroplacental blood flow. They are also integral to conditions such as preeclampsia, fetal-growth restriction, and preterm birth. Spiral artery modifications are carried out by two populations of extravillous trophoblasts—*endovascular trophoblasts*, which penetrate the spiral-artery lumen, and *interstitial trophoblasts*, which surround the arteries (see Fig. 5-5).

Interstitial trophoblasts constitute a major portion of the placental bed. They penetrate the decidua and adjacent myometrium and aggregate around spiral arteries, where they may aid endovascular trophoblast invasion.

Endovascular trophoblasts first enter the spiral artery lumens and initially form cellular plugs. They then promote apoptosis of the native endothelium and replace the vessel lumen with cells of fetal origin. Fibrinoid material replaces smooth muscle and connective tissue of the vessel media. This decreases resistance of blood flow into the intervillous space. Invading endovascular trophoblasts can extend several centimeters along the vessel lumen, and they must migrate against arterial flow. Of note, invasion by trophoblasts involves only the decidual spiral arteries and not decidual veins.

Uteroplacental vessel development proceeds in two waves or stages (Ramsey, 1980). First, before 12 weeks' postfertilization, spiral arteries are invaded and modified up to the border between the decidua and myometrium. The second wave, between 12 and 16 weeks, involves some invasion of the intramyometrial segments of spiral arteries. Remodeling converts narrow-lumen, muscular spiral arteries into dilated, low-resistance uteroplacental vessels. Molecular mechanisms of these crucial events and their significance for preeclampsia and fetal-growth restriction have been reviewed (Pereira de Sousa, 2017; Xie, 2016).

Although early placenta development occurs in a low-oxygen-tension environment (2 to 3 percent O_2), this vascular remodeling increases blood flow and oxygenation such that the oxygen concentration more than doubles around the end of the first trimester (Chang, 2018).

Villus Branching

Although certain villi of the chorion frondosum extend from the chorionic plate to the decidua to serve as anchoring villi, most villi arborize and end freely within the intervillous space. As gestation proceeds, the short, thick, early stem villi branch to form progressively finer subdivisions and greater numbers of increasingly smaller villi (Fig. 5-10). This increasing villous surface area correlates with gestational age and aids fetal growth. In cases of restricted blood flow, more highly branched villi than expected for gestational age is a compensatory mechanism.

Each truncal or main stem villus and its ramifications constitutes a placental lobule or cotyledon. Each lobule has a single chorionic artery and vein, such that lobules constitute the functional units of placental architecture.

Placental Growth and Maturation

In the first trimester, placental growth is more rapid than that of the fetus. However, by 17 weeks' gestation, placental and fetal weights are nearly equal. By term, placental weight approximates one sixth of fetal weight.

The mature placenta and its variant forms are discussed in detail in Chapter 6 (p. 108). Briefly, viewed from the maternal surface, which attaches to the uterine wall, the number of slightly elevated convex areas, called lobes, varies from 10 to 38. Lobes are incompletely separated by grooves of variable depth. These tissue grooves form in response to placental septa, which rise up as projections of decidua. The total number of placental lobes remains the same throughout gestation, and individual lobes continue to grow—although less actively in late pregnancy (Crawford, 1959). Although grossly visible lobes are commonly referred to as cotyledons, this is inaccurate. Correctly used, lobules or cotyledons are the functional units supplied by each main stem villus.

As villi continue to branch and the terminal ramifications become more numerous and smaller, the volume of cytotrophoblasts decline. This layer attenuates, and by 16 weeks' gestation, the apparent continuity of the cytotrophoblasts is lost. As the syncytium also thins, the fetal vessels become more prominent within the villus and lie closer to the intervillous space (see Fig. 5-8). At term, villi may be focally reduced to a thin layer of syncytium covering minimal villous connective tissue in which thin-walled fetal capillaries abut the trophoblast and dominate the villi.

The villous stroma also exhibits changes as gestation progresses. In early pregnancy, the branching connective-tissue

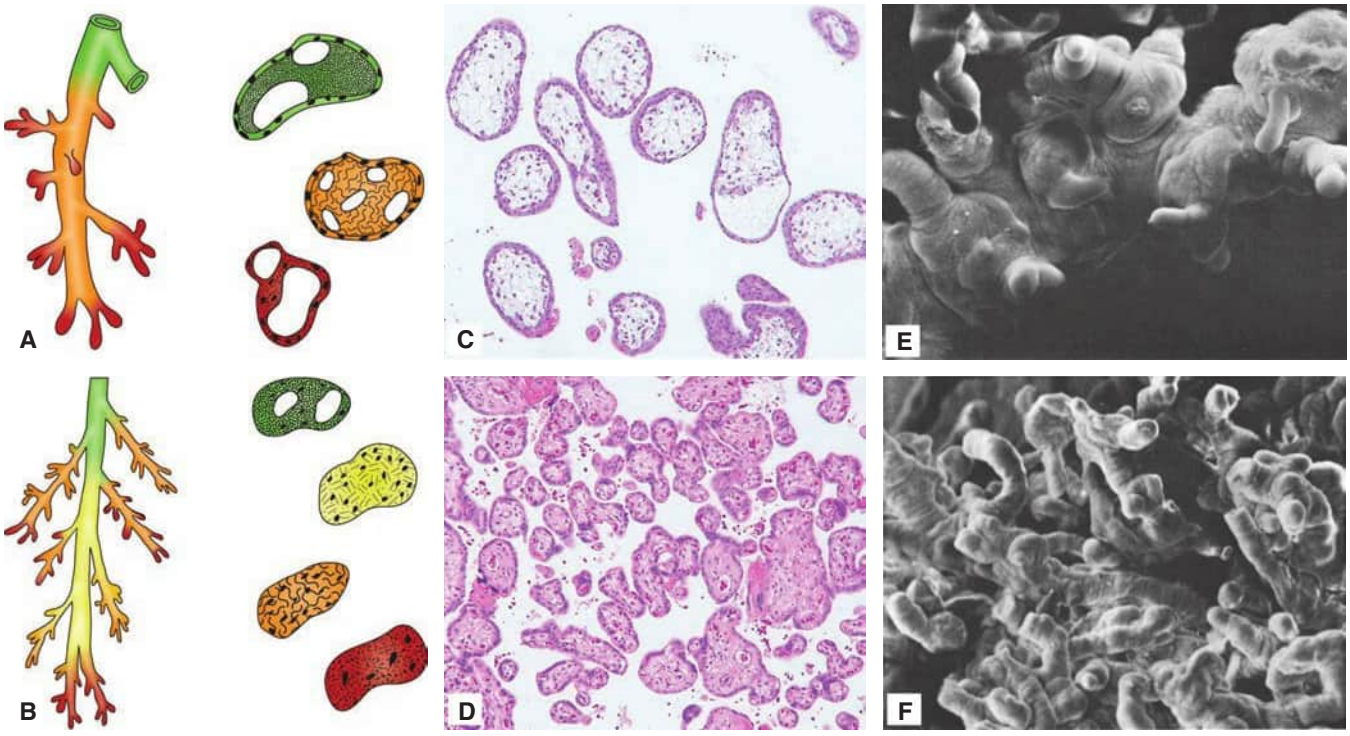

FIGURE 5-10 Illustration **(A, B)**, histology **(C, D)**, and electron microscopy **(E, F)** of early (top panel) and late (bottom panel) human placenta villi. Limited branching of villi is seen in the early placenta. With maturation, increasing villous arborization is seen, and villous capillaries lie closer to the surface of each villus. (Electron micrographs reproduced with permission from King BF, Menton DN: Scanning electron microscopy of human placental villi from early and late in gestation. Am J Obstet Gynecol 122:824, 1975.)

cells are separated by an abundant loose intercellular matrix. Later, the villous stroma becomes denser, and the cells are more spindly and closely packed. Another stromal change involves infiltration of *Hofbauer cells*, which are fetal macrophages. These are round with vesicular, often eccentric nuclei and with very granular or vacuolated cytoplasm. They grow in number and maturational state throughout pregnancy and appear to be important mediators of protection at the maternal–fetal interface (Johnson, 2012). These macrophages are phagocytic, have an immunosuppressive phenotype, produce various cytokines, and provide paracrine regulation of trophoblastic functions (Cervar, 1999; Reyes, 2017).

Some architectural changes, if substantive, can lower placental exchange efficiency. These include thickening of the basal lamina of trophoblast or capillaries, obliteration of certain fetal vessels, greater villous stroma, and fibrin deposition on the villous surface (Chap. 6, p. 109).

■ Placental Circulation

The gross anatomy of the placenta reflects the intimate approximation of the fetal capillary bed to maternal blood. The fetal surface is covered by the transparent amnion, beneath which chorionic vessels course. A section through the placenta includes amnion, chorion, chorionic villi and intervillous space, decidual (basal) plate, and myometrium (Figs. 5-11 and 5-12).

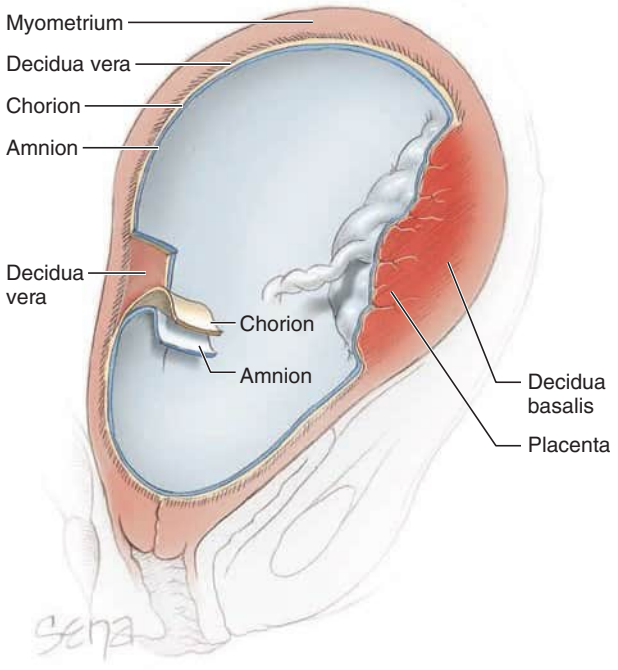

FIGURE 5-11 Uterus showing a normal placenta and its membranes in situ.

FIGURE 5-12 Photomicrograph of implantation site with partial section of an early embryo. Anchoring villi are seen with extravillous trophoblasts invading the decidua basalis. CNS = central nervous system. (Reproduced with permission from Dr. Kurt Benirschke.)

Fetal Circulation

Deoxygenated venous-like fetal blood flows to the placenta through the two umbilical arteries. As the cord joins the placenta, these umbilical vessels branch repeatedly beneath the amnion as they run across the chorionic plate. Branching continues within the villi to ultimately form capillary networks in the terminal villous branches. Blood with significantly higher oxygen content returns from the placenta via a single umbilical vein to the fetus.

The branches of the umbilical vessels that traverse along the chorionic plate are called placental surface vessels or chorionic vessels. They respond to vasoactive substances, but anatomically, morphologically, histologically, and functionally, they are unique. Chorionic arteries always cross over chorionic veins. Vessels are most readily recognized by this anatomical relationship, but they are difficult to distinguish by histological criteria.

Truncal arteries are perforating branches of the surface arteries and pass through the chorionic plate. Each truncal artery supplies one main stem villus and thus one cotyledon. As the artery penetrates the chorionic plate, its wall loses smooth muscle, and its caliber increases. The loss of muscle continues as the truncal arteries and veins branch into their smaller rami.

Before 10 weeks' gestation, end-diastolic flow is not detected within the umbilical artery at the end of the fetal cardiac cycle (Fisk, 1988; Loquet, 1988). After 10 weeks, however, end-diastolic flow appears and is maintained throughout normal pregnancy. Clinically, these flow patterns are studied with Doppler sonography to assess fetal well-being (Chap. 4, p. 262).

Maternal Circulation

Mechanisms of placental blood flow must allow blood to leave maternal circulation; flow into an amorphous space lined by syncytiotrophoblast; and return through maternal veins without producing arteriovenous-like shunts that would prevent adequate exchange between maternal blood and fetal villi. For this, maternal blood enters through the basal plate and is driven high up toward the chorionic plate by arterial pressure before laterally dispersing (Fig. 5-13). After bathing the external microvillous surface, maternal blood drains back through venous orifices in the basal plate and enters uterine veins. Thus, maternal blood traverses the placenta randomly without preformed channels. Trophoblast invasion of the spiral arteries creates low-resistance vessels that can accommodate massive increase in uterine perfusion during gestation. Generally, spiral arteries are perpendicular to, but veins are parallel to, the uterine wall. This arrangement aids closure of veins during a uterine contraction and prevents the exit of maternal blood from the intervillous space. The number of arterial openings into the intervillous space is gradually reduced by cytotrophoblastic invasion to approximately 120 entry sites at term (Brosens, 1963). These discharge blood in spurts to bath

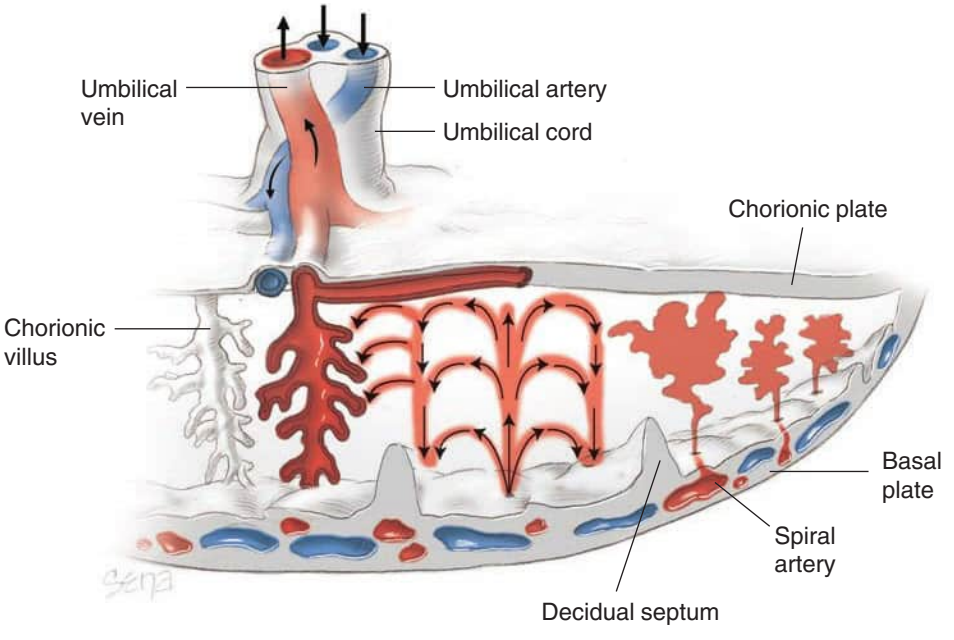

FIGURE 5-13 Schematic drawing of a section through a full-term placenta. Maternal blood flows into the intervillous spaces in funnel-shaped spurts, and umbilical arteries carry deoxygenated fetal blood to the placenta. Exchanges between the maternal and fetal systems occur as maternal blood flows around the villi. The umbilical vein carries oxygenated blood back to the fetus. Inflowing arterial blood pushes maternal venous blood into the endometrial veins, which are scattered over the entire surface of the decidua basalis. Placental lobes are separated from each other by placental (decidual) septa.

the adjacent villi (Borell, 1958). After the 30th week, a prominent venous plexus lies between the decidua basalis and myometrium and helps develop the cleavage plane needed for placental separation after delivery.

Both inflow and outflow are curtailed during uterine contractions. Bleker and associates (1975) used serial sonography during normal labor and found that placental length, thickness, and surface area grew during contractions. They attributed this to distention of the intervillous space by impairment of venous outflow compared with arterial inflow. During contractions, therefore, a somewhat larger volume of blood is available for exchange even though the rate of flow is decreased. Similarly, Doppler velocimetry has shown that diastolic flow velocity in spiral arteries is diminished during uterine contractions. Thus, principal factors regulating intervillous space blood flow are arterial blood pressure, intrauterine pressure, uterine contraction pattern, and factors that act specifically on arterial walls.

Breaks in the Placental "Barrier"

The placenta does not maintain absolute integrity of the fetal and maternal circulations, and cells traffic between mother and fetus in both directions. This situation is best exemplified clinically by erythrocyte D-antigen alloimmunization (Chap. 18, p. 353). Fetal cell transfer is small in most cases, although rarely the fetus exsanguinates into the maternal circulation.

Fetal cells can also engraft in the mother during pregnancy and still be detected decades later. Fetal lymphocytes, mesenchymal stem cells, and endothelial colony-forming cells all reside in maternal blood, bone marrow, or uterine vasculature (Huu, 2006; Piper, 2007; Sipos, 2013). This frequent phenomenon, termed *microchimerism*, is implicated in the disparate female: male ratio of autoimmune disorders (Greer, 2011; Stevens, 2006). As discussed in Chapter 62 (p. 1109), fetal cell engraftment has been associated with the pathogenesis of lymphocytic thyroiditis, scleroderma, and systemic lupus erythematosus.

Maternal–Fetal Interface

This maternal–fetal interface is an active hub of immunological interactions that allows implantation, appropriate placental development, and immunotolerance of the fetus. At the same time, a functional immune system must be maintained to protect the mother.

Immunogenicity of the Trophoblasts

Trophoblastic cells are the only fetus-derived cells in direct contact with maternal tissues and blood. Fetal syncytiotrophoblast synthesizes and secretes numerous factors that regulate the immune responses of maternal cells both at the implantation site and systemically.

Human leukocyte antigens (HLAs) are the human analogue of the major histocompatibility complex (MHC) (Hunt, 1992). There are 17 HLA class I genes and include three classic genes, *HLA-A*, *-B*, and *-C*, that encode the major class I (class Ia) transplantation antigens. Three other class I genes, designated *HLA-E*, *-F*, and *-G*, encode class Ib HLA antigens. MHC class I and II antigens are absent from villous trophoblasts, which appear to be immunologically inert at all gestational stages (Weetman, 1999). Invasive extravillous trophoblasts do express MHC class I molecules but avoid rejection by the maternal immune system.

Moffett-King (2002) reasoned that normal implantation depends on controlled trophoblastic invasion of maternal decidua and spiral arteries. Such invasion must proceed far enough to provide for normal fetal growth and development but avoid the pathogenic invasion seen in placenta accreta spectrum disorders (Chap. 43, p. 759). She suggests that dNK cells combined with extravillous trophoblasts' unique expression of three specific HLA class I genes act in concert to permit and subsequently limit trophoblast invasion.

Extravillous trophoblasts express the class Ia antigen HLA-C and nonclassic class Ib molecules HLA-E and HLA-G. HLA-G antigen is expressed only in humans and is restricted to extravillous trophoblasts in contact with maternal tissues. Expressed in both membrane-bound and soluble isoforms detectable in maternal circulation, HLA-G is thought to protect extravillous trophoblasts from immune rejection by modulating the function of both decidual and circulating NK populations (Apps, 2011; Rajagopalan, 2012). The importance of this molecule is highlighted by the observation that IVF embryos fail to implant if they do not express a soluble HLA-G isoform (Fuzzi, 2002). Thus, HLA-G may act through multiple mechanisms to aid tolerance of the maternal–fetal antigen mismatch (LeBouteiller, 1999). Abnormal HLA-G expression in extravillous trophoblasts from women with preeclampsia suggests immune dysregulation as one etiology (Goldman-Wohl, 2000).

Decidual Immune Cells

Of leukocytes, NK cells predominate in midluteal phase endometrium and in first-trimester decidua, but numbers decline by term (Johnson, 1999). In first-trimester decidua, dNK cells lie close to extravillous trophoblasts and purportedly regulate invasion. Their infiltration is increased by progesterone and by stromal cell production of IL-15 and decidual prolactin (Dunn, 2002; Gubbay, 2002). Although dNK cells have the capacity for cytotoxicity, they are not cytotoxic toward fetal trophoblasts. Their cytotoxic potential is prevented by molecular cues from decidual macrophages. As noted, specific HLA molecule expression protects against dNK cells' damaging actions.

Decidual macrophages are another decidual immune cell type and are distinct from proinflammatory M1 or antiinflammatory M2 macrophages. These cells regulate adaptive T cell responses; control dNK differentiation, activation, and cytotoxicity; and produce antiinflammatory cytokines such as IL-10.

Dendritic cells are antigen-presenting cells that educate maternal T cells. They affect development of a receptive endometrium for implantation.

Maternal T cells, as part of the adaptive immune response, increase in number and function after encounter with a specific antigen. These cells subsequently retain the ability to respond rapidly in a subsequent encounter with the same antigen. In contrast, Tregs are immunosuppressive, and during pregnancy systemic maternal populations expand. Specific Treg cell populations persist and protect against aberrant immune responses.

AMNION

At term, the amnion is a tough and tenacious but pliable membrane. This innermost avascular fetal membrane is contiguous with amniotic fluid and provides almost all of the tensile strength of the fetal membranes. Its resilience to rupture is vital to successful pregnancy outcomes. Indeed, preterm rupture of fetal membranes is a major cause of preterm delivery (Chap. 45, p. 787).

Bourne (1962) described five separate amnion layers. Here, progression of discussed layers moves from amniotic fluid to the chorion. The innermost layer, which is bathed by amniotic fluid, is a single-layer *cuboidal epithelium* (Fig. 5-14). This epithelium attaches firmly to a distinct *basement membrane*. Next, an acellular *compact layer* composed primarily of interstitial collagens is followed by the *fibroblast-like mesenchymal cell layer*. The outermost layer is the relatively acellular *zona spongiosa*, which is contiguous with the chorion laeve. The amnion also contains a few fetal macrophages, which predominate in the outer two layers. The amnion lacks smooth muscle cells, nerves, lymphatics, and importantly, blood vessels.

Amnion Development

Early during implantation, a space develops between the embryonic cell mass and adjacent trophoblastic cells (see Fig. 5-7). Small cells that line this inner surface of trophoblasts are precursors of amniotic epithelium, and the amnion is first identifiable on the 7th or 8th day of embryo development. It is initially a minute vesicle, which then develops into a small sac that covers the dorsal embryo surface. As the amnion enlarges, it gradually engulfs the growing embryo, which prolapses into its cavity (Benirschke, 2012).

Distention of the amniotic sac eventually brings it into contact with the interior surface of the chorion laeve. Apposition of the chorion laeve and amnion near the end of the first trimester obliterates the extraembryonic coelom. The amnion and chorion laeve, although slightly adhered, are never intimately connected and can be separated easily. Placental amnion covers the placental surface and thereby is in contact with the chorionic vessels. Umbilical amnion covers the umbilical cord. As discussed in Chapter 48 (p. 842), with monochorionic-diamnionic placentas, no tissue intervenes between the fused amnions. With dichorionic-diamnionic twin placentas, amnions are separated by fused chorion laeves.

Amniotic fluid fills the amniotic sac. As pregnancy progresses, this normally clear fluid increases in volume until approximately 34 weeks' gestation. After this, the volume declines. At term, it averages 1000 mL, although this may vary widely in normal and especially abnormal conditions. Amniotic fluid origin, composition, circulation, and function of are discussed further in Chapter 14 (p. 256).

Amnion Cell Histogenesis

Amniotic epithelium derives from fetal ectoderm of the embryonic disc and not from trophoblasts. This is an important consideration both embryologically and functionally. For example, HLA class I gene expression in amnion is more akin to that in embryonic cells than to that in trophoblasts.

The fibroblast-like mesenchymal cell layer likely originates from embryonic mesoderm. Early in human embryogenesis, the amniotic mesenchymal cells lie immediately adjacent to the basal surface of the amnion epithelium. At this time, the amnion has two-cell layers and approximately equal numbers of epithelial and mesenchymal cells. Simultaneously with growth and development, interstitial collagens are deposited between these two cell layers. This marks formation of the amnion compact layer, which separates the two early layers.

Amniotic epithelium early in pregnancy replicates at a rate appreciably faster than mesenchymal cells. Thus, as the amniotic sac expands, its epithelial cells form a continuous, uninterrupted layer. Instead, mesenchymal cells become more sparsely distributed. Connected by a lattice network of extracellular matrix, they appear as long, slender fibrils.

Amnion Epithelial Cells

The apical surface of the amniotic epithelium is replete with highly developed microvilli. This structure reflects its function as a major site of transfer between amniotic fluid and amnion layers. This epithelium is metabolically active, and its cells synthesize tissue inhibitor of MMP-1, prostaglandin E_2 (PGE_2), and fetal fibronectin (fFN) (Rowe, 1997). Although epithelia produce fFN, studies suggest that fFN acts in the underlying mesenchymal cells. Here, fFN promotes synthesis of MMPs that break down strength-bearing collagens. It also enhances prostaglandin synthesis to prompt uterine contractions (Mogami, 2013). This pathway is upregulated with premature rupture of membranes induced by thrombin or infection-induced release of fFN (Chigusa, 2016; Mogami, 2014).

Epithelial cells may respond to signals derived from the fetus or the mother, and they are responsive to various endocrine or paracrine modulators. Examples include oxytocin and vasopressin, both of which increase PGE_2 production in vitro (Moore, 1988). These cells may also produce cytokines such as IL-8 during labor initiation (Elliott, 2001).

Amnionic epithelium also synthesizes vasoactive peptides, which function in both maternal and fetal tissues in diverse physiological processes. These peptides include endothelin and parathyroid hormone-related protein (Economos, 1992; Germain, 1992). Others are brain natriuretic peptide (BNP) and corticotropin-releasing hormone, which are peptides that invoke smooth-muscle relaxation (Riley, 1991; Warren, 1995). BNP production is positively regulated by mechanical stretch in fetal membranes and is proposed to function in uterine quiescence. Epidermal growth factor, a negative regulator of BNP, is upregulated in the membranes at term and leads to a decline in BNP-regulated uterine quiescence (Carvajal, 2013).

Amnion Mesenchymal Cells

These cells are responsible for other major functions. Mesenchymal cells synthesize the interstitial collagens that compose the amnionic compact layer—the major source of its tensile strength (Casey, 1996). At term, the generation of cortisol by 11β-hydroxysteroid dehydrogenase may contribute to membrane rupture by reducing collagen abundance (Mi, 2017). Mesenchymal cells also synthesize cytokines that include IL-6, IL-8, and MCP-1. Cytokine synthesis rises in response to bacterial toxins and IL-1. This ability of amnion mesenchymal cells to synthesize chemokines is an important consideration in interpreting studies of labor-associated accumulation of inflammatory mediators in amnionic fluid (Garcia-Velasco, 1999). Last, mesenchymal cells may be a greater source of PGE_2 than epithelial cells, especially in the case of premature membrane rupture (Mogami, 2013; Whittle, 2000).

■ Tensile Strength

During tests of tensile strength, the decidua and then the chorion laeve give way long before the amnion ruptures. Indeed, the membranes are elastic and can expand to twice normal size during pregnancy (Benirschke, 2012). The amnion tensile strength resides almost exclusively in the compact layer, which is composed of cross-linked interstitial collagens I and III, and lesser amounts of collagens V and VI.

Amnion tensile strength is regulated in part by fibrillar collagen assembly. This process is influenced by the interaction between fibrils and proteoglycans such as decorin and biglycan (Chap. 21, p. 405). Reduction of these proteoglycans is reported to perturb fetal membrane function (Horgan, 2014; Wu, 2014). Fetal membranes overlying the cervix have a regional shift in gene expression and lymphocyte activation that set in motion an inflammatory cascade (Marcellin, 2017). This change may contribute to tissue remodeling and loss of tensile strength in the amnion (Moore, 2009).

■ Metabolic Functions

The amnion is metabolically active, is involved in solute and water transport for amnionic fluid homeostasis, and produces an impressive array of bioactive compounds. The amnion is responsive both acutely and chronically to mechanical stretch, which alters amnionic gene expression (Carvajal, 2013; Nemeth, 2000). This in turn may trigger both autocrine and paracrine responses that include production of MMPs, IL-8, and collagenase (Bryant-Greenwood, 1998; Mogami, 2013). Such factors may modulate changes in membrane properties during labor.

UMBILICAL CORD

The yolk sac and the umbilical vesicle into which it develops are prominent early in pregnancy. Initially, the embryo is a flattened disc interposed between amnion and yolk sac (see Fig. 5-7). The embryonic dorsal surface, in association with the elongation of its neural tube, grows faster than the ventral surface. As a result, the embryo bulges into the amnionic sac, and the embryo body incorporates the adjacent yolk sac to form the gut. The body stalk connects the caudal embryo to the chorion. The fetal allantois forms as a diverticulum from the caudal wall of the yolk sac and projects into the base of the body stalk.

As pregnancy advances, the yolk sac becomes smaller and its pedicle relatively longer. By the middle of the third month, the expanding amnion fuses with the chorion laeve to obliterate the extraembryonic coelom. In its expansion, the amnion covers the bulging placental disc and the lateral surface of the body stalk. The latter is then called the *umbilical cord* or *funis*. A more detailed description of this cord and potential abnormalities is found in Chapter 6 (p. 113).

The cord at term normally has two arteries and one vein. The right umbilical vein usually disappears early during fetal development, leaving only the original left vein. The umbilical cord extends from the fetal umbilicus to the fetal surface of the placenta, that is, the chorionic plate. As discussed in detail in Chapter 7 (p. 126), blood flows from the umbilical vein toward the fetus. Blood then takes a path of least resistance via two routes within the fetus. One is the ductus venosus, which empties directly into the inferior vena cava. The other route consists of numerous smaller openings into the hepatic circulation. Blood from the liver flows into the hepatic vein and then the inferior vena cava. Resistance in the ductus venosus is controlled by a sphincter situated at the origin of the ductus at the umbilical recess and is innervated by a vagus nerve branch.

Blood exits the fetus via the two umbilical arteries. These are anterior branches of the internal iliac artery and become obliterated after birth to form the medial umbilical ligaments.

PLACENTAL HORMONES

The production of steroid and protein hormones by human trophoblasts is greater in amount and diversity than that of any single endocrine tissue in all of mammalian physiology. Table 5-1 is a compendium of average production rates for various steroid hormones in nonpregnant and in near-term pregnant women. It demonstrates the remarkable increase in steroid hormone production during pregnancy. The human placenta also synthesizes an enormous amount of protein and peptide hormones, summarized in Table 5-2. The successful physiological adaptations of pregnant women to this unique endocrine milieu is discussed throughout Chapter 4.

TABLE 5-1. Steroid Production Rates in Nonpregnant and Near-Term Pregnant Women

Steroid[a]	Production Rates (mg/24 hr)	
	Nonpregnant	Pregnant
Estradiol	0.1–0.6	15–20
Estriol	0.02–0.1	50–150
Progesterone	0.1–40	250–600
Aldosterone	0.05–0.1	0.250–0.600
Deoxycorticosterone	0.05–0.5	1–12
Cortisol	10–30	10–20

[a]Estrogens and progesterone are produced by placenta. Aldosterone is produced by the maternal adrenal in response to the stimulus of angiotensin II. Deoxycorticosterone is produced in extraglandular tissue sites by way of the 21-hydroxylation of plasma progesterone. Cortisol production during pregnancy is not increased, even though the blood levels are elevated because of decreased clearance caused by increased cortisol-binding globulin.

Human Chorionic Gonadotropin

Biosynthesis

Chorionic gonadotropin is a glycoprotein with biological activity similar to that of LH, and both act via the LH-hCG receptor. hCG varies in molecular weight from 36,000 to 40,000 Da and is highly glycosylated with the most carbohydrate content of any human hormone—30 percent. This glycosylation protects the molecule from catabolism and results in a 36-hour plasma half-life for intact hCG compared with 2 hours for LH. The hCG molecule is composed of two dissimilar subunits, α and β. These are noncovalently linked but held together by electrostatic and hydrophobic forces. Isolated subunits are unable to bind the LH-hCG receptor and thus lack biological activity.

The hCG hormone is structurally related to three other glycoprotein hormones—LH, FSH, and thyroid-stimulating hormone (TSH). All four glycoproteins share a common α-subunit. However, each of their β-subunits is characterized by a distinct (although related) amino acid sequence.

Synthesis of the α- and β-chains of hCG is regulated separately from gene loci on different chromosomes. A single gene

TABLE 5-2. Protein Hormones Produced by the Human Placenta

Hormone	Primary Non-placental Site of Expression	Shares Structural or Function Similarity	Functions
Human chorionic gonadotropin (hCG)	—	LH, FSH, TSH	Maintains corpus luteum function Regulates fetal testis testosterone secretion Stimulates maternal thyroid
Placental lactogen (PL)	—	GH, prolactin	Aids maternal adaptation to fetal energy requirements
Adrenocorticotropin (ACTH)	Hypothalamus	—	
Corticotropin-releasing hormone (CRH)	Hypothalamus	—	Relaxes smooth-muscle; initiates parturition? Promotes fetal and maternal glucocorticoid production
Gonadotropin-releasing hormone (GnRH)	Hypothalamus	—	Regulates trophoblast hCG production
Thyrotropin (TRH)	Hypothalamus		Unknown
Growth hormone-releasing hormone (GHRH)	Hypothalamus	—	Unknown
Growth hormone variant (hGH-V)	—	GH variant not found in pituitary	Potentially mediates pregnancy insulin resistance
Neuropeptide Y	Brain		Potential regulates CRH release by trophoblasts
Parathyroid-releasing protein (PTH-rp)	—		Regulates transfer of calcium and other solutes; regulates fetal mineral homeostasis
Inhibin	Ovary/testis		Potentially inhibits FSH-mediated ovulation; regulates hCG synthesis
Activin	Ovary/testis		Regulates placental GnRH synthesis

GH = growth hormone; FSH = follicle-stimulating hormone; LH = luteinizing hormone; TSH = thyroid-stimulating hormone.

on chromosome 6 encodes the α-subunit. Chromosome 19 encodes the β-hCG–β-LH family of subunits with six genes for β-hCG and one for β-LH (Miller-Lindholm, 1997). Both subunits are synthesized as larger precursors and then cleaved by endopeptidases to their mature form. Intact hCG is assembled and released by secretory granule exocytosis (Morrish, 1987). Modifications during synthesis and subsequent enzymatic degradation give rise to multiple forms of hCG in maternal plasma and urine that vary enormously in bioactivity and immunoreactivity.

Before 5 weeks, hCG is expressed both in the syncytiotrophoblast and cytotrophoblasts (Maruo, 1992). Later in the first trimester, hCG is produced almost solely in the syncytiotrophoblast, peaks around 9 weeks' gestation, and then declines to a plateau for the remainder of gestation (Beck, 1986; Kurman, 1984). Dynamic changes in hCG concentration in the first trimester highlight the importance of accurate gestational age estimation when interpreting aneuploidy screening strategies that include hCG.

Circulating levels of free β-subunit are low to undetectable throughout pregnancy, and their concentration is the limiting factor for secretion of complete hCG molecules. Levels of the α-subunit rise gradually and roughly correspond to placental mass, until they plateau at approximately 36 weeks' gestation (Cole, 1997).

Concentrations in Serum and Urine

The combined hCG molecule is detectable in plasma of pregnant women 7 to 9 days after the midcycle LH surge preceding ovulation. Thus, hCG likely enters maternal blood at the time of blastocyst implantation. Plasma levels rise rapidly, doubling approximately every 2 days in the first trimester (Fig. 5-15). Appreciable fluctuations in levels for a given patient are observed on the same day.

Intact hCG circulates as multiple, highly related isoforms that have variable cross-reactivity between commercial assays. This emphasizes the need to use the same assay type when measuring serial hCG levels for clinical indications such as evaluating pregnancy of unknown location or medical management of ectopic pregnancy. Peak maternal plasma levels reach approximately 50,000 to 100,000 mIU/mL between the 60th and 80th days after menses. Plasma levels then decline, and a nadir is reached by approximately 16 weeks' gestation. Plasma levels remain at this lower level for the rest of pregnancy.

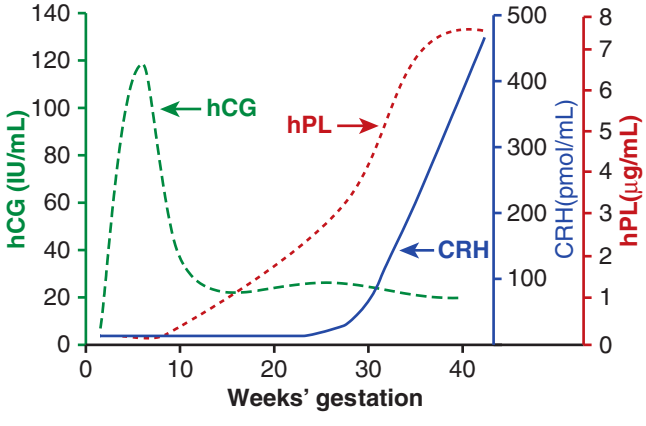

FIGURE 5-15 Distinct profiles for the concentrations of human chorionic gonadotropin (hCG), human placental lactogen (hPL), and corticotropin-releasing hormone (CRH) in serum of women throughout normal pregnancy.

Although maternal urine, like plasma, contains various hCG degradation products, the principal urinary form is the terminal product of hCG degradation, namely, the β-core fragment. Concentrations of this fragment follow the same general pattern as that in maternal plasma, peaking at approximately 10 weeks' gestation. Importantly, the β-subunit antibody used in most pregnancy tests reacts with both intact hCG (the major form in the plasma) and with fragments of hCG (the major form found in urine).

hCG Regulation

Placental GnRH is likely involved in the regulation of hCG formation. Both GnRH and its receptor are expressed by cytotrophoblasts and syncytiotrophoblast (Wolfahrt, 1998). GnRH administration elevates circulating hCG levels, and cultured trophoblasts respond to GnRH treatment with increased hCG secretion (Iwashita, 1993; Siler-Khodr, 1981). Pituitary GnRH production is regulated by inhibin and activin. Likewise, in cultured placental cells, activin stimulates and inhibin inhibits GnRH and hCG production (Petraglia, 1989; Steele, 1993).

hCG is cleared by the kidney (about 30 percent), and the remainder is likely cleared by liver metabolism (Wehmann, 1980). Thus, levels can be markedly altered in gravidas with chronic renal disease.

Biological Functions

Noted earlier, hCG maintains corpus luteum function—that is, continued progesterone production. Both hCG subunits are required for binding to the LH-hCG receptor in the corpus luteum. However, maximum plasma hCG concentrations are attained well after hCG-stimulated corpus luteum secretion of progesterone has ceased. Specifically, luteal progesterone synthesis begins to decline at approximately 6 weeks' gestation despite continued and increasing hCG production. Therefore, this incompletely explains the physiological function of hCG in pregnancy. LH-hCG receptors are present in various other tissues, and roles are discussed subsequently.

In pregnancies with male fetuses, hCG stimulates fetal testicular testosterone secretion. This reaches a maximum when hCG levels peak. Thus, at a critical time in male sexual differentiation, hCG enters fetal plasma from the syncytiotrophoblast. In the fetus, it acts as an LH surrogate to stimulate Leydig cell replication and testosterone synthesis to promote male sexual differentiation (Chap. 3, p. 35). Before approximately 110 days, the fetal anterior pituitary lacks vascularization from the hypothalamus and produces minimal LH secretion. Thereafter, as hCG levels fall, pituitary LH maintains modest testicular stimulation.

The maternal thyroid gland also is stimulated by large quantities of hCG. In women with gestational trophoblastic disease, biochemical and clinical evidence of hyperthyroidism sometimes develops (Chap. 13, p. 238). Some forms of

hCG bind to TSH receptors on thyrocytes (Hershman, 1999). The thyroid-stimulatory activity in plasma of first-trimester pregnant women varies appreciably from sample to sample. Modifications of hCG oligosaccharides likely are important in the capacity of hCG to stimulate thyroid function. Acidic isoforms stimulate thyroid activity, and some more basic isoforms stimulate iodine uptake (Kraiem, 1994; Tsuruta, 1995). Last, the LH-hCG receptor is also expressed by thyrocytes, which suggests that hCG stimulates thyroid activity via the LH-hCG receptor as well (Tomer, 1992).

LH-hCG receptors are found in myometrium and in uterine vascular tissue. It has been hypothesized that hCG may promote uterine vascular vasodilation and myometrial smooth muscle relaxation (Kurtzman, 2001). hCG also modulates maternal immune cell functions in the decidua during early stages of placentation (Schumacher, 2019; Silasi, 2020).

Abnormally High or Low Levels

Several clinical circumstances display substantively higher maternal plasma hCG levels. Some examples include multifetal pregnancy, erythroblastosis fetalis associated with fetal hemolytic anemia, and gestational trophoblastic disease. Relatively higher hCG levels may be found in women carrying a fetus with Down syndrome, and this has been incorporated into screening strategies (Table 17-4, p. 336). Various malignant tumors also produce hCG, sometimes in large amounts—especially trophoblastic neoplasms (Chap. 13, p. 241).

Relatively lower hCG plasma levels are found in women with failing early pregnancies and ectopic pregnancy (Chap. 12, p. 222). hCG is produced in very small amounts in normal tissues of men and nonpregnant women, perhaps primarily in the anterior pituitary gland. Nonetheless, the detection of hCG in blood or urine almost always indicates pregnancy (Chap. 10, p. 176).

Human Placental Lactogen

Biosynthesis

This single, nonglycosylated polypeptide chain shares a 96-percent amino-acid-sequence homology with human growth hormone (hGH) and a 67-percent homology with human prolactin (hPRL). Because of these similarities, it was called chorionic growth hormone or human placental lactogen. Currently, the latter term is used by most.

Five genes in the growth hormone–placental lactogen gene cluster are linked and located on chromosome 17: *GH1*, *GH2*, *CSHL1, CSH1*, and *CSH2*. Human placental lactogen (hPL) is encoded by the last two genes. hPL is concentrated in syncytiotrophoblast, but similar to hCG, hPL is demonstrated in cytotrophoblasts before 6 weeks (Grumbach, 1964; Maruo, 1992). Within 5 to 10 days after conception, hPL is demonstrable in the placenta and can be detected in maternal serum as early as 3 weeks. Levels of mRNA for hPL in syncytiotrophoblast remain relatively constant throughout pregnancy. This finding supports the idea that the hPL secretion rate is proportional to placental mass. Levels rise steadily until 34 to 36 weeks' gestation. The hPL production rate near term—approximately 1 g/d—is by far the greatest of any known hormone in humans. It is rapidly cleared and has a half-life between 10 and 30 minutes (Walker, 1991). In late pregnancy, maternal serum concentrations reach levels of 5 to 15 μg/mL (see Fig. 5-15).

Very little hPL is detected in fetal blood, and amnionic fluid levels are somewhat lower than that in maternal plasma. Thus, although hPL may have a direct effect on fetal tissues, such as modulating fetal vasculature formation, its primary role is to act on maternal physiology to ensure adequate nutrient delivery to the placenta (Corbacho, 2002).

Metabolic Actions

hPL has putative actions in several important maternal metabolic processes. First, hPL promotes lipolysis to raise circulating free fatty acid levels. This provides an energy source for maternal metabolism and fetal nutrition. In vitro studies suggest that hPL inhibits secretion by term syncytiotrophoblast of leptin (Coya, 2005). Prolonged maternal starvation in the first half of pregnancy leads to higher hPL plasma concentrations.

Second, hPL aids maternal adaptation to fetal energy requirements (Hill, 2018). For example, increased maternal insulin resistance ensures nutrient flow to the fetus. It also favors protein synthesis and provides a readily available amino acid source to the fetus. To counterbalance the greater insulin resistance and prevent maternal hyperglycemia, maternal insulin levels rise. Both hPL and prolactin signal through the prolactin receptor to increase maternal beta cell proliferation, which augments insulin secretion (Georgia, 2010). In animals, prolactin and hPL upregulate serotonin synthesis, which increases beta cell proliferation (Kim, 2010). Short-term changes in plasma glucose or insulin, however, have relatively little effect on plasma hPL levels. In vitro studies of syncytiotrophoblast suggest that hPL synthesis is stimulated by insulin and insulin-like growth factor-1 and inhibited by PGE_2 and $PGF_{2\alpha}$ (Bhaumick, 1987; Genbacev, 1977).

Other Placental Protein Hormones

The placenta has a remarkable capacity to synthesize numerous peptide hormones, including some that are analogous or related to hypothalamic and pituitary hormones. In contrast to their counterparts, some of these placental peptide/protein hormones are not subject to feedback inhibition.

Hypothalamic-Like Releasing Hormones

The known hypothalamic-releasing or -inhibiting hormones include GnRH, corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), growth hormone–releasing hormone (GHRH), and somatostatin. For each of these, the human placenta produces an analogous hormone (Petraglia, 1992; Siler-Khodr, 1988).

GnRH in the placenta shows its highest expression in the first trimester (Siler-Khodr, 1978, 1988). Interestingly, it is found in cytotrophoblasts but not syncytiotrophoblast. Placenta-derived GnRH functions to regulate trophoblast hCG production and extravillous trophoblast invasion via regulation of MMP-2 and MMP-9 (Peng, 2016). Placenta-derived GnRH is also the likely source of elevated maternal GnRH levels in pregnancy (Siler-Khodr, 1984).

CRH is a member of a larger family of CRH-related peptides that includes CRH and urocortins (Dautzenberg, 2002). Maternal serum CRH levels rise from 5 to 10 pmol/L in the nonpregnant woman to approximately 100 pmol/L in the early third trimester and then to almost 500 pmol/L abruptly during the last 5 to 6 weeks (see Fig. 5-15). After labor begins, maternal plasma CRH levels rise even further (Petraglia, 1989, 1990). Urocortin, involved in the stress response, is also produced by the placenta and secreted into the maternal circulation, but at much lower levels than that seen for CRH (Florio, 2002).

The function of CRH synthesized in the placenta, membranes, and decidua has been somewhat defined. For example, trophoblast, amniochorion, and decidua express both CRH-R1 and CRH-R2 receptors and several variant receptors (Florio, 2000). Both CRH and urocortin enhance trophoblast secretion of adrenocorticotropic hormone (ACTH), and this suggests an autocrine–paracrine role (Petraglia, 1999). Large amounts of trophoblast CRH enter maternal blood.

CRH receptors are also present in many tissues outside the placenta. Proposed biological roles include induction of smooth-muscle relaxation in vascular and myometrial tissue and immunosuppression. The physiological reverse, however, induction of myometrial contractions, has been proposed for the rising CRH levels seen near term. Some hypothesize that CRH may be involved with parturition initiation (Wadhwa, 1998).

Glucocorticoids act in the hypothalamus to inhibit CRH release. But, in the trophoblast, glucocorticoids stimulate CRH gene expression (Jones, 1989a; Robinson, 1988). Thus, a novel positive feedback loop in the placenta may allow placental CRH to stimulate placental ACTH and thereby prompt fetal and maternal adrenal glucocorticoid production, with subsequent stimulation of placental CRH expression (Nicholson, 2001; Riley, 1991).

GHRH is expressed in placenta, but its function is unclear (Berry, 1992). GHRH may play an autocrine role in trophoblast survival via the GHRH receptor (Liu, 2016). Ghrelin is another regulator of hGH secretion and is produced by placental tissue (Horvath, 2001). Trophoblast ghrelin expression peaks at midpregnancy and is a paracrine regulator of differentiation or is a potential regulator of human growth hormone variant production, described next (Fuglsang, 2005; Gualillo, 2001).

Pituitary-Like Hormones

A *human growth hormone variant (hGH-V)* that is not expressed in the pituitary is expressed in the placenta. The gene encoding hGH-V is located in the hGH–hPL gene cluster on chromosome 17. Sometimes referred to as placental growth hormone, hGH-V is a 191-amino-acid protein that differs in 15 amino acid positions from the sequence for hGH. Although hGH-V retains growth-promoting and antilipogenic functions that are similar to those of hGH, it has reduced diabetogenic and lactogenic functions relative to hGH (Vickers, 2009). Placental hGH-V presumably is synthesized in the syncytiotrophoblast. It is believed that hGH-V is present in maternal plasma by 21 to 26 weeks' gestation, rises in concentration until approximately 36 weeks, and remains relatively constant thereafter. hGH-V levels in maternal plasma and those of insulin-like growth factor 1 positively correlate. Moreover, hGH-V secretion by trophoblast in vitro is inhibited by glucose in a dose-dependent manner (Patel, 1995). Overexpression of hGH-V in mice causes severe insulin resistance, making it a likely candidate to mediate insulin resistance of pregnancy (Liao, 2016).

Pro-opiomelanocortin (POMC) is a polypeptide produced in the pituitary and other tissues including the placenta. It is proteolytically cleaved into numerous active hormones including ACTH, β-lipotropic hormone, melanocyte-stimulating hormone (α-, β-, and γ-MSH), and β–endorphin (Harno, 2018). These hormones play a role in maintaining energy balance. As discussed, placental CRH stimulates synthesis and release of placental ACTH, demonstrating the autocrine and paracrine functions of the placenta in addition to its systemic endocrine activity.

Relaxin

The peptide is expressed in human corpus luteum, decidua, and placenta (Bogic, 1995). Two of the three relaxin genes—*H2* and *H3*—are transcribed in the corpus luteum (Bathgate, 2002; Hudson, 1983, 1984). Decidua, placenta, and membranes express *H1* and *H2* (Hansell, 1991). Relaxin is synthesized as a single, 105-amino-acid preprorelaxin molecule that is cleaved to A and B molecules. Relaxin is structurally similar to insulin and insulin-like growth factor.

The rise in maternal circulating relaxin levels in early pregnancy is attributed to corpus luteum secretion, and levels parallel those of hCG. Relaxin, along with rising progesterone levels, may act on myometrium to promote relaxation and the quiescence of early pregnancy (Chap. 21, p. 404). In addition, the production of relaxin and relaxin-like factors within the placenta and fetal membranes may play an autocrine-paracrine role in postpartum regulation of extracellular matrix remodeling (Qin, 1997a,b). One important relaxin function is enhancement of the maternal glomerular filtration rate that is apparent early in gestation (Chap. 4, p. 68).

Parathyroid Hormone-Related Protein

Levels of this peptide are elevated within maternal but not fetal circulation (Bertelloni, 1994; Saxe, 1997). Parathyroid hormone-related protein (PTH-rP) synthesis is found in several normal adult tissues, especially in reproductive organs that include myometrium, endometrium, corpus luteum, and lactating mammary tissue. PTH-rP is not produced in the parathyroid glands of normal adults. Although yet undefined, placenta-derived PTH-rP may regulate genes involved in transfer of calcium and other solutes. It also contributes to mineral homeostasis in fetal bone, amnionic fluid, and the fetal circulation (Simmonds, 2010).

Leptin

This hormone is normally secreted by adipocytes, but cytotrophoblasts and syncytiotrophoblast also synthesize leptin (Henson, 2002). Relative contributions of leptin from maternal adipose tissue versus placenta are currently undefined. Leptin functions as an antiobesity hormone that decreases food

intake through its hypothalamic receptor. It also regulates bone growth and immune function (Cock, 2003; La Cava, 2004). Placental leptin promotes placental cell proliferation, protein synthesis, and activation of immune tolerance and antiapoptotic responses (Rosario, 2016a; Schanton, 2018). Maternal serum levels are significantly higher than those in nonpregnant women. Fetal leptin levels correlate positively with birthweight and likely function in fetal development and growth. Studies suggest that reductions in leptin availability contribute to adverse fetal metabolic programing in intrauterine growth-restricted offspring (Nusken, 2016, Perez-Perez, 2018).

Neuropeptide Y

This 36-amino-acid peptide is widely distributed in brain. It also is found in sympathetic neurons innervating the cardiovascular, respiratory, gastrointestinal, and genitourinary systems. Neuropeptide Y has been isolated from the placenta and localized in cytotrophoblasts (Petraglia, 1989). Trophoblasts possess neuropeptide Y receptors, and treatment of these with neuropeptide Y causes CRH release (Robidoux, 2000).

Transforming Growth Factor Beta Superfamily

This family of cytokines regulates various cellular functions that include placental development, trophoblast differentiation, and invasion into the decidua (Adu-Gyamafi, 2020). This process is finely tuned, and extreme invasion results in placenta accreta spectrum disorders, whereas shallow implantation can lead to early pregnancy loss or preeclampsia. Members of the family include transforming growth factor beta (TGF-β), activin, inhibin, nodal, bone morphogenic proteins (BMPs), antimüllerian hormone, and growth differentiation factors (GDFs).

These cytokines bind to a suite of receptors composed of a type 1 subunit and a type 2 receptor subunit to ultimately direct gene expression. This combinatorial diversity leads to divergent functions in the placenta and decidua. Activin A promotes syncytialization, extravillous trophoblast formation, and invasion. BMP2 enhances invasion, and BMP4 may direct embryonic stem cells toward a trophoblast lineage (Zhang 2018, Xu 2002). Inhibin A promotes syncytialization but inhibits invasion (Debiève, 2000; Jones, 2006). Nodal inhibits proliferation, extravillous trophoblast formation, and invasion. The complete role this superfamily in normal and abnormal placental development is yet to be fully defined.

■ Placental Progesterone Production

After 6 to 7 weeks' gestation, little progesterone is produced in the ovary (Diczfalusy, 1961). Surgical removal of the corpus luteum or even bilateral oophorectomy during the 7th to 10th week does not decrease excretion rates of urinary pregnanediol, the principal urinary metabolite of progesterone. Before this time, however, corpus luteum removal will lead to spontaneous abortion unless an exogenous progestin is given, and Chapter 66 (p. 1170) lists suitable dosing. After approximately 8 weeks, the placenta assumes progesterone secretion, and maternal serum levels throughout pregnancy gradually rise (Fig. 5-16). By term, these levels are 10 to 5000 times of those in nonpregnant women, depending on the ovarian cycle stage.

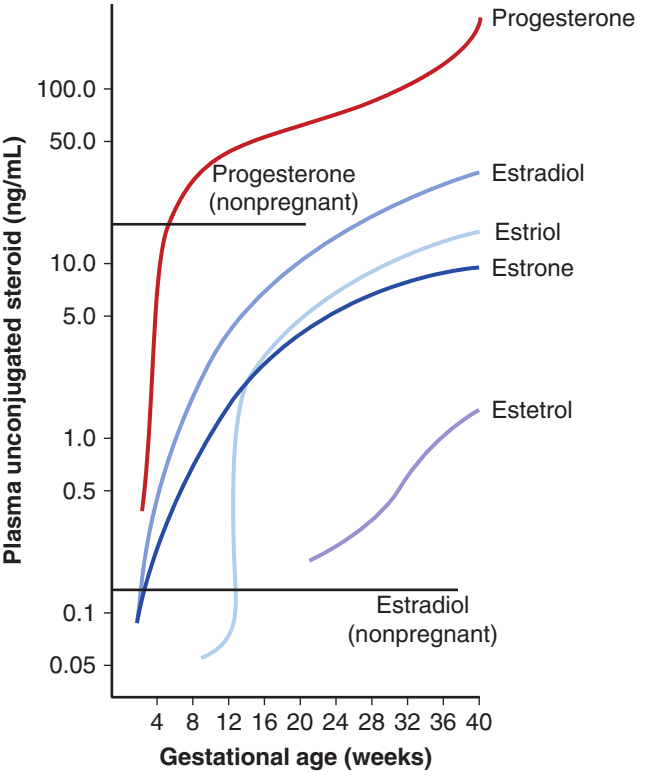

FIGURE 5-16 Plasma levels of progesterone, estradiol, estrone, estetrol, and estriol in women during the course of gestation. (Modified and redrawn with permission from Mesiano S: The endocrinology of human pregnancy and fetoplacental neuroendocrine development. In Strauss JF, Barbieri RL (eds) Yen and Jaffe's Reproductive Endocrinology: Physiology, Pathophysiology, and Clinical Management, 6th ed. Philadephia, PA: Saunders; 2009.)

The daily production rate of progesterone in late, normal, singleton pregnancies approximates 250 mg. In multifetal pregnancies, the daily production rate may exceed 600 mg. Progesterone is synthesized from cholesterol in a two-step enzymatic reaction. First, cholesterol is converted to pregnenolone within the mitochondria in a reaction catalyzed by cytochrome P450 cholesterol side-chain cleavage enzyme. Pregnenolone leaves the mitochondria and is converted to progesterone in the endoplasmic reticulum by 3β-hydroxysteroid dehydrogenase. Progesterone is released immediately by diffusion.

Although the placenta produces a prodigious amount of progesterone, the syncytiotrophoblast has a limited capacity for cholesterol biosynthesis. The rate-limiting enzyme in its biosynthesis is 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase. Because of this, the placenta must rely on an exogenous source, that is, maternal cholesterol, for progesterone formation. The trophoblast preferentially uses LDL cholesterol for progesterone biosynthesis (Simpson, 1979, 1980). This mechanism differs from placental production of estrogens, which relies principally on fetal adrenal precursors.

Although fetal well-being and placental estrogen production show a relationship, this is not the case for placental progesterone. Thus, placental endocrine function, including progesterone biosynthesis and formation of protein hormones such as hCG, may persist for weeks after fetal demise.

The metabolic clearance rate of progesterone in pregnant women is similar to that found in men and nonpregnant women. One metabolite is 5α-dihydroprogesterone (5α-DHP), and levels disproportionately rise due to synthesis in syncytiotrophoblast from both placenta-produced progesterone and fetus-derived precursor (Dombroski, 1997). Thus, the concentration ratio of 5α-DHP to progesterone is elevated in pregnancy, although the mechanisms for this are incompletely defined. Progesterone also is converted to the potent mineralocorticoid deoxycorticosterone in pregnant women and in the fetus. The concentration of deoxycorticosterone is strikingly higher in both maternal and fetal compartments (see Table 5-1). The extraadrenal formation of deoxycorticosterone from circulating progesterone accounts for most of its production in pregnancy (Casey, 1982a,b).

■ Placental Estrogen Production

During the first 2 to 4 weeks or pregnancy, rising hCG levels maintain production of estradiol in the corpus luteum. Ovarian production of both progesterone and estrogens drops significantly by the 7th week of pregnancy. At this time, there is a luteal–placental transition. Subsequently, more than half of estrogen entering maternal circulation is produced in the placenta, and it produces a continually increasing magnitude of estrogen (MacDonald, 1965a; Siiteri, 1963, 1966). Near term, normal human pregnancy is a hyperestrogenic state, and syncytiotrophoblast is producing estrogen in amounts equivalent to that produced in one day by the ovaries of no fewer than 1000 ovulatory women. This hyperestrogenic state terminates abruptly after delivery of the placenta.

Biosynthesis

In human trophoblast, neither cholesterol nor in turn progesterone can serve as precursor for estrogen biosynthesis. This is because *steroid 17α-hydroxylase/17,20-lyase (CYP17A1)* is not expressed in the human placenta. This essential enzyme converts 17-OH progesterone (a C_{21} steroid) to androstenedione, which is a C_{19} steroid and an estrogen precursor. Consequently, conversion of C_{21} steroids to C_{19} steroids is not possible.

However, dehydroepiandrosterone (DHEA) and its sulfate (DHEA-S) are also C_{19} steroids and are produced by maternal and fetal adrenal glands. These two steroids can serve as estrogen precursors in the placenta (Fig. 5-17). Ryan (1959a) found that the placenta had an exceptionally high capacity to convert appropriate C_{19} steroids to estrone and estradiol. The conversion of DHEA-S to estradiol requires placental expression of four key enzymes that are located principally in syncytiotrophoblast (Bonenfant, 2000; Salido, 1990). First, the placenta expresses high levels of steroid sulfatase (STS), which converts the conjugated DHEA-S to DHEA. DHEA is then acted upon by 3β-hydroxysteroid dehydrogenase type 1 (3βHSD) to produce androstenedione. Cytochrome P450 aromatase (CYP19) then converts androstenedione to estrone, which is then converted to estradiol by 17β-hydroxysteroid dehydrogenase type 1 (17βHSD1).

DHEA-S is the major precursor of estrogens in pregnancy (Baulieu, 1963; Siiteri, 1963). However, maternal adrenal glands do not produce sufficient amounts of DHEA-S to account for more than a fraction of total placental estrogen biosynthesis. The fetal adrenal glands are quantitatively the most important source of placental estrogen precursors in human pregnancy. Thus, estrogen production during pregnancy reflects the unique interactions among fetal adrenal glands, fetal liver, placenta, and maternal adrenal glands.

Directional Secretion

Of estradiol and estriol formed in syncytiotrophoblast, >90 percent enters maternal plasma (Gurpide, 1966). Of placental progesterone production, ≥85 percent enters maternal plasma, and little maternal progesterone crosses the placenta to the fetus (Gurpide, 1972).

This directional secretion stems from the architecture of hemochorioendothelial placentation. Steroids produced in the syncytiotrophoblast are secreted directly into maternal blood. To reach the fetus, they must first traverse the cytotrophoblast layer and then enter the stroma of the villous core and then fetal capillaries. From either of these spaces, steroids can reenter the

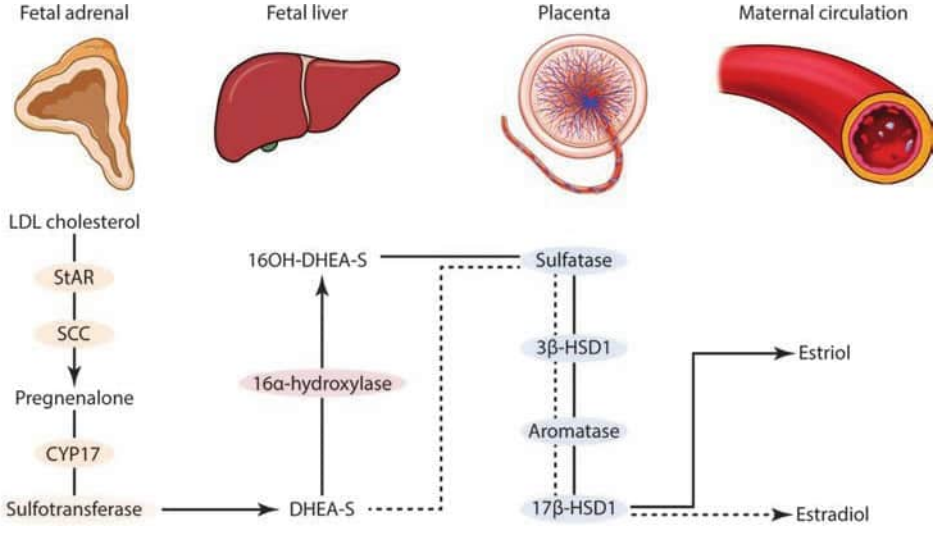

FIGURE 5-17 Schematic presentation of estrogen biosynthesis in the human placenta. Dehydroepiandrosterone sulfate (DHEA-S) is secreted in prodigious amounts by the fetal adrenal glands, and a portion is converted to 16α-hydroxydehydroepiandrosterone sulfate (16OH-DHEA-S) in the fetal liver. DHEA-S and 16OH-DHEA-S are converted in the placenta to the estrogens 17β-estradiol (E_2) and estriol (E_3). These estrogens then enter the maternal circulation. Near term, half of E_2 is derived from fetal adrenal DHEA-S and half from maternal DHEA-S. On the other hand, 90 percent of E_3 in the placenta arises from fetal 16OH-DHEA-S and only 10 percent from all other sources. 3βHSD1 = 3β-hydroxysteroid dehydrogenase type 1; 17βHSD1 = 17β-hydroxysteroid dehydrogenase type 1; CYP17 = steroid 17α-hydroxylase/17,20-lyase; LDL = low-density lipoprotein; SCC = cholesterol side-chain cleavage enzyme; StAR = steroidogenic acute regulatory protein.

syncytium. The net result of this hemochorial arrangement is that entry of steroids into the maternal circulation is substantially greater than that into fetal blood.

FETAL ADRENAL GLAND–PLACENTAL INTERACTIONS

As noted, the fetal adrenal gland is a vital source of steroid precursors for placental estrogen synthesis. This fetal gland is remarkable both morphologically and functionally. At term, its mass exceeds that in adults (Chap. 7, p. 134). More than 85 percent of the fetal gland is composed of a unique fetal zone, which has a great capacity for steroid biosynthesis. Its daily steroid production near term is 100 to 200 mg/d, which exceeds the adult steroid secretion of 30 to 40 mg/d. The unique fetal zone subsequently regresses in the first year of life.

In addition to responding to ACTH from the fetal brain, fetal adrenal gland growth is influenced by factors secreted by the placenta. This is exemplified by the continued adrenal gland growth throughout gestation and by its rapid involution immediately after birth and placenta delivery.

Placental Estriol Synthesis

Estradiol is the primary placental estrogen product at term. In addition, significant levels of *estriol* and *estetrol* are found in the maternal circulation, particularly late in gestation (see Fig. 5-16). These hydroxylated forms of estrogen derive from the placenta using substrates formed by the combined efforts of the fetal adrenal gland and fetal liver enzymes (see Fig. 5-17). For this, high levels of hepatic 16α-hydroxylase act on adrenal-derived steroids (MacDonald, 1965b; Ryan, 1959b). Thus, the disproportionate rise in estriol formation during pregnancy is accounted for by placental synthesis from plasma-borne 16-OH-DHEA-S. Near term, the fetus produces 90 percent of placental estriol and estetrol precursors in normal human pregnancy. Thus, in the past, levels of these steroids were used as an indicator of fetal well-being.

Fetal Adrenal Steroid Precursor

Cholesterol is the precursor for fetal adrenal steroidogenesis. Here, the steroid biosynthesis rate is so great that its steroidogenesis alone is equivalent to a fourth of the total daily LDL cholesterol turnover in adults. Fetal adrenal glands synthesize cholesterol from acetate, and all enzymes involved in this biosynthesis are elevated compared with those of the adult adrenal gland (Rainey, 2001). Thus, the de novo cholesterol synthesis rate by fetal adrenal tissue is extremely high. Even so, it is insufficient to account for the steroids produced by fetal adrenal glands. Therefore, cholesterol must be assimilated from the fetal circulation and mainly from LDL produced in the fetal liver (Carr, 1980, 1984; Simpson, 1979).

Fetal Conditions Affecting Estrogen Production

Several fetal disorders alter the availability of substrate for placental steroid synthesis and thus highlight the interdependence of fetal development and placental function. *Fetal demise* is followed by a striking reduction in maternal urinary estrogen levels. Similarly, after ligation of the umbilical cord with the fetus and placenta left in situ, placental estrogen production declines markedly (Cassmer, 1959). However, as previously discussed, placental progesterone production is maintained. These observations indicate that an important source of precursors for placental estrogen—but not for progesterone—biosynthesis derive from the fetus.

Anencephalic fetuses have markedly atrophic adrenal glands due to absent hypothalamic and pituitary structures that would otherwise release ACTH for adrenal stimulation. In the absence of the adrenal cortical fetal zone development, placental formation of estrogen is severely limited because of diminished availability of C_{19} steroid precursors. Indeed, urinary estrogen levels in women pregnant with an anencephalic fetus approximate only 10 percent of those found in normal pregnancy (Frandsen, 1961). With an anencephalic fetus, almost all estrogens produced arise from placental use of maternal plasma DHEA-S.

Fetal adrenal cortical hypoplasia occurs in perhaps 1 in 12,500 births (McCabe, 2001). Estrogen production in these pregnancies is also limited, which suggests the absence of C_{19} precursors.

Fetal–placental sulfatase deficiency is associated with very low estrogen levels in otherwise normal pregnancies (France, 1969). Namely, sulfatase deficiency precludes the hydrolysis of C_{19} steroid sulfates, the first enzymatic step in the placental use of these circulating prehormones for estrogen biosynthesis. This deficiency is an X-linked disorder, and thus all affected fetuses are male. Its estimated frequency is 1 case in 2000 to 5000 births and is associated with delayed labor onset. It also is associated with development of ichthyosis in affected males later in life (Bradshaw, 1986).

Fetal–placental aromatase deficiency is a rare autosomal recessive disorder in which individuals cannot synthesize endogenous estrogens (Grumbach, 2011; Simpson, 2000). Fetal adrenal DHEA-S is converted in the placenta to androstenedione, but in cases of placental aromatase deficiency, androstenedione cannot be converted to estradiol. Rather, androgen metabolites of DHEA produced in the placenta, including androstenedione and some testosterone, are secreted into the maternal or fetal circulation, or both. This can virilize the mother and the female fetus (Belgorosky, 2009; Harada, 1992).

Trisomy 21—Down syndrome—screening searches for abnormal levels of hCG, alpha-fetoprotein, and other analytes (Chap. 17, p. 338). Of these, serum unconjugated estriol levels can be low in women with Down syndrome fetuses (Benn, 2002). This likely stems from inadequate formation of C_{19} steroids in the adrenal glands of these trisomic fetuses.

Fetal erythroblastosis in some cases of severe fetal D-antigen alloimmunization can lead to elevated maternal plasma estrogen levels. A suspected cause is the greater placental mass from hypertrophy, which can be seen with such fetal hemolytic anemia (Chap. 18, p. 360).

Complete hydatidiform mole and *gestational trophoblastic neoplasias* lack a fetus and also a fetal adrenal source of C_{19} steroid precursors for trophoblast estrogen biosynthesis. Placental estrogen formation is consequently limited to the use of C_{19}

steroids from the maternal plasma, and thus estradiol is principally produced (MacDonald, 1964, 1966).

Maternal Conditions Affecting Estrogen Production

Maternal conditions can likewise affect placental estrogen production. *Glucocorticoid treatment* can inhibit ACTH secretion from the maternal and fetal pituitary glands. This diminishes maternal and fetal adrenal secretion of the placental estrogen precursor DHEA-S and leads to a striking reduction in placental estrogen formation.

With *Addison disease,* pregnant women show lower estrogen levels, principally estrone and estradiol levels (Baulieu, 1956). However, the fetal adrenal gland contribution to estriol synthesis, particularly in later pregnancy, is quantitatively much more important than that of the maternal adrenal gland.

Maternal *androgen-producing tumors* can present the placenta with elevated androgen levels. Fortunately, placenta is extraordinarily efficient in the aromatization of C_{19} steroids. For example, virtually all androstenedione entering the intervillous space is taken up by syncytiotrophoblast and converted to estradiol (Edman, 1981). None of the C_{19} steroid enters the fetus, and a female fetus is rarely virilized by a maternal androgen-secreting tumor. Indeed, virilized female fetuses of women with an androgen-producing tumor may be cases in which a nonaromatizable C_{19} steroid androgen is produced by the tumor—for example, 5α-dihydrotestosterone. Alternatively, tumor-derived testosterone could be produced very early in pregnancy in amounts that exceed the placental aromatase capacity at that time.

CHAPTER 6

Placental Abnormalities

During pregnancy, the placenta provides the indispensable interface between mother and fetus (Chap. 5, p. 86). However, in part due to inaccessibility throughout gestation, the placenta's anatomy, physiology, and molecular structure still remain some of the most understudied and intriguing topics in obstetrics. Furthermore, the parallels between placental formation and cancer afford opportunities to understand tumor biology and pathogenesis (Costanzo, 2018; Guttmacher, 2014).

Visual placental inspection by the obstetrician is recommended, but routine pathological examination is not mandatory. Indeed, specific conditions that merit submission for detailed inspection are still debated. For example, the College of American Pathologists recommends placental examination for an extensive list of indications, however many providers are not aware (Langston, 1997; Odibo, 2016). Moreover, data are insufficient to support all of these. At minimum, the placenta and cord should be inspected in the delivery room. The decision to request pathological examination should be based on clinical and placental findings (Table 6-1) (Redline, 2008; Roberts, 2008).

NORMAL PLACENTA

At term, the typical placenta weighs 470 g, is round to oval with a 22-cm diameter, and has a central thickness of 2.5 cm (Benirschke, 2012). It is composed of a placental disc, extraplacental membranes, and three-vessel umbilical cord. The disc surface that lies against the uterine wall is the *basal plate*, which is divided by clefts into portions—termed cotyledons. The fetal surface is the *chorionic plate*. Here, the umbilical cord inserts, typically in the center. Large fetal vessels that originate from the cord vessels then spread and branch across the chorionic plate before entering stem villi of the placenta parenchyma. In tracing these, fetal arteries almost invariably cross over veins. The chorionic plate and its vessels are covered by thin amnion, which can be easily peeled away from a postdelivery specimen.

During prenatal sonographic examinations, multiple societies, including the American Institute of Ultrasound in Medicine (2018), recommend identifying and recording placental location and its relationship to the internal cervical os. As seen sonographically, the normal placenta is homogenous and 2 to 4 cm thick, lies against the myometrium, and indents into the amnionic sac. The retroplacental space is a hypoechoic area that separates the myometrium from the basal plate and measures less than 1 to 2 cm. The umbilical cord is also imaged, its fetal and placental insertion sites examined, and its vessels counted.

Many placental lesions can be identified grossly or sonographically, but other abnormalities require histopathological examination for clarification. A detailed description of these is beyond the scope of this chapter, and interested readers are referred to textbooks by Benirschke (2012), Fox (2007), and Faye-Petersen (2006) and their colleagues. Moreover, the placenta accreta spectrum, placenta previa, and gestational

TABLE 6-1. Some Indications for Placental Pathological Examination[a]

Maternal Indications
Abruption
Antepartum infection with fetal risks
Anti-CDE alloimmunization
Cesarean hysterectomy
Oligohydramnios or hydramnios
Peripartum fever or infection
Preterm (<32 wks) delivery
Postterm (>42 wks) delivery
Severe trauma
Suspected placental injury
Systemic disorders with known placental effects
Thick meconium
Unexplained late pregnancy bleeding
Unexplained or recurrent pregnancy complications
Fetal and Neonatal Indications
Admission to an acute care nursery
Birth weight <10th or >95th percentile
Fetal anemia
Fetal or neonatal compromise
Neonatal seizures
Hydrops fetalis
Infection or sepsis
Major anomalies or abnormal karyotype
Multifetal gestation
Stillbirth or neonatal death
Vanishing twin beyond the first trimester
Placental Indications
Gross lesions
Markedly abnormal placental shape or size
Markedly adhered placenta
Term cord >32 cm or <100 cm
Umbilical cord lesions
Velamentous cord insertion

[a]Indications are organized alphabetically.

trophoblastic disease are presented in detail in Chapters 41 and 20, respectively.

SHAPE AND SIZE VARIANTS

Of variants, placentas may infrequently form as separate, nearly equally sized discs. This *bilobate placenta* may also be called bipartite placenta or placenta duplex. In these, the cord inserts between the two placental lobes—either into a connecting chorionic bridge or into intervening membranes. A placenta containing three or more equivalently sized lobes is rare and termed *multilobate*. Unlike this equal distribution, one or more disparately smaller accessory lobes—*succenturiate lobes*—may develop in the membranes at a distance from the main placenta (Fig. 6-1). These lobes have vessels that course through the membranes. Of clinical importance, if these vessels overlie the cervix to create a vasa previa, dangerous fetal hemorrhage can follow vessel laceration (p. 115). An accessory lobe can also be retained in the uterus after delivery to cause postpartum uterine atony and hemorrhage or later endometritis.

Rarely, the placental surface area varies from the norm. With *placenta membranacea*, villi cover all or nearly all the uterine cavity. This may occasionally give rise to serious hemorrhage because of associated placenta previa or accreta (Pereira, 2013). A *ring-shaped placenta* may be a variant of placenta membranacea. This placenta is annular, and a partial or complete ring of placental tissue is present. These abnormalities appear to be associated with a greater likelihood of antepartum and postpartum bleeding and fetal-growth restriction (Faye-Petersen, 2006; Steemers, 1995). With *placenta fenestrata*, the central portion of a placental disc is missing. In some cases, there is

A

B

FIGURE 6-1 Succenturiate lobe. **A.** Vessels extend from the main placental disc to supply the small round succenturiate lobe located to the left. (Reproduced with permission from Dr. Rachel Gardner.) **B.** Sonographic imaging with color Doppler shows the main placental disc implanted posteriorly (*asterisk*). The succenturiate lobe is located on the anterior uterine wall across the amnionic cavity. Vessels are identified as the long red and blue crossing tubular structures that travel within the membranes to connect these two portions of placenta.

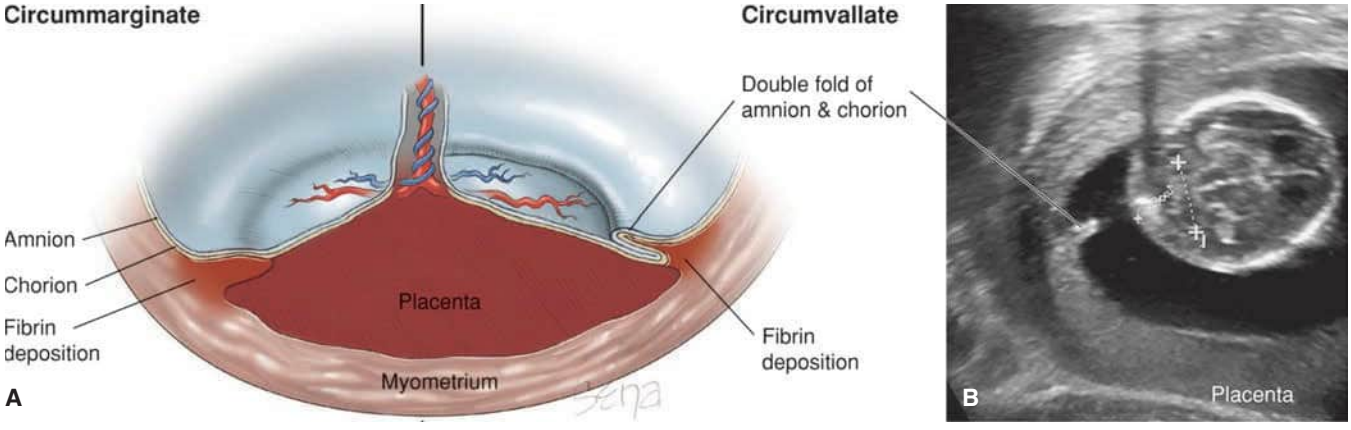

FIGURE 6-2 A. In this illustration, circummarginate (*left*) and circumvallate (*right*) varieties of extrachorial placentation are shown. A circummarginate placenta is covered by a single layer of amniochorion. **B.** This transabdominal grayscale sonographic image shows a circumvallate placenta. The double fold of amnion and chorion creates a broad, opaque white ring and ridge on the fetal surface.

an actual hole in the placenta. More often, only villous tissue is missing, and the chorionic plate remains intact.

During pregnancy, the normal placenta increases its thickness at a rate that approximates 1 mm per week. Although not measured as a component of routine sonographic evaluation, this thickness typically does not exceed 40 mm (Hoddick, 1985). *Placentomegaly* defines those thicker than 40 mm and commonly results from striking villous enlargement. Underlying maternal etiologies are diabetes mellitus or severe anemia, whereas fetal sources include hydrops, anemia, syphilis, toxoplasmosis, or infection caused by parvovirus or cytomegalovirus. In these conditions, the placenta is homogeneously thickened. In other cases placentas are thick but inhomogeneous. Partial mole is a classic example. The thickened placenta contains edematous villi, which appear as multiple, small, anechoic placental cysts (Chap. 13, p. 239). Cystic vesicles also are seen with *placental mesenchymal dysplasia*. In this rare condition, vesicles correspond to enlarged stem villi. However, unlike molar pregnancy, trophoblast proliferation is not excessive, and chromosomal complements are diploid (Woo, 2011).

Rather than villous enlargement, inhomogeneous placentomegaly often may result from collections of blood or fibrin, which impart heterogeneity to the placenta. Examples of this are discussed later and include massive perivillous fibrin deposition, intervillous or subchorionic thromboses, and large retroplacental hematomas (p. 110).

EXTRACHORIAL PLACENTATION

The chorionic plate normally extends to the periphery of the placental disc and has a diameter similar to that of the basal plate. With extrachorial placentation, however, the chorionic plate fails to extend to this periphery and leads to a chorionic plate that is smaller than the basal plate (Fig. 6-2). Circummarginate and circumvallate placentas are the two types. In a *circummarginate placenta*, fibrin and old hemorrhage lie between the placental disc and the overlying sheer amniochorion. In contrast, with a *circumvallate placenta*, the chorionic plate periphery is a thickened, opaque, gray-white circular ridge composed of a double fold of chorion and amnion.

Sonographically, the circumvallate fold can be seen as a thick, linear band of echoes extending from one placental edge to the other. On cross section, however, it appears as two "shelves," with each lying above an opposing placental margin (see Fig. 6-2). This anatomy can help differentiate this shelf from other bands (Table 6-2).

In small observational studies of circumvallate placenta diagnosed postpartum, it was associated with increased risk for antepartum bleeding, abruption, fetal demise, and preterm birth (Suzuki, 2008; Taniguchi, 2014). In a prospective sonographic investigation of 17 cases, however, Shen and associates (2007a) found most circumvallate placentas to be transient. Persistent cases were benign. In general, most otherwise uncomplicated pregnancies with either type of extrachorial placentation have normal outcomes, and no increased surveillance is usually required.

CIRCULATORY DISTURBANCES

Functionally, placental perfusion disorders can be grouped into: (1) those in which maternal blood flow to or within the intervillous space is disrupted, and (2) those with disturbed fetal blood flow through the villi. These lesions are frequently identified in the normal, mature placenta. Although they can limit maximal placental blood flow, functional reserve within the placental prevents harm in most cases. Indeed, some estimate that up to 30 percent of placental villi can be lost without untoward fetal effects (Fox, 2007). If extensive, however, these lesions can profoundly limit fetal growth.

Lesions that disrupt perfusion are frequently seen grossly or sonographically, whereas smaller lesions are seen only histologically. With sonography, many of these, such as subchorionic fibrin deposition, perivillous fibrin deposition, and intervillous thrombosis, appear as focal sonolucencies within the placenta. Greater magnetic resonance (MR) imaging use in pregnancy has permitted detection and further characterization of these lesions (Bockoven, 2020; Capuani, 2017). Importantly, in the absence of maternal or fetal complications, small isolated placental sonolucencies are considered incidental findings.

TABLE 6-2. Sonographic Bands During Pregnancy

Condition	Sonographic Findings
Normal early chorioamnionic separation	Crescent-shaped amnion mirrors the chorion's curve; distinct from the fetus; fuses after 16 weeks' gestation
Subchorionic hematoma	Echogenic blood lies between the myometrium and chorioamnion, which appears as a thin band crossing the cavity. Hemorrhage and band resolve over time
Uterine synechiae (Amnionic sheet)	2.5- to 4.0-mm-thick, broad-based band crosses the cavity. Appears shelflike on cross section
Circumvallate placenta	Broad-based band extends from one placental edge to the other, just above the placental surface. Appears shelflike on cross section
Amnionic band	Thin strands cross and appear to tether fetal parts
Pseudoamnionic band syndrome	Thin strands tether fetal parts and form after fetoscopic surgeries or amniocenteses that are complicated by membrane laceration
Uterine septum	Chorioamnionic sac of an early pregnancy fills one horn of a septate or partial bicornuate uterus. Thick band of echoes, which may be wedge-shaped, extend from uterine fundus in midline
Membranes from vanishing twin	Depending on chorionicity either a thin amnion or thicker chorioamnion spans the cavity
Placental vessels supported by membranes: velamentous insertion, succenturiate lobe	With grayscale imaging, vessels appear as bands. Color Doppler will clarify (see Figs. 6-1 and 6-6)

Modified from Dashe, 2017; Lafitte, 2017.

■ Maternal Blood Flow Disruption

Subchorionic Fibrin Deposition

These collections are caused by slowing of maternal blood flow within the intervillous space. In the upper portion of this space near the chorionic plate, blood stasis is prominent and leads to subsequent fibrin deposition. In viewing the placental fetal surface, subchorionic lesions are seen as white or yellow, firm, round, elevated plaques just beneath the chorionic plate.

Perivillous Fibrin Deposition

Stasis of maternal blood flow around an individual villus also results in fibrin deposition and can lead to diminished villous oxygenation and necrosis of syncytiotrophoblast (Fig. 6-3). These small yellow-white placental nodules are grossly visible within the parenchyma of a sectioned placenta. Within limits, these reflect normal placental aging. Deposition that affects >25 percent of villi is associated with fetal-growth restriction and adverse neonatal outcomes (Devisme, 2017; Spinillo, 2019).

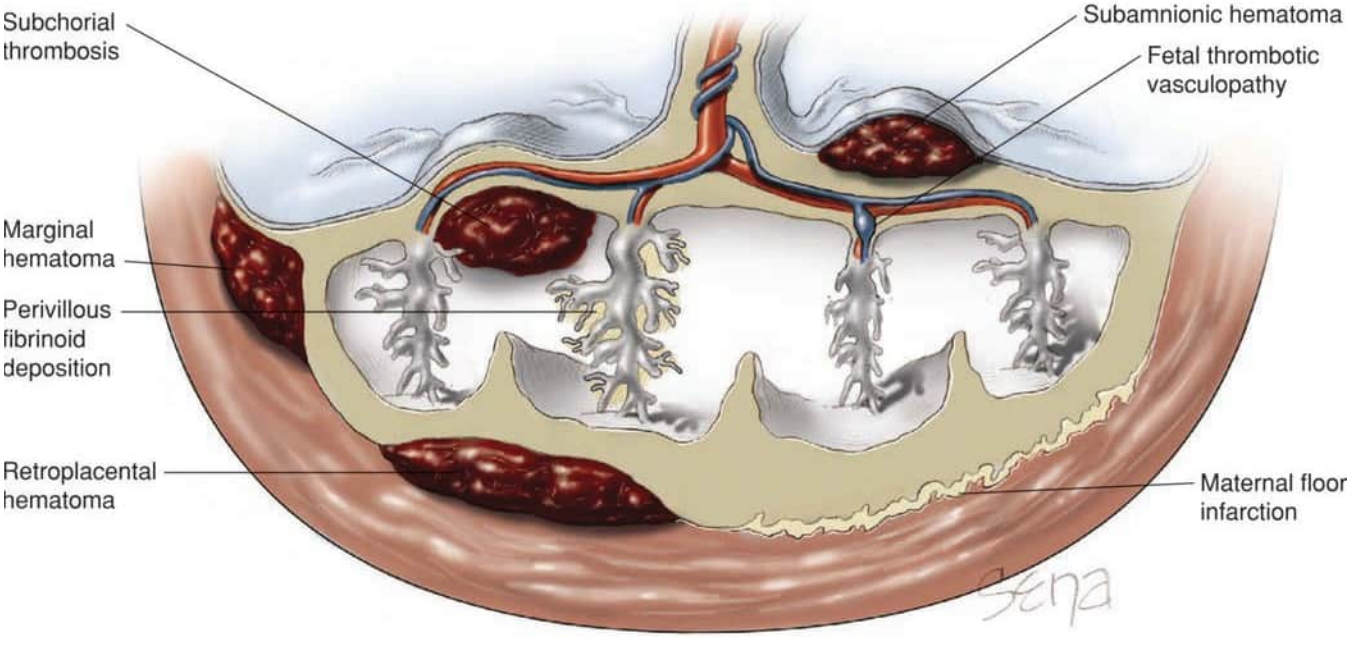

FIGURE 6-3 Potential sites of maternally and fetally related placental circulatory disturbances.

Maternal Floor Infarction. This extreme variant of perivillous fibrin deposition is a dense fibrinoid layer within the placental basal plate and is erroneously termed an infarction. *Maternal floor infarction* has a thick, yellow or white, firm corrugated surface that impedes normal maternal blood flow into the intervillous space. In specific cases that extend up and beyond the basal plate to entrap villi and obliterate the intervillous space, the term *massive perivillous fibrin deposition* is used. The etiopathogenesis is unclear, but maternal auto- or alloimmunity appears contributory (Faye-Peterson, 2018; Romero, 2013). Antiphospholipid antibody syndrome and angiogenic factors involved with preeclampsia also have been implicated (Sebire, 2002; Whitten, 2013).

These lesions are not reliably imaged with prenatal sonography, but they may create a thicker basal plate. Affected pregnancies are associated with miscarriage, fetal-growth restriction, preterm delivery, and stillbirth (Andres, 1990; Mandsager, 1994). Importantly, these adverse outcomes can recur in subsequent pregnancies.

Intervillous Thrombus

This is a collection of coagulated maternal blood normally found in the intervillous space mixed with fetal blood from a break in a villus. Grossly, these round or oval collections vary in size up to several centimeters. They appear red if recent or white-yellow if older, and they develop at any placental depth. Intervillous thrombi are common and typically not associated with adverse fetal sequelae. These reflect potential communication between maternal and fetal circulations, and thus large lesions are one cause of elevated maternal serum alpha-fetoprotein (MSAFP) levels (Table 17-5, p. 338). (Salafia, 1988).

Infarction

Chorionic villi themselves receive oxygen solely from maternal circulation and specifically from blood supplied into the intervillous space. Any uteroplacental disease that diminishes or obstructs this supply can result in infarction of an individual villus. These are common lesions in mature placentas and are benign in limited numbers. If numerous, however, placental insufficiency can develop. When they are thick, centrally located, and randomly distributed, they may be associated with preeclampsia or lupus anticoagulant.

Hematoma

The maternal–placental–fetal unit can develop several hematoma types. As depicted in Figure 6-3, these include: (1) *retroplacental hematoma*—formed between the placenta and its adjacent decidua; (2) *marginal hematoma*—formed between the chorion and decidua at the placental periphery—known clinically as *subchorionic hemorrhage*; (3) *subamnionic hematoma*—derived of fetal vessel origin and found beneath the amnion but above the chorionic plate, and (4) *subchorial thrombus* along the roof of the intervillous space and beneath the chorionic plate. With this last type, *massive subchorionic hematomas* are also known as *Breus moles.*

Sonographically, hematomas evolve with time and appear hyperechoic to isoechoic in the first week after hemorrhage, hypoechoic at 1 to 2 weeks, and finally, anechoic after 2 weeks. Most subchorionic hematomas visible sonographically are fairly small and of no clinical consequence (Naert, 2019). However, extensive retroplacental, marginal, and subchorial collections are associated with higher rates of miscarriage, stillbirth, placental abruption, and preterm delivery (Tuuli, 2011). In essence, placental abruption is a large, clinically significant retroplacental hematoma.

■ Fetal Blood Flow Disruption

Fetal Vascular Malperfusion

Placental lesions that arise from fetal circulatory disturbances are also depicted in Figure 6-3. Normally, deoxygenated fetal blood flows from the two umbilical arteries into arteries within the chorionic plate. These surface arteries divide and send branches out across the placental surface. These eventually supply individual stem villi. Remember that fetal blood is oxygenated within each villus by passive diffusion of oxygen from maternal blood contained within the intervillous space. Thus, with fetal vessel thrombosis, portions of the villus distal to the obstruction become nonfunctional. Normally, thrombi in limited numbers are found in mature placentas. If many villi are affected, which can be seen with preeclampsia, the fetus may suffer growth restriction, stillbirth, or nonreassuring fetal heart rate patterns (Chisholm, 2015; Lepais, 2014; Saleemuddin, 2010).

Villous Vascular Lesions

Villous capillaries show a spectrum of histological lesions. *Chorangiosis* describes an increased number of capillaries within terminal villi. Its definition requires ≥10 capillaries to be present in ≥10 villi in ≥10 fields viewed through a 10× lens (Altshuler, 1984). Clinically, long-standing hypoperfusion or hypoxia is thought to be causative (Stanek, 2016). *Focal chorangiosis* is increased capillary vascularity in a significant portion of the placenta but not diffusely. In one small study, lower Apgar scores and fetal vascular malperfusion were associated outcomes (Sung, 2019). Prenatal detection of chorangiosis has been reported (Inubashiri, 2017). *Chorangiomatosis* describes increased capillary number in stem villi, but terminal villi are spared. This finding has been linked with fetal-growth restriction and anomalies (Bagby, 2011). Despite these associations, the clinical significance of both vascular conditions remains unclear. *Chorioangiomas* are described subsequently.

Subamnionic Hematoma

As noted earlier, these hematomas lie between the chorionic plate and amnion. They most often are acute iatrogenic events of no clinical consequence during third-stage labor when cord traction ruptures a vessel near the cord insertion.

Large, chronic antepartum lesions may cause fetomaternal hemorrhage or fetal-growth restriction (Deans, 1998). They also may be confused with other placental masses such as chorioangioma. In most cases, color Doppler interrogation will show absent internal blood flow within a hematoma and permit differentiation (Sepulveda, 2000).

PLACENTAL CALCIFICATION

Calcium salts can be deposited throughout the placenta but are most common on the basal plate. Calcification accrues

with advancing gestation, and greater degrees are associated with smoking and higher maternal serum calcium levels (Bedir Findik, 2015). These hyperechoic deposits can easily be seen sonographically, and a grading scale from 0 to 3 reflects increasing calcification with increasing numerical grade (Grannum, 1979). Following this scheme, a grade 0 placenta is homogeneous, lacks calcification, and displays a smooth, flat chorionic plate. A grade 1 placenta has scattered echogenicities and subtle chorionic plate undulations. Grade 2 shows echogenic stippling at the basal plate. Large, echogenic comma shapes originate from an indented chorionic plate, but their curve falls short of the basal plate. Last, a grade 3 placenta has echogenic indentations extending from the chorionic plate to the basal plate, which create discrete components that resemble cotyledons. Basal plate densities also increase.

This grading scale poorly predicts neonatal outcome near term (McKenna, 2005; Mirza, 2018). However, data from two small studies link grade 3 placenta prior to 32 weeks with stillbirth and some other adverse pregnancy outcomes (Chen, 2011, 2015; Mirza, 2018).

PLACENTAL TUMORS

Chorioangioma

These benign tumors have components similar to the blood vessels and stroma of the chorionic villus. Also called chorangiomas, these placental tumors have an incidence that approximates 1 percent (Guschmann, 2003). In some cases, fetal-to-maternal hemorrhage across tumor capillaries leads to elevated levels of MSAFP. This typically prompts sonographic evaluation to exclude a neural-tube defect, which also shows high MSAFP levels. Sonographically, chorangiomas appear as a well-circumscribed, rounded, predominantly hypoechoic lesion lying near the chorionic plate and protruding into the amnionic cavity (Fig. 6-4). Documenting increased blood flow by color Doppler helps to distinguish these lesions from other placental masses such as hematoma, partial hydatidiform mole, teratoma, metastases, and leiomyoma (Prapas, 2000). Although rare, *chorangiocarcinoma* tumors mirror chorioangiomas clinically (Huang, 2015).

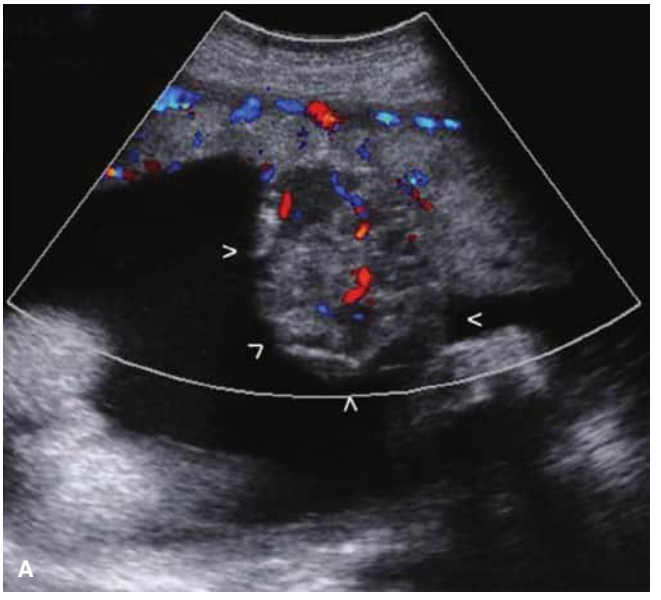
Small chorioangiomas are usually asymptomatic. Large tumors, typically those measuring >4 cm, can create significant arteriovenous shunting within the placenta to cause high-output heart failure, hydrops, and fetal death (Al Wattar, 2014). Compression or shearing of fetal erythrocytes within tumor vessels can lead to hemolysis and microangiopathic anemia (Bauer, 1978). Hydramnios, preterm delivery, and fetal-growth restriction are other sequelae (Dong, 2020). Large tumor size and fetal hydrops are the primary determinants and signal a potential adverse perinatal outcome (Buca, 2020).

Grayscale and color Doppler interrogation of the placenta and amnionic fluid volume are used to identify these tumors. Diagnostic tools that can affirm associated fetomaternal hemorrhage include MSAFP level and Kleihauer-Betke stain (Chap. 18, p. 358). With fetal concern, echocardiography assesses cardiac function, whereas middle cerebral artery interrogation is used to identify fetal anemia.

Several fetal therapies interfere with the vascular supply to the tumor and reverse fetal heart failure. At specialized perinatal centers, endoscopic laser ablation of feeder vessels to the tumor is most frequently used and is associated with favorable fetal outcomes (Hosseinzadeh, 2015). Discussed in Chapter 16, fetal transfusion can treat serious anemia, amnioreduction can temporize hydramnios, and digoxin therapy can assist fetal heart failure.

Metastatic Tumors

Maternal malignant tumors rarely metastasize to the placenta. Of those that do, melanomas, leukemias and lymphomas,



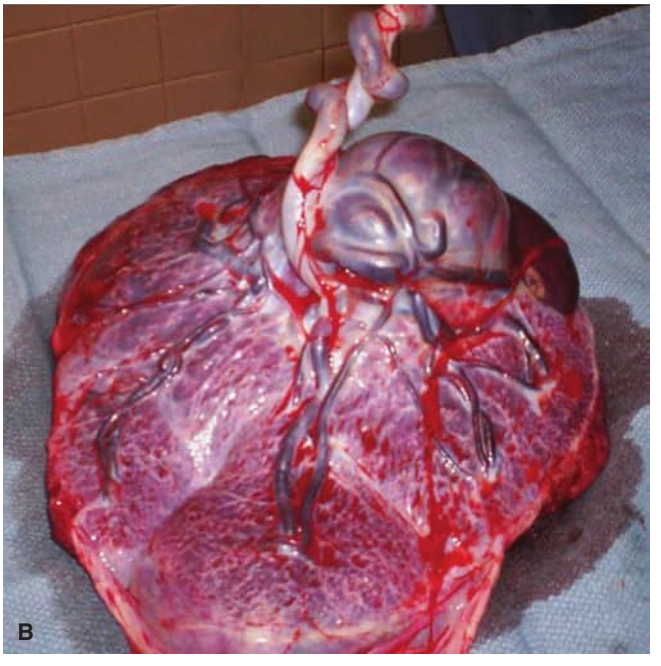


FIGURE 6-4 Placental chorioangioma. **A.** Color Doppler imaging displays blood flow through a large chorioangioma with its border outlined by white arrows. **B.** Grossly, the chorioangioma is a round, well-circumcised mass protruding from the fetal surface.

and breast cancer are the most common (Al-Adnani, 2007). Tumor cells usually are confined within the intervillous space. As a result, metastasis to the fetus is uncommon but is most often seen with melanoma (Alexander, 2003).

Similarly, cases in which fetal malignancy metastasizes to the placenta are rare (Reif, 2014). These are predominantly fetal neuroectodermal tumors, and only one case in the literature describes transplantation of tumor to the maternal uterus (Nath, 1995).

AMNIOCHORION

Chorioamnionitis

Normal genital-tract flora can colonize and infect the membranes, umbilical cord, and eventually the fetus. Bacteria most commonly ascend after prolonged membrane rupture and during labor to cause infection. Organisms initially infect the chorion and adjacent decidua in the area overlying the internal os. Subsequently, progression leads to full-thickness involvement of the membranes—chorioamnionitis. Organisms often then spread along the chorioamnionic surface to colonize and replicate in amnionic fluid. Inflammation of the chorionic plate and of the umbilical cord—*funisitis*—may follow (Kim, 2015; Redline, 2012).

Most commonly, chorioamnionitis is microscopic or occult and caused by a wide variety of microorganisms. This is frequently cited as a possible explanation for many otherwise unexplained cases of ruptured membranes, preterm labor, or both (Chap. 45, p. 789). In some cases, gross infection is characterized by visible membrane clouding and is sometimes accompanied by a foul odor that depends on bacterial species.

Other Membrane Abnormalities

Amnion nodosum is a condition characterized by numerous small, light-tan nodules affixed to the amnion that overlies the chorionic plate. These may be scraped off the fetal surface and contain deposits of fetal squames and fibrin that reflect prolonged and severe oligohydramnios (Adeniran, 2007).

Two notable bands can be formed by the fetal membranes. First, *amnionic band sequence* is an anatomical disruption sequence in which amnion bands tether, constrict, or amputate fetal parts. Bands may form spontaneously or follow fetal surgery procedures (see Table 6-2) (Lafitte, 2017). Amnionic bands commonly cause limb-reduction defects, facial clefts, or encephalocele (Barzilay, 2015; Guzmán-Huerta, 2013). Umbilical cord compromise is another sequela (Barros, 2014). Severe defects of the spine or ventral wall that accompany amnionic bands suggest a *limb-body wall complex*, described in Chapter 15 (p. 297).

Sonography often first identifies the sequelae of this sequence rather than the bands themselves. As with any fetal anomaly, targeted sonography is indicated. Identification of a limb-reduction defect, an encephalocele in an atypical location, or an extremity with edema or positional deformity should prompt careful evaluation for amnionic bands.

Management depends on the degree of anatomic deformity (Society of Maternal–Fetal Medicine, 2019). Fetoscopic laser interruption of the band may be suitable in highly selected antepartum cases (Gueneuc, 2019; Javadian, 2013).

Second, an *amnionic sheet* in contrast is formed by normal amniochorion draped over a preexisting uterine synechia. Generally, these sheets pose little fetal risk, although slightly higher rates of preterm membrane rupture and placental abruption have been described (Nelson, 2010; Tuuli, 2012).

UMBILICAL CORD

Length

Most umbilical cords at delivery measure 40 to 70 cm long, and very few measure <30 cm or >100 cm. Cord length is influenced positively by both maternal parity and body mass index (Linde, 2018). In retrospective studies, short cords have been linked with congenital malformations and intrapartum distress (Krakowiak, 2004; Linde, 2018; Yamamoto, 2016). Excessively long cords are linked with cord entanglement or prolapse and with fetal anomalies (Olaya-C, 2015; Rayburn, 1981).

Because antenatal determination of cord length is technically limited, cord diameter has been evaluated as a predictive marker for fetal outcomes. Some have linked lean cords with poor fetal growth and large-diameter cords with macrosomia (Proctor, 2013). However, the clinical utility of this parameter is still unclear (Cromi, 2007; Raio, 2003).

Coiling

Cord coiling characteristics are not currently part of standard sonographic evaluation. Usually the umbilical vessels spiral through the cord in a sinistral, that is, left-twisting direction (Fletcher, 1993; Lacro, 1987). The number of complete coils per centimeter of cord length is termed the *umbilical coiling index—UCI* (Strong, 1994). A normal, antepartum, sonographically derived UCI is 0.4, and this contrasts with a normal, postpartum, physically measured value of 0.2 (Sebire, 2007). UCIs <10th percentile are considered *hypocoiled,* and those >90th percentile are *hypercoiled*.

Clinically, the significance of coiling extremes is controversial. Some studies evaluating large, unselected cohorts find no associations between UCI values and poor neonatal outcome (Jessop, 2014; Pathak, 2010). In others, extremes are linked with various adverse outcomes but most consistently with intrapartum fetal heart rate abnormalities, preterm labor, or fetal-growth restriction (Chitra, 2012; de Laat, 2006; Pergialiotis, 2019).

Vessel Number

Counting cord vessel number is a standard component of anatomical evaluation during fetal sonographic examination and immediately after delivery (Fig. 6-5). Embryos initially have two umbilical veins. In the first trimester, the right vein typically atrophies to leave one large vein to accompany the two, thick-walled umbilical arteries. Four-vessel cords are rare and often associated with congenital anomalies (Puvabanditsin,

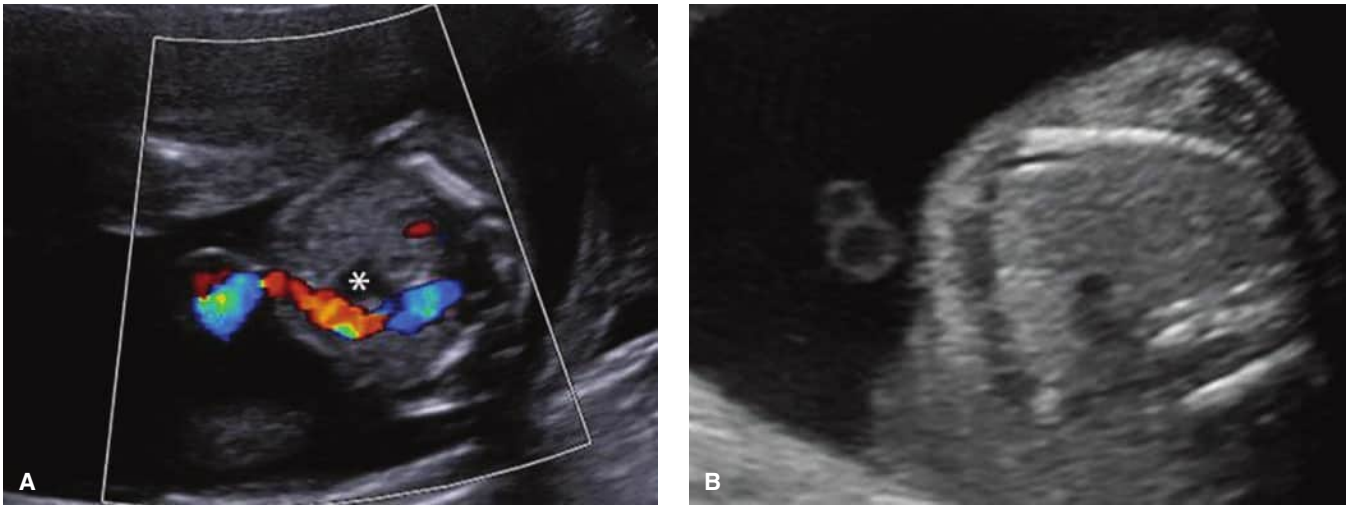

FIGURE 6-5 Two umbilical arteries are typically documented sonographically in the second trimester. They encircle the fetal bladder (*asterisk*) as extensions of the superior vesical arteries. **A.** In this color Doppler sonographic image, a single umbilical artery, shown in red, runs along the bladder wall before joining the umbilical vein (blue) in the cord. Remember with color Doppler that color signifies only blood flow direction relative to the transducer. **B.** A cross section of a floating cord segment shows the two vessels of the cord. The smaller circle is the single umbilical artery and the larger circle, the umbilical vein.

2011). If it is an isolated finding, however, prognosis can be good (Avnet, 2011).

The most common aberration is that of a single umbilical artery (SUA). Its cited incidence is 0.63 percent in liveborn neonates, 1.92 percent in perinatal deaths, and 3 percent in twins (Heifetz, 1984). Fetuses with major malformations frequently have an SUA. Thus, its identification often prompts consideration for targeted sonography and possibly fetal echocardiography. The most frequent anomalies are cardiovascular and genitourinary (Hua, 2010; Murphy-Kaulbeck, 2010). In an anomalous fetus, an SUA greatly increases the aneuploidy risk, and amniocentesis is recommended for karyotype assessment (Dagklis, 2010).

If targeted sonography finds otherwise normal anatomy, an isolated SUA in an otherwise low-risk pregnancy does not significantly raise the fetal aneuploidy risk. However, as an isolated finding, it has been associated with fetal-growth restriction and perinatal death in some but not all studies (Chetty-John, 2010; Ebbing, 2019; Voskamp, 2013). Thus, clinical monitoring of growth is reasonable, but the value of sonographic surveillance is unclear.

In contrast, a fused umbilical artery with a shared lumen is rare. It arises from failure of the two arteries to split during embryological development. The common lumen may extend through the entire cord, but, if partial, it is typically found near the placental insertion site (Yamada, 2005). In one report, these malformations were associated with a higher incidence of marginal or velamentous cord insertion but not of congenital fetal anomalies (Fujikura, 2003).

Found in most placentas, the *Hyrtl anastomosis* is a connection between the two umbilical arteries, and it lies near the cord's insertion into the placenta. This anastomosis acts physiologically to equalize pressures between the arteries (Gordon, 2007). The resulting redistribution of pressure gradients and blood flow improves placental perfusion, especially during uterine contractions or during compression of one umbilical artery. Fetuses with an SUA lack this safety valve (Raio, 1999, 2001).

Remnants and Cysts

Several structures are housed in the umbilical cord during fetal development, and their remnants may be seen when the mature cord is inspected transversely. Indeed, in grossly sectioned cords, remnants of the allantoic duct, vitelline duct, and embryonic vessels are found in 25 to 50 percent (Grottling, 2019; Jauniaux, 1989). These are not associated with congenital malformations or perinatal complications.

Cysts occasionally are found along the course of the cord. They are designated according to their origin. *True cysts* are epithelium-lined remnants of the allantoic or vitelline ducts and tend to be located closer to the fetal insertion site. In contrast, the more common *pseudocysts* form from local degeneration of Wharton jelly and occur anywhere along the cord. Both have a similar sonographic appearance. Single umbilical cord cysts identified in the first trimester tend to resolve completely, however, multiple cysts may portend miscarriage or aneuploidy (Ghezzi, 2003; Hannaford, 2013). Cysts persisting beyond this time are associated with a risk for structural defects and chromosomal anomalies (Bonilla, 2010; Zangen, 2010).

Insertion

The cord normally inserts centrally into the placental disc, but eccentric, marginal, or velamentous insertions are variants. Of these, eccentric insertions in general pose no identifiable fetal risk. Marginal insertion is a common variant—sometimes referred to as a *battledore placenta*—in which the cord anchors at the placental margin. In one population-based study, the rate was 6 percent in singleton gestations and 11 percent in twins (Ebbing, 2013). This common insertion variant rarely causes problems, but it and velamentous insertion occasionally result in the cord being pulled off during delivery of the placenta (Ebbing, 2015; Luo, 2013). In monochorionic twins, marginal insertion may be associated with weight discordance (Kent, 2011).

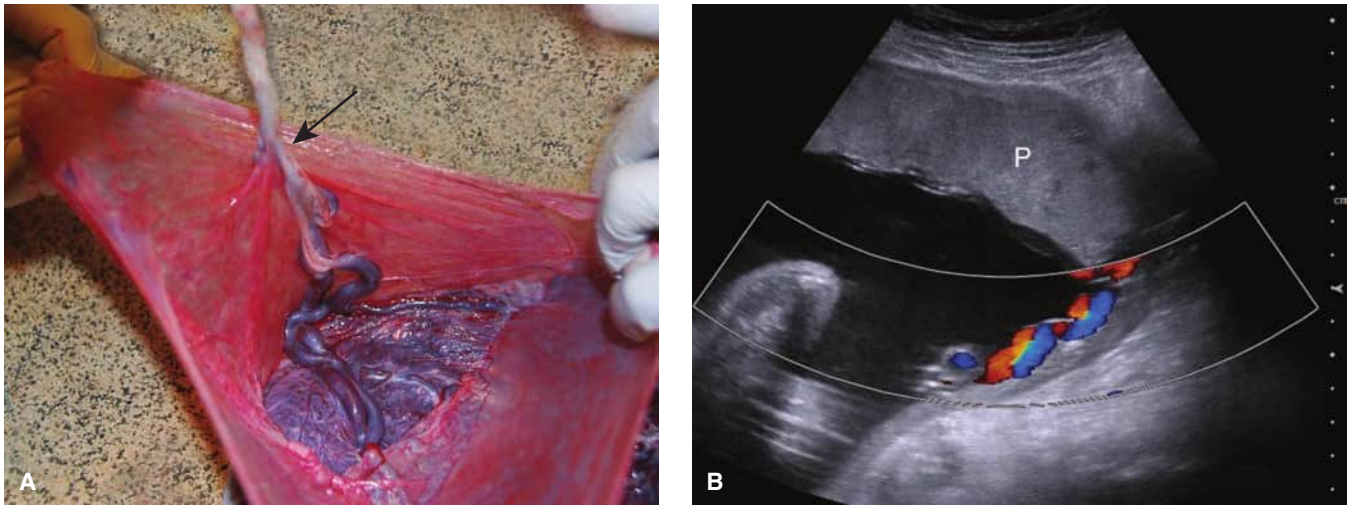

FIGURE 6-6 Velamentous cord insertion. **A.** The umbilical cord inserts into the membranes (*arrow*). From here, the cord vessels branch and are supported only by membrane until they reach the placental disc. **B.** When viewed sonographically and using color Doppler, the cord vessels appear to lie against the myometrium as they travel to insert into the margin of the placental disc (*P*).

With velamentous insertion, the umbilical vessels characteristically travel within the membranes before reaching the placental margin (Fig. 6-6). The incidence of velamentous insertion approximates 1 percent but is 6 percent with twins (Ebbing, 2013). It is more commonly seen with placenta previa (Papinniemi, 2007; Räisänen, 2012). Antenatal diagnosis is possible sonographically, and cord vessels are seen traveling along the uterine wall before entering the placental disc. Clinically, vessels are vulnerable to compression, which may lead to fetal hypoperfusion and acidemia. Higher associated rates of low Apgar scores, stillbirth, preterm delivery, and small for gestational age have been noted (de Los Reyes, 2018; Ebbing, 2017; Esakoff, 2015; Vahanian, 2015). Accordingly, monitoring of fetal growth is reasonable either clinically or sonographically (Vintzileos, 2015).

Last, with the rare furcate insertion, umbilical vessels lose their protective Wharton jelly shortly before they insert. As a result, they are covered only by an amnion sheath and prone to compression, twisting, and thrombosis.

Vasa Previa

With this condition, vessels travel within the membranes and overlie the cervical os. There, they can be torn with cervical dilation or membrane rupture, and laceration can lead to rapid fetal exsanguination. Over the cervix, vessels can also be compressed by a presenting fetal part (Matsuzaki, 2019). Vasa previa may be more common than previously estimated, and rates are 1 case in 338 to 365 pregnancies (Hasegawa, 2012; Klahr, 2019). Vasa previa is classified as type 1, in which vessels are part of a velamentous cord insertion, and type 2, in which involved vessels span between portions of a bilobate or a succenturiate placenta (Catanzarite, 2001). Two other risks are conception with in vitro fertilization and second-trimester placenta previa, with or without later migration (Baulies, 2007; Schachter, 2003).

Compared with intrapartum diagnosis, antepartum diagnosis greatly improves the perinatal survival rate, which ranges from 97 to 100 percent (Oyelese, 2004; Swank, 2016; Zhang, 2021). Thus, vasa previa is ideally identified early, although this is not always possible. Effective screening for vasa previa begins during scheduled midtrimester sonographic examination. In suspicious cases, transvaginal sonography is added and shows cord vessels inserting into the membranes and vessels running above the cervical internal os (Fig. 6-7). Routine color Doppler interrogation of the placental cord insertion site, particularly in cases of placenta previa or low-lying placenta, may aid its detection. With this, the vessel waveform reflects the fetal heart rate. In one systematic review, the median prenatal detection rate was 93 percent (Ruiter, 2015).

Once vasa previa is identified, subsequent imaging is reasonable because up to 39 percent of cases ultimately resolve (Erfani, 2019; Klahr, 2019). Bed rest apparently has no added advantage. Antenatal corticosteroids can be provided as indicated or given prophylactically at 28 to 32 weeks' gestation to cover possible urgent preterm delivery. Antenatal hospitalization may be considered at 30 to 34 weeks to permit surveillance and expedited delivery for labor, bleeding, or rupture of membranes. Data supporting this are limited, and admission may best serve women with risk factors that portend early delivery (Society for Maternal-Fetal Medicine, 2015). A few cases of antepartum fetoscopic surgery with vessel laser ablation are described (Hosseinzadeh, 2015; Johnston, 2014). However, current practice is early scheduled cesarean delivery. The American College of Obstetricians and Gynecologists (2021) recommends cesarean delivery at 34 to 36 weeks' gestation.

At delivery, the fetus is expeditiously delivered after the hysterotomy incision in case a vessel is lacerated during uterine entry. Delayed cord clamping is not encouraged.

In all pregnancies, otherwise unexplained vaginal bleeding either antepartum or intrapartum should prompt consideration of vasa previa and a lacerated fetal vessel. In many cases, bleeding is rapidly fatal, and neonatal salvage is not possible. With less hemorrhage, however, it may be possible to distinguish fetal versus maternal bleeding. Various tests can be used, and

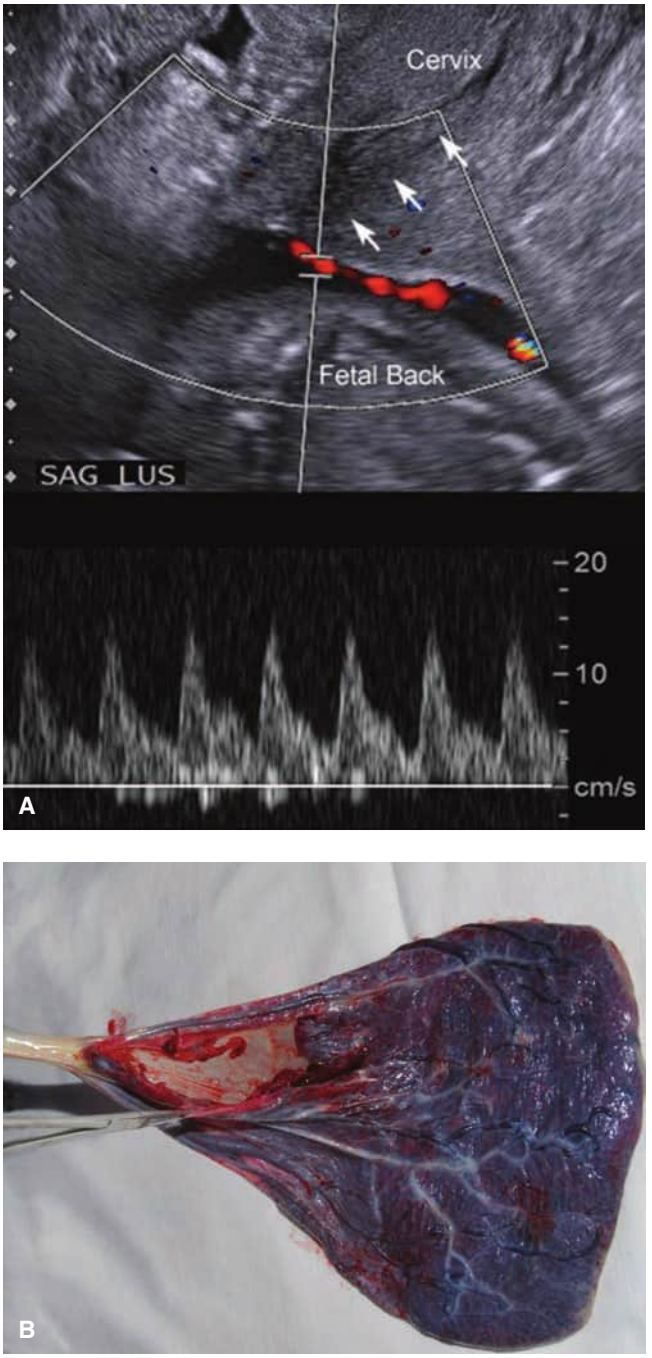

FIGURE 6-7 Vasa previa. **A.** Using color Doppler, an umbilical vessel (*red linear structure*) is seen overlying the internal os and cervical canal (*arrows*). At the bottom, the Doppler waveform seen with this vasa previa has the typical appearance of an umbilical artery. **B.** The amniotomy site (*held open by hemostat*), which was created at the time of cesarean hysterotomy, illustrates how fetal vessels may be lacerated and why fetal delivery should be prompt (Reproduced with permission from Dr. Julie Lo.)

each relies on the increased resistance of fetal hemoglobin to denaturing by alkaline or acid reagents (Odunsi, 1996).

Knots, Strictures, and Loops

Various mechanical abnormalities in the cord can impede blood flow and sometimes cause fetal harm. Of these, *true knots* are found in approximately 1 percent of births. These form from fetal movement, and associated risks include hydramnios and diabetes mellitus (Hershkovitz, 2001; Räisänen, 2013). Knots are especially common and dangerous in monoamnionic twins, which are discussed in Chapter 48 (p. 845). In singleton fetuses, the stillbirth risk is increased four- to tenfold compared with those without knots (Airas, 2002; Sørnes, 2000).

Knots can be found incidentally during antepartum sonography, and a "hanging noose" sign is suggestive (Ramon y Cajal, 2006). Three-dimensional and color Doppler aid diagnostic accuracy (Hasbun, 2007). With these knots, optimal fetal surveillance is unclear but may include umbilical artery Doppler velocimetry, nonstress testing, or subjective fetal movement monitoring (Rodriguez, 2012). Allowing vaginal delivery is suitable, and intrapartum fetal heart rate tracings do not differ from unaffected pregnancies (Carter, 2018). In these cases, cesarean delivery rates are not increased and cord blood acid-base values are usually normal (Airas, 2002; Maher, 1996).

In contrast, *false knots* form from focal redundancy and folding of an umbilical cord vessel rather than knotting. These lack clinical significance.

A cord stricture is a focal narrowing of the diameter that usually develops near the fetal cord insertion site (Peng, 2006). Pathological features typically include absent Wharton jelly at the narrowed segment and obliteration of cord vessels (Sun, 1995). In most instances, the fetus is stillborn (French, 2005). Even less common is a cord stricture caused by an amnionic band.

Cord loops are frequently encountered and are caused by coiling around various fetal parts during movement. A cord around the neck—a *nuchal cord*—is common, and vaginal delivery is suitable. One loop is reported in 20 to 34 percent of deliveries; two loops in 2.5 to 5 percent; and three loops in 0.2 to 0.5 percent (Kan, 1957; Sørnes, 1995; Spellacy, 1966). During labor, up to 20 percent of fetuses with a nuchal cord have moderate to severe variable heart rate decelerations, and these are associated with a lower umbilical artery pH (Hankins, 1987). Decelerations are not relieved by amnioinfusion (Spong, 1996). Cords wrapped around the body can have similar effects (Kobayashi, 2015). Despite their frequency, nuchal cords are not associated with greater rates of adverse perinatal outcome (Henry, 2013; Masad, 2019).

Last, in a *funic presentation,* the umbilical cord is the presenting part. These are uncommon and most often are associated with fetal malpresentation (Kinugasa, 2007). A funic presentation in some cases is identified with placental sonography and color flow Doppler (Ezra, 2003). Overt or occult cord prolapse can complicate labor. Thus, once identified at term, cesarean delivery is typically recommended.

Vascular

Cord hematomas are rare and generally follow rupture of an umbilical vessel, usually the vein, and hemorrhage into the Wharton jelly. Hematomas have been associated with abnormal cord length, umbilical vessel aneurysm, trauma, entanglement, umbilical vessel venipuncture, and funisitis (Gualandri, 2008). Most are identified postpartum, but hematomas are recognized

sonographically as hypoechoic masses that lack blood flow (Chou, 2003). Sequelae include stillbirth or intrapartum abnormal fetal heart rate pattern (Abraham, 2015; Barbati, 2009; Sepulveda, 2005; Towers, 2009). However, case reports have described normal outcomes (Sanchex-Codez, 2018).

Umbilical cord vessel thromboses are rare in utero events and seldom diagnosed antepartum. Approximately 70 percent are venous, 20 percent are venous and arterial, and 10 percent are arterial thromboses (Heifetz, 1988). These all have high associated rates of stillbirth, fetal-growth restriction, and intrapartum fetal distress (Minakami, 2001; Sato, 2006; Shilling, 2014). If these are identified antepartum as hypoechoic masses without blood flow, data from case reports support consideration of prompt delivery of viable-aged fetuses (Kanenishi, 2013).

An *umbilical vein varix* can complicate either the intraamnionic or fetal intraabdominal portion of the umbilical vein. Sonographically and complemented by color Doppler, rare intraamnionic varices show cystic dilation of the umbilical vein that is contiguous with a normal-caliber portion. Of complications, an intraamnionic varix may compress an adjacent umbilical artery or can rupture or thrombose. A systematic review of 250 cases found that approximately one fifth is associated with other anomalies. Isolated cases had reassuring outcomes but typically required antenatal surveillance (di Pasquo, 2018).

The rare *umbilical artery aneurysm* is caused by congenital thinning of the vessel wall with diminished support from Wharton jelly. Indeed, most form at or near the cord's placental insertion site, where this support is absent. These are associated with SUA, trisomy 18, amnionic fluid volume extremes, fetal-growth restriction, and stillbirth (Hill, 2010; Vyas, 2016). At least theoretically, these aneurysms could cause fetal compromise and death by compression of the umbilical vein. With aneurysms measuring >5 cm, the blood reservoir within the aneurysm may pose a risk for high-output heart failure (Matsuki, 2017). These aneurysms may appear sonographically as a cyst with a hyperechoic rim. Within the aneurysm, color flow and spectral Doppler interrogation demonstrate either low-velocity or turbulent nonpulsatile flow (Olog, 2011; Shen, 2007b). Although not codified, management may include fetal karyotyping, antenatal fetal surveillance, and early delivery to prevent stillbirth (Doehrman, 2014). Some recommend delivery by cesarean to avoid aneurysm rupture.

CHAPTER 7

Embryogenesis and Fetal Development

Contemporary obstetrics incorporates physiology and pathophysiology of the fetus, and its development and environment. As a result, the fetus is considered a patient and is given the same meticulous care provided for the mother. Section 6 is dedicated to the fetal patient, however, virtually every aspect of obstetrics can affect the developing fetus.

GESTATIONAL AGE

Several terms define pregnancy duration and thus fetal age (Fig. 7-1). *Gestational age* or *menstrual age* is the time elapsed since the first day of the last menstrual period (LMP), a time that actually precedes conception. This starting time, which is usually approximately 2 weeks before ovulation and fertilization and nearly 3 weeks before blastocyst implantation, has traditionally been used. Embryologists describe embryofetal development in *ovulation age*, or the time in days or weeks from ovulation. Another term is *postconceptional age,* which is nearly identical to ovulation age.

Until recently, clinicians customarily calculated menstrual age, and with this, term pregnancy averages 280 days or 40 weeks between the first day of the LMP and birth. This corresponds to 9 and 1/3 calendar months. However, menstrual cycle length variability among women renders many of these calculations inaccurate. This realization, combined with the frequent use of first-trimester sonography, has led to more accurate gestational age determination (Duryea, 2015). Much of this change stems from the accuracy of early sonographic measurement. As a result, the American College of Obstetricians and Gynecologists, the American Institute of Ultrasound in Medicine, and the Society for Maternal-Fetal Medicine (2019) together recommend the following:

1. First-trimester sonography is the most accurate method to establish or reaffirm gestational age.
2. In conceptions achieved with in vitro fertilization (IVF), the embryo age and egg transfer date are used.
3. If available, the gestational ages calculated from the LMP and from first-trimester sonography are compared, and the estimated date of confinement (EDC) is recorded and discussed with the patient.
4. The best obstetrical estimate of gestational age at delivery is recorded on the birth certificate.

The embryofetal crown-rump length in the first trimester is accurate ± 5 to 7 days. Thus, if sonographic gestational

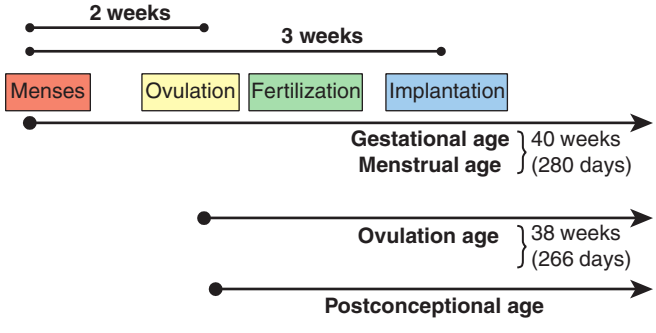

FIGURE 7-1 Terminology used to describe pregnancy duration.

age differs by more than 5 days prior to 9 weeks' gestation, or by more than 7 days later in the first trimester, the EDC is changed. These and discrepant values in the second and third trimester are discussed further in Chapter 14 (p. 248).

Naegele Rule

An EDC based on the LMP can be quickly estimated as follows: add 7 days to the first day of the LMP and subtract 3 months. For example, if the first day of the LMP was October 5, the due date is 10–05 minus 3 (months) plus 7 (days) = 7–12, or July 12 of the following year. This calculation has been termed the *Naegele rule*. The period of gestation can also be divided into three units of approximately 14 weeks each. These three *trimesters* are important obstetrical milestones.

In addition to estimating the EDC with either Naegele rule or "pregnancy wheels," calculator tools in the electronic medical record and smartphone applications can provide a calculated EDC and gestational age. For example, the American College of Obstetricians and Gynecologists (2020) has developed a calculator application that incorporates sonographic criteria and the LMP or embryo transfer date (Chap. 14, p. 248).

EMBRYONIC DEVELOPMENT

The complexity of embryofetal development is immense. Figure 7-2 shows a developmental sequence of various organ systems. New information regarding organ development continues to accrue. For example, imaging techniques help to unravel the contributions of gene regulation and tissue interaction to eventual three-dimensional organ morphology (Anderson, 2016). Others have described the sequence of gene activation that underlies cardiac development (p. 126).

Zygote and Blastocyst Development

During the first 2 weeks after ovulation and then fertilization, the zygote—or preembryo—progresses to the blastocyst stage. The blastocyst implants 6 or 7 days following fertilization. The 58-cell blastocyst differentiates into five cells—*the inner cell mass*, which develops into the embryo. The remaining 53 cells form placental trophoblast. Details of implantation and early development of the blastocyst and placenta are described in Chapter 5 (p. 86).

Embryonic Period

The conceptus is termed an embryo at the beginning of the third week after ovulation and fertilization. Primitive chorionic villi form, and this coincides with the expected day of menses. The embryonic period, during which time organogenesis takes place, lasts 6 weeks. It begins the third week from the LMP and continues through the eighth week. The embryonic disc is well defined, and most pregnancy tests that measure human

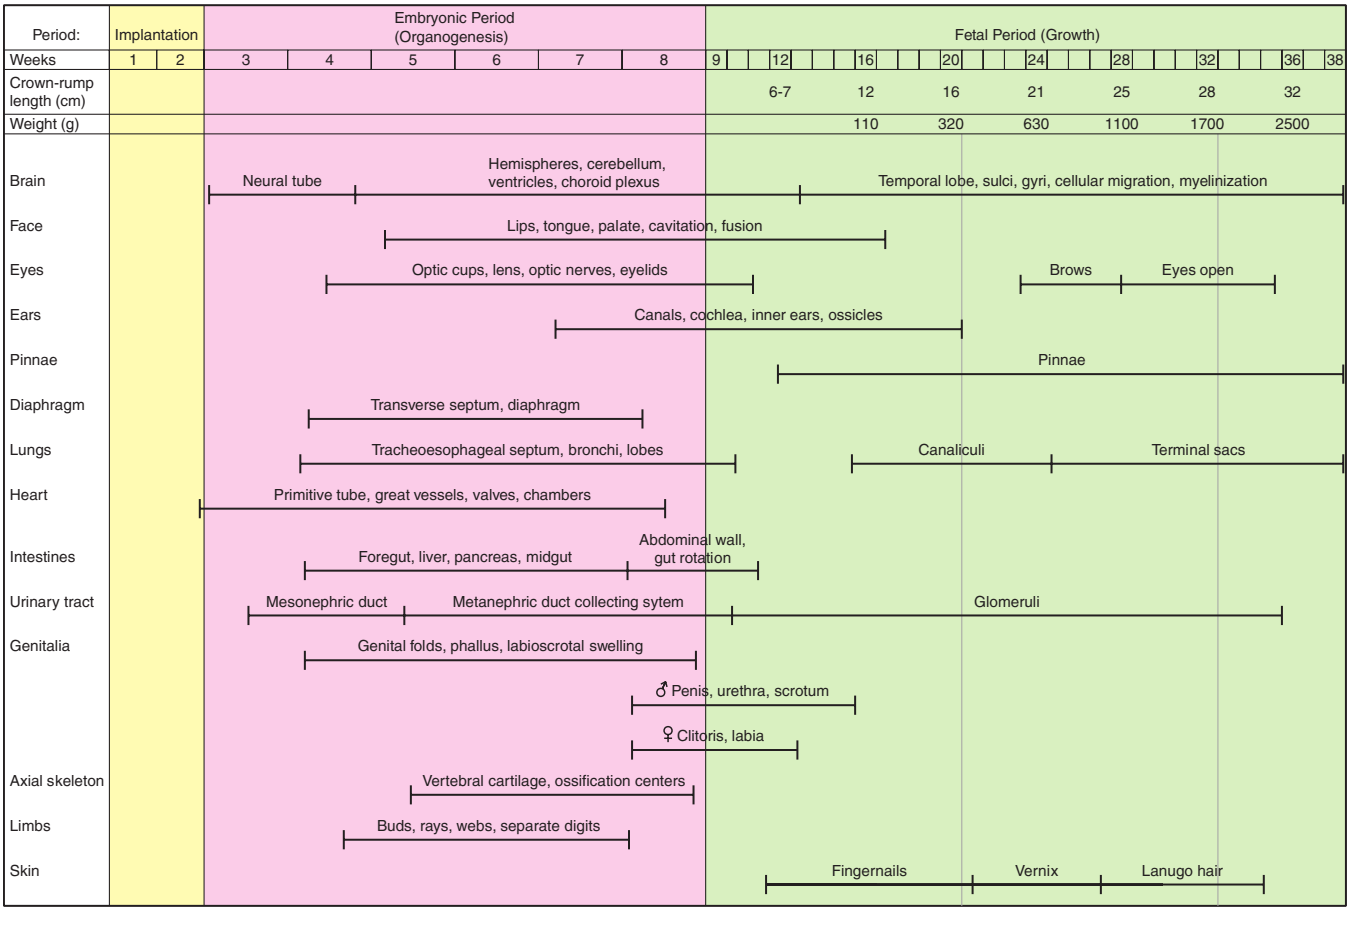

FIGURE 7-2 Embryofetal development according to gestational age determined by the first day of the last menses. Times are approximate.

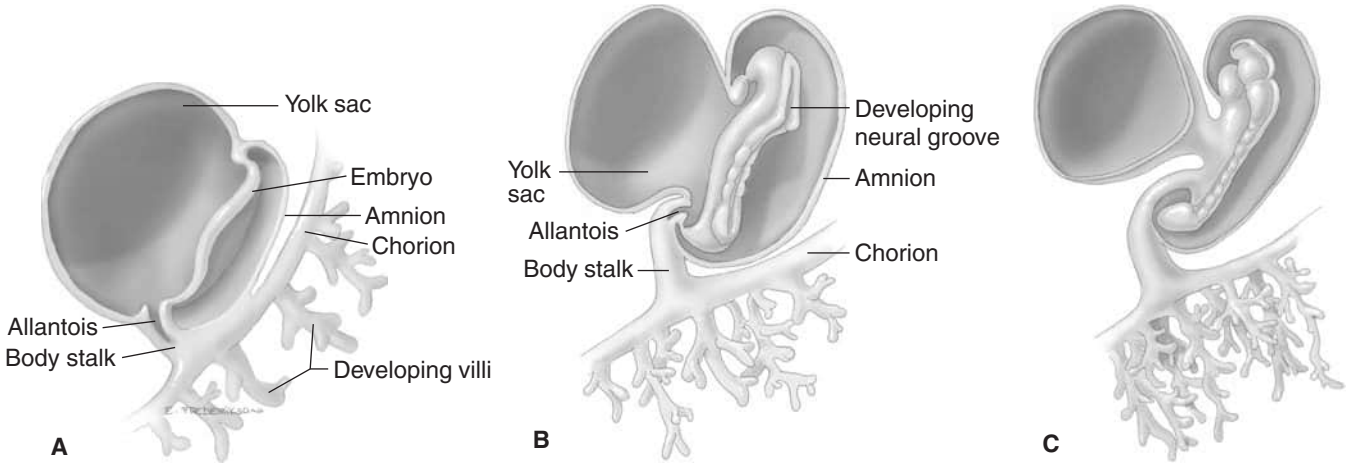

FIGURE 7-3 Early human embryos. Ovulation ages: **A.** 19 days (presomite). **B.** 21 days (7 somites). **C.** 22 days (17 somites). (After drawings and models in the Carnegie Institute.)

chorionic gonadotropin (hCG) become positive by this time. As shown in Figure 7-3, the body stalk is now differentiated. There are villous cores in which angioblastic chorionic mesoderm can be distinguished and a true intervillous space that contains maternal blood.

During the third week, fetal blood vessels in the chorionic villi appear. In the fourth week, a cardiovascular system has formed (Fig. 7-4) (Moore, 2008). Thereby, a true circulation is established both within the embryo and between the embryo and the chorionic villi. Partitioning of the primitive heart begins. Also in the fourth week, the neural plate forms, and it subsequently folds to form the neural tube. By the end of the fifth menstrual week, the chorionic sac measures approximately 1 cm in diameter. The embryo is 3 mm long and can be

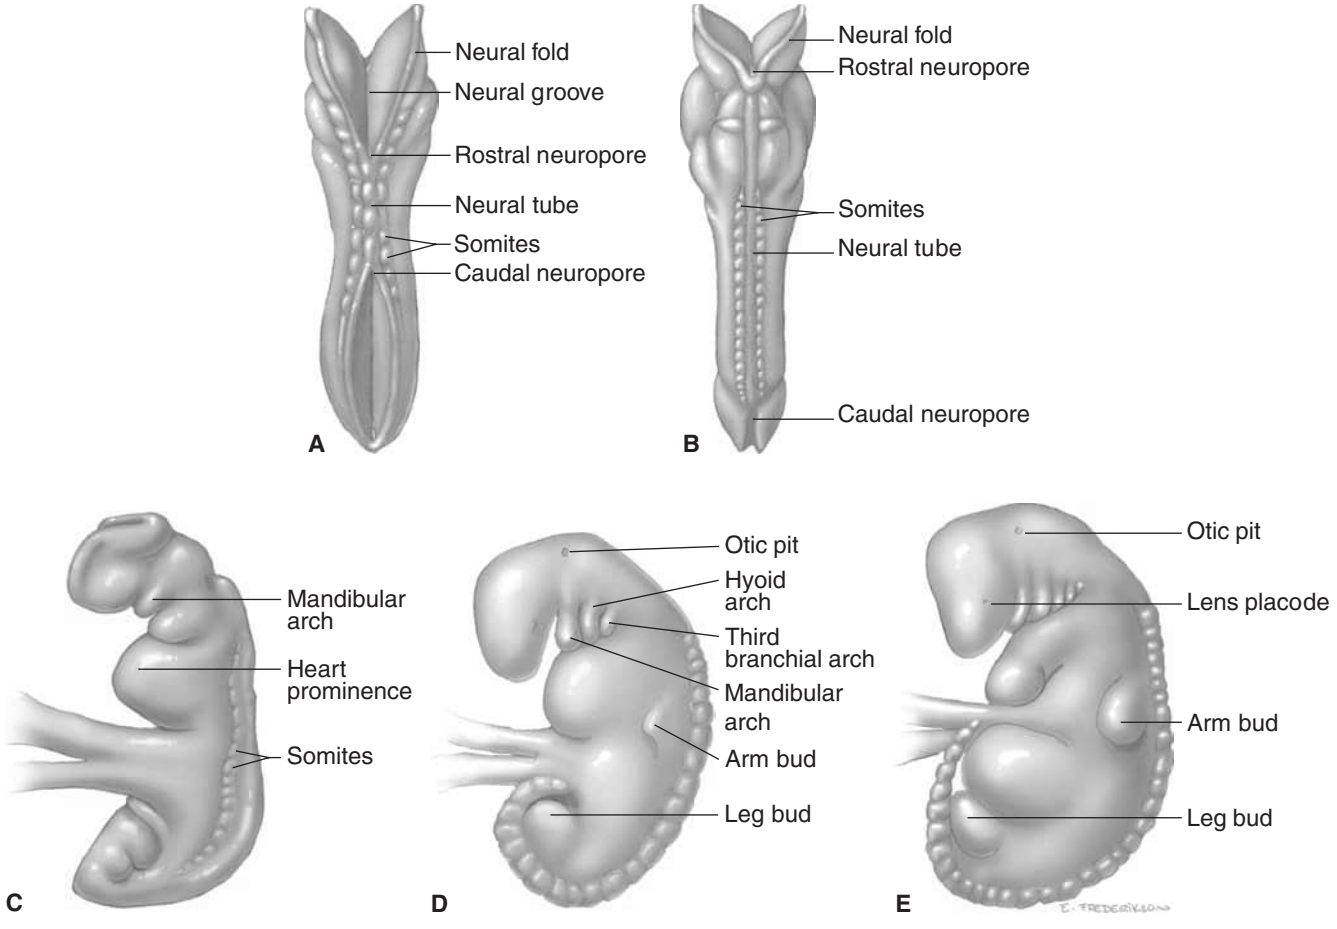

FIGURE 7-4 Three- to four-week-old embryos. **A, B.** Dorsal views of embryos during 22 to 23 days of development showing 8 and 12 somites, respectively. **C–E.** Lateral views of embryos during 24 to 28 days, showing 16, 27, and 33 somites, respectively.

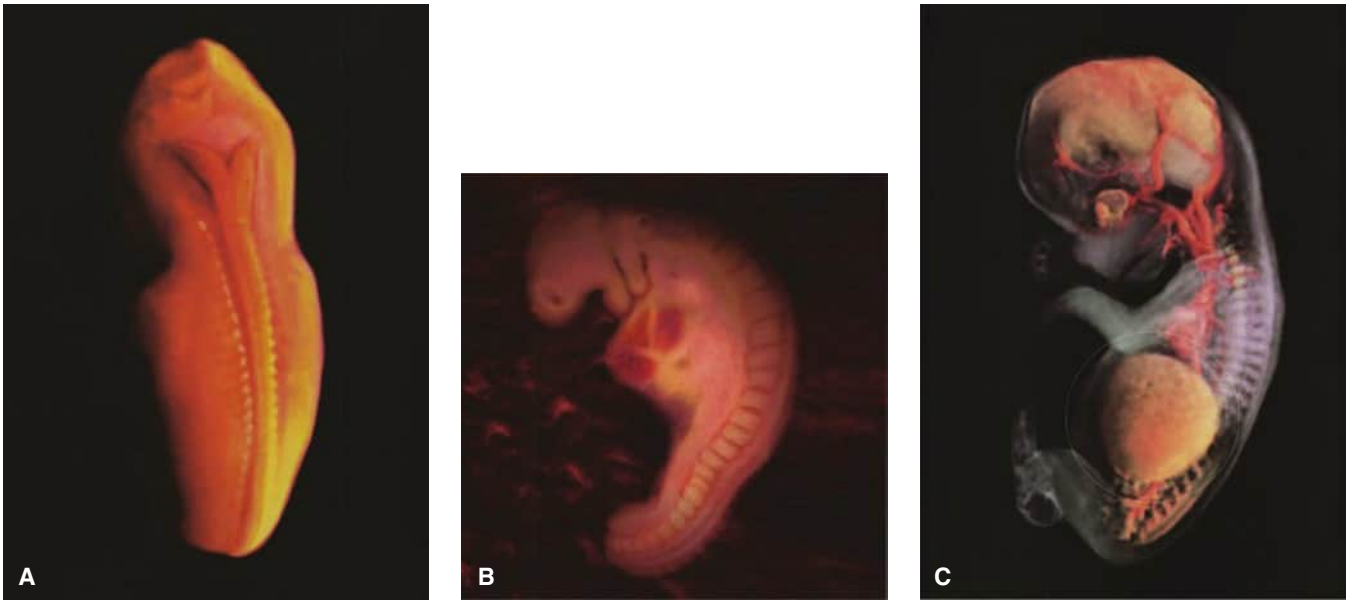

FIGURE 7-5 Embryo photographs. **A.** Dorsal view of an embryo at 24 to 26 days and corresponding to Figure 7-4C. **B.** Lateral view of an embryo at 28 days and corresponding to Figure 7-4D. **C.** Lateral view of embryofetus at 56 days, which marks the end of the embryonic period and the beginning of the fetal period. The liver is within the white, halo circle. (From Werth B, Tsiaras A: From Conception to Birth: A Life Unfolds. New York, Doubleday, 2002.)

measured sonographically. Arm and leg buds have developed, and the amnion is beginning to ensheathe the body stalk, which thereafter becomes the umbilical cord. At the end of the sixth week, the embryo is approximately 9 mm long, and the neural tube has closed (Fig. 7-5). Cardiac motion is almost always discernable sonographically (Fig. 7-6).

The cranial end of the neural tube closes by 38 days from the LMP, and the caudal end closes by 40 days. Thus, the neural tube has closed by the end of the sixth week. And by the end of the eighth week, the crown-rump length approximates 22 mm. Fingers and toes are present, and the arms bend at the elbows. The upper lip is complete, and the external ears form definitive elevations on either side of the head. Three-dimensional images and videos of human embryos from the Multi-Dimensional Human Embryo project can be seen at: embryo.soad.umich.edu/.

FETAL DEVELOPMENT AND PHYSIOLOGY

Fetal Period Epochs

The transition from embryonic to fetal periods occurs at 7 weeks after fertilization, corresponding to 9 weeks after the LMP. At this time, the fetus approximates 24 mm in length, most organ systems have developed, and the fetus enters a period of growth and maturation. These phases are outlined in Figure 7-2.

FIGURE 7-6 **A.** This image of an 8-week, 3-day embryo depicts measurement of the crown-rump length, which is 1.93 cm at this gestational age. **B.** Despite the early gestational age, M-mode imaging readily demonstrates embryonic cardiac activity. The heart rate in this image is 161 beats per minute.

FIGURE 7-7 This image of a 12-week, 2-day embryo depicts measurement of the crown-rump length. The fetal profile, cranium, and a hand and foot also are visible in this image.

12 Gestational Weeks

The uterus usually is just palpable above the symphysis pubis. Fetal growth is rapid, and the fetal crown-rump length is 5 to 6 cm (Fig. 7-7). Centers of ossification have appeared in most fetal bones, and the fingers and toes have become differentiated. Skin and nails develop, and scattered rudiments of hair appear. The external genitalia are beginning to show definitive signs of male or female gender. The fetus begins to make spontaneous movements.

16 Gestational Weeks

Fetal growth slows at this time. The crown-rump length is 12 cm, and the fetal weight approximates 150 g. Clinically, the sonographic crown-rump length is not measured beyond 13 weeks, which corresponds to approximately 8.4 cm. Instead, biparietal diameter, head circumference, abdominal circumference, and femur length are measured. Fetal weight in the second and third trimesters is estimated from a combination of these measurements (Chap. 14, p. 248).

Eye movements begin at 16 to 18 weeks, coinciding with midbrain maturation. By 18 weeks in the female fetus, the uterus is formed and vaginal canalization begins. By 20 weeks in the male, testicles start to descend.

20 Gestational Weeks

This is the midpoint of pregnancy as estimated from the LMP. The fetus now weighs somewhat more than 300 g, and weight increases substantially in a linear manner. From this point onward, the fetus moves approximately every minute and is active 10 to 30 percent of the day (DiPietro, 2005). Brown fat forms, and the fetal skin becomes less transparent. Downy lanugo covers its entire body, and some scalp hair can be seen. Cochlear function develops between 22 and 25 weeks, and this maturation continues for 6 months after delivery.

24 Gestational Weeks

The fetus now weighs almost 700 g. The skin is characteristically wrinkled, and fat deposition begins. The head is still comparatively large, and eyebrows and eyelashes are usually recognizable. By 24 weeks, the secretory type II pneumocytes have initiated surfactant secretion (Chap. 32, p. 587). The canalicular period of lung development, during which the bronchi and bronchioles enlarge and alveolar ducts develop, is nearly completed. Despite this, a fetus born at this time will attempt to breathe, but many will die because the terminal sacs, required for gas exchange, have not yet formed. Although dependent on racial and ethnic factors, and as discussed in Chapter 45 (p. 785), the overall survival rate at 24 weeks barely exceeds 50 percent (Janevic, 2018). By 26 weeks, the eyes open. Nociceptors are present over all the body, and the neural pain system is developed (Kadic, 2012). The fetal liver and spleen are important early sites for hemopoiesis (Fanni, 2018).

28 Gestational Weeks

The crown-rump length approximates 25 cm, and the fetus weighs about 1100 g. The thin skin is red and covered with vernix caseosa. The pupillary membrane has just disappeared from the eyes. Isolated eye blinking peaks at 28 weeks. The bone marrow now becomes the major site of hemopoiesis. The otherwise normal neonate born at this age has a 90-percent chance of survival without physical or neurological impairment.

32 and 36 Gestational Weeks

At 32 weeks, the fetus has attained a crown-rump length approximating 28 cm and a weight of about 1800 g. The skin surface is still red and wrinkled. In contrast, by 36 weeks, the fetal crown-rump length averages about 32 cm, and the weight approximates 2800 g (Duryea, 2014). Because of subcutaneous fat deposition, the body is more rotund, and the previous wrinkled facies are now fuller. Normal fetuses have a nearly 100-percent survival rate.

40 Gestational Weeks

This is considered term, and the fetus is fully developed. The average crown-rump length measures about 36 cm, and the average weight approximates 3500 g.

■ Central Nervous System Development

Brain Development

The cranial end of the neural tube closes by 38 days from the last menstrual period, and the caudal end closes by 40 days. Hence, folic acid supplementation to prevent neural-tube defects must be in place before this point to be efficacious (Chap. 9, p. 168). The walls of the neural tube form the brain and spinal cord. The lumen becomes the ventricular system of the brain and the central canal of the spinal cord. During the sixth week, the cranial end of the neural tube forms three primary vesicles. In the seventh week, five secondary vesicles develop: the telencephalon—future cerebral hemispheres; diencephalon—thalami; mesencephalon—midbrain; metencephalon—pons and cerebellum; and myelencephalon—medulla. This is, in part, controlled by *Hox* genes, and defects result in abnormal signaling that leads to neuropathic anomalies (Arendt, 2018). Meanwhile, flexures develop and fold the brain into its typical

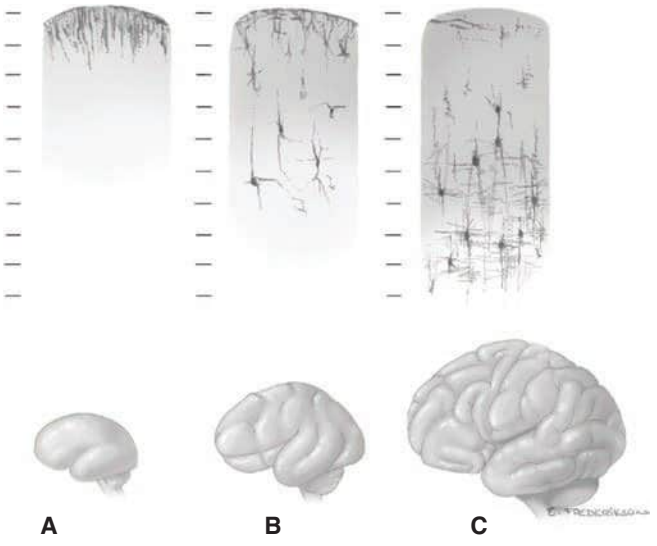

FIGURE 7-8 Neuronal proliferation and migration are complete at 20 to 24 weeks. During the second half of gestation, organizational events proceed with gyral formation and proliferation, differentiation, and migration of cellular elements. Approximate gestational ages are shown. **A.** 20 weeks. **B.** 35 weeks. **C.** 40 weeks.

configuration. The end of the embryonic period signifies completion of primary and secondary neutralization.

At 3 to 4 months' gestation, *neuronal proliferation* peaks. As expected, disorders in this cerebral development phase profoundly worsen function (Ortega, 2017; Volpe, 2018). One example is Zika virus infection (Rothan, 2019). *Neuronal migration* occurs almost simultaneously and peaks at 3 to 5 months. This process is characterized by movement of millions of neuronal cells from their ventricular and subventricular zones to areas of the brain in which they reside for life (Fig. 7-8). Upregulation of gene expression for neuronal migration has been described (Di Donato, 2017). Noninvasive methods to study fetal neurodevelopment also have been reported (Goetzl, 2016; Wang, 2015).

As gestation progresses, the fetal brain appearance steadily changes. Thus, it is possible to identify fetal age from its external appearance (Volpe, 2018). Neuronal proliferation and migration proceed along with gyral growth and maturation (see Fig. 7-8). Sequential maturation studies using magnetic resonance (MR) imaging have characterized the developing fetal brain (Dubois, 2014; Meng, 2012; Wang, 2015).

Myelination of the ventral roots of the cerebrospinal nerves and brainstem begins at approximately 6 months, but most myelination progresses after birth. This lack of myelin and incomplete skull ossification permit fetal brain structure to be seen sonographically throughout gestation.

Spinal Cord

Whereas the superior two thirds of the neural tube give rise to the brain, the inferior third forms the spinal cord. In the embryo, the spinal cord extends along the entire vertebral column length, but after that it lags behind vertebral growth. Ossification of the entire sacrum is visible sonographically by approximately 21 weeks (Chap. 15, p. 276). By 24 weeks, the spinal cord extends to S_1, at birth to L_3, and in the adult to L_1. Spinal cord myelination begins at midgestation and continues through the first year of life. Synaptic function is sufficiently developed by the eighth week to demonstrate flexion of the neck and trunk. During the third trimester, integration of nervous and muscular function proceeds rapidly (Molina, 2017).

Cardiovascular System

The embryology of the heart is highly complex. At its earliest stages of formation, the fetal heart undergoes molecular programming, and more than a hundred genes and molecular factors are integral to its morphogenesis (Kathiriya, 2015; Moore, 2020). These molecular factors include the *hypoxia-inducible factor—HIF* and *homeobox (HOX)*—family.

To summarize its embryology, the straight cardiac tube is formed by the 23rd day during an intricate morphogenetic sequence, during which each segment arises at a unique time. Between 4 and 7 weeks the heart undergoes extensive growth and morphological modification, leading to the formation of a partially septated four-chambered heart with a set of primitive valves (Sylva, 2014). The valves develop, and the aortic arch forms by vasculogenesis. Chapter 8 of Hurst's The Heart has a full description (Torres, 2017). Late in fetal life, coronary angiogenesis vascularizes the myocardium (Lu, 2021).

Fetal Circulation

This unique circulation is substantially different from that of the adult and functions until birth, when it changes dramatically. For example, fetal blood is oxygenated by the placenta and does not need to enter the pulmonary vasculature. Thus, most of the right ventricular output bypasses the lungs. In addition, the fetal heart chambers work in parallel, not in series. This effectively supplies the brain and heart, compared with the rest of the body, with more highly oxygenated blood from the dominant right ventricle.

Oxygen and nutrient materials required for fetal growth and maturation are delivered from the placenta by the single umbilical vein (Fig. 7-9). The vein then divides into the ductus venosus and the portal sinus. The ductus venosus is the major branch of the umbilical vein and traverses the liver to enter the inferior vena cava directly. Because it does not supply oxygen to the intervening tissues, it carries well-oxygenated blood directly to the heart. In contrast, the portal sinus carries blood to the hepatic veins primarily on the left side of the liver, and oxygen is extracted. The relatively deoxygenated blood from the liver then flows back into the inferior vena cava, which also receives more deoxygenated blood returning from the lower body. Blood flowing to the fetal heart from the inferior vena cava, therefore, consists of an admixture of arterial-like blood that passes directly through the ductus venosus and less well-oxygenated blood that returns from most of the veins below the level of the diaphragm. The oxygen content of blood delivered to the heart from the inferior vena cava is thus lower than that leaving the placenta.

Because the ventricles of the fetal heart work in parallel, this allows the right ventricle to account for two thirds of the total cardiac output. Well-oxygenated blood enters the left ventricle,

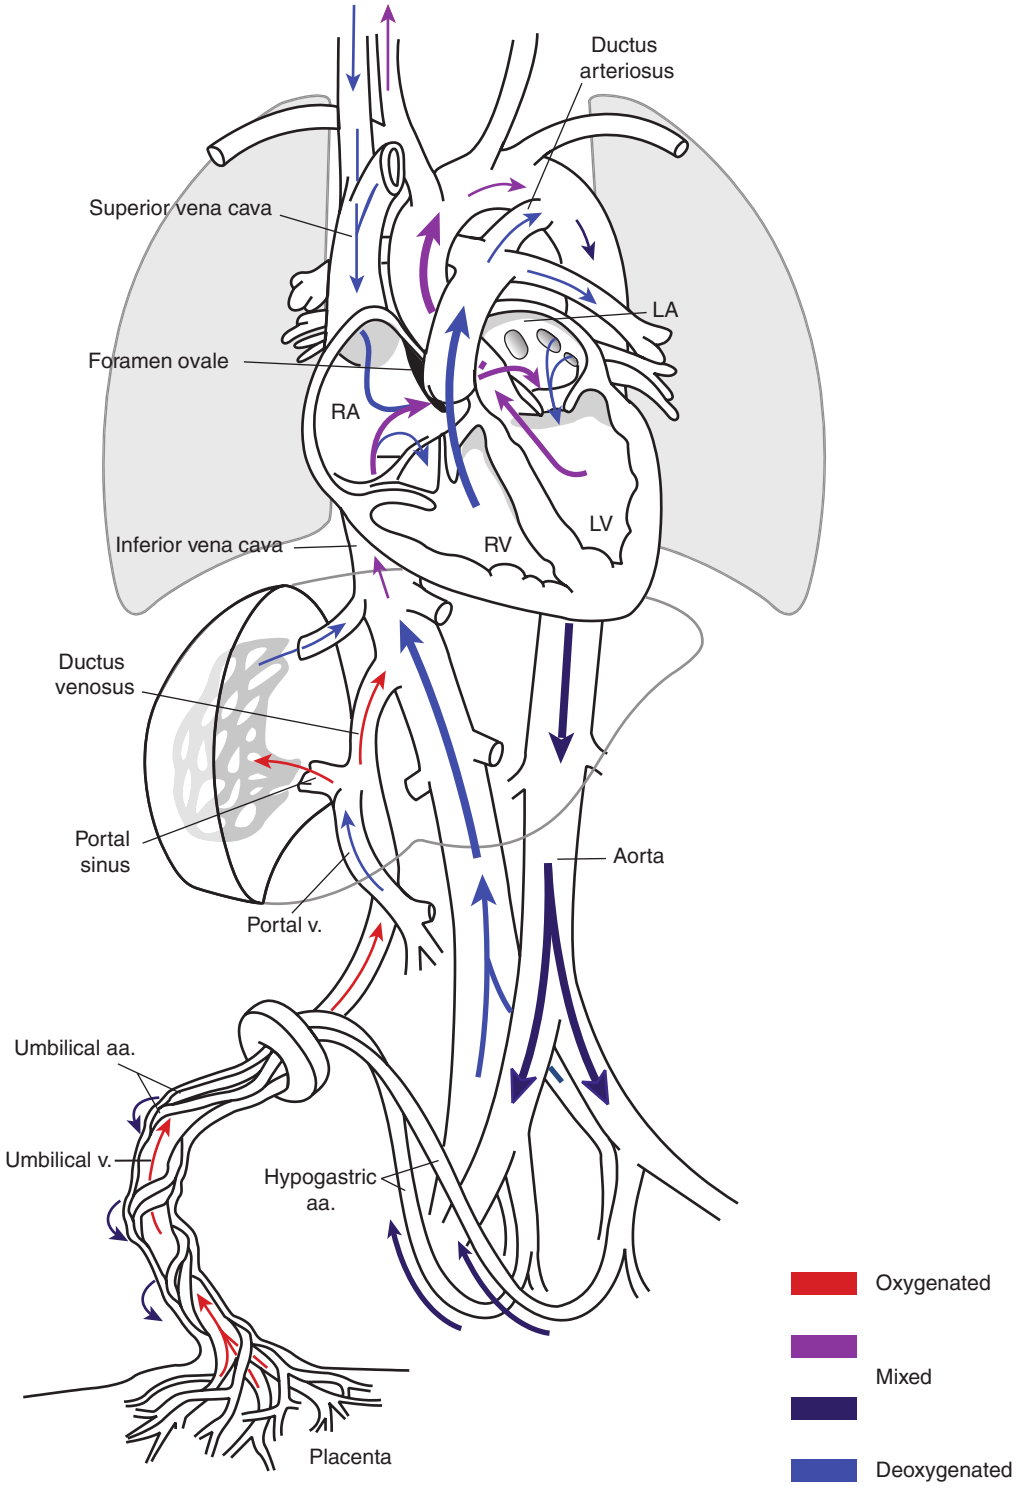

FIGURE 7-9 The intricate nature of the fetal circulation is evident. The degree of blood oxygenation in various vessels differs appreciably from that in the postnatal state. aa = arteries; LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle; v = vein.

which supplies the heart and brain, and less oxygenated blood enters the right ventricle, which supplies the rest of the body. Congenital cardiac defects may contribute to dysregulated brain development or placenta dysfunction (Fantasia, 2018; Lauridsen, 2017).

These two separate circulations are maintained by right-atrium anatomy, which effectively directs entering blood to either the left atrium or the right ventricle, depending on its oxygen content. This separation of blood according to its oxygen content is aided by the pattern of blood flow in the inferior vena cava. The well-oxygenated blood tends to course along the dorsomedial aspect of the inferior vena cava and the less oxygenated blood flows along the lateral vessel wall. This aids their shunting into opposite sides of the heart. Once this blood enters the right atrium, the configuration of the upper interatrial septum—the *crista dividens*—preferentially shunts

the well-oxygenated blood from the medial side of the inferior vena cava through the foramen ovale into the left heart. Here, it is directed to the heart and brain (Dawes, 1962). After these tissues extract needed oxygen, the resulting less oxygenated blood returns to the right atrium through the superior vena cava. Blood flow velocity in the superior vena cava rises from 20 weeks until term (Stefopoulou, 2021).

The less oxygenated blood coursing along the lateral wall of the inferior vena cava enters the right atrium and is deflected through the tricuspid valve to the right ventricle. The superior vena cava courses inferiorly and anteriorly as it enters the right atrium, ensuring that less well-oxygenated blood returning from the brain and upper body also will be shunted directly to the right ventricle. Similarly, the ostium of the coronary sinus lies just superior to the tricuspid valve so that less oxygenated blood from the heart also returns to the right ventricle. As a result of this blood flow pattern, blood in the right ventricle is 15 to 20 percent less saturated with oxygen than blood in the left ventricle.

Almost 90 percent of blood exiting the right ventricle is shunted through the ductus arteriosus to the descending aorta. High pulmonary vascular resistance and comparatively lower resistance in the ductus arteriosus and the umbilical–placental vasculature ensure that only about 8 percent of right ventricular output goes to the lungs (Fineman, 2014). Thus, one third of the blood passing through the ductus arteriosus is delivered to the body. The remaining right ventricular output returns to the placenta through the two hypogastric arteries. These two arteries course from the level of the bladder along the abdominal wall to the umbilical ring and into the cord as the umbilical arteries. In the placenta, this blood picks up oxygen and other nutrients and is recirculated to the umbilical vein.

Circulatory Changes at Birth

After birth, the umbilical vessels, ductus arteriosus, foramen ovale, and ductus venosus normally constrict or collapse. With the functional closure of the ductus arteriosus and the expansion of the lungs, blood leaving the right ventricle preferentially enters the pulmonary vasculature to become oxygenated before it returns to the left heart (Hillman, 2012). Virtually instantaneously, the ventricles, which had worked in parallel in fetal life, now effectively work in series. The more distal portions of the hypogastric arteries undergo atrophy and obliteration within 3 to 4 days after birth. These become the umbilical ligaments, whereas the intraabdominal remnants of the umbilical vein form the ligamentum teres. The ductus venosus constricts by 10 to 96 hours after birth and is anatomically closed by 2 to 3 weeks. This ultimately forms the ligamentum venosum (Fineman, 2014).

Fetoplacental Blood Volume

Although precise measurements of human fetoplacental blood volume are lacking, Usher and associates (1963) reported values in term normal newborns to average 78 mL/kg when immediate cord clamping was conducted. Gruenwald (1967) found that the fetal blood volume contained in the placenta after prompt cord clamping averaged 45 mL/kg of fetal weight. Thus, fetoplacental blood volume at term is approximately 125 mL/kg of fetal weight. This is important when assessing the magnitude of fetomaternal hemorrhage, which is discussed in Chapter 18 (p. 358).

Hemopoiesis

Embryo hemopoiesis begins in the yolk sac and endothelium, followed by the liver, and then spleen and bone marrow (Canu, 2021). Transitions are intricate and involve several genes and protein complexes (Shao, 2018). Both myeloid and erythroid cells are continually produced by progenitors that derive from hemopoietic stem cells (Fanni, 2018; Heinig, 2015). The first erythrocytes released into the fetal circulation are nucleated and macrocytic. The mean cell volume is at least 180 fL in the embryo and decreases to 105 to 115 fL at term. Normal adult volume ranges from 80 to 95 fL. The erythrocytes of aneuploid fetuses generally do not undergo this maturation and maintain high mean cell volumes, which average 130 fL (Sipes, 1991). As fetal development progresses, more and more circulating erythrocytes are smaller and nonnucleated. With fetal growth, both the blood volume in the common fetoplacental circulation and hemoglobin concentration increase. As shown in Table 7-1, fetal hemoglobin concentrations rise across pregnancy. For clinical purposes, the Society for Maternal-Fetal Medicine (2015) recommends a cutoff fetal hematocrit value of 30 percent to define anemia.

Because of their large size, fetal erythrocytes have a short life span, which progressively lengthens to approximately 90 days at term (Pearson, 1966). As a consequence, red blood cell concentrations rise. Reticulocytes are initially present at high levels but decrease to 4 to 5 percent of the total at term. Fetal erythrocytes differ structurally and metabolically from those in the adult (Baron, 2012). They are more deformable, which serves

TABLE 7-1. Fetal Hemoglobin Concentrations Across Pregnancy

to offset their higher volume and viscosity. They also contain several enzymes with appreciably different activities.

Erythropoiesis is controlled primarily by fetal erythropoietin because maternal erythropoietin does not cross the placenta. Fetal hormone production is influenced by testosterone, estrogen, prostaglandins, thyroid hormone, lipoproteins, and importantly, by fetal hypoxia (Teramo, 2018). Serum erythropoietin levels rise with fetal maturity. The fetal liver is an important source until renal production begins near term. The erythropoietin concentration in amnionic fluid correlates closely with that in umbilical venous blood obtained by cordocentesis. After birth, erythropoietin normally may not be detectable for up to 3 months.

In contrast, platelet production reaches stable levels by midpregnancy, although there is some variation across gestation (Fig. 7-10). The fetal and neonatal platelet count is subject to various agents, which are discussed in Chapter 18 (p. 359).

Fetal Hemoglobin

This tetrameric protein is composed of two copies of two different peptide chains, which determine the type of hemoglobin produced (Fig. 7-11). Normal adult hemoglobin A1 is made of α and β chains. During embryonic and fetal life, various α and β chain precursors are produced. This results in the serial production of several different embryonic hemoglobins. At least 17 genetic loci potentially regulate erythropoiesis (Tumburu, 2017). Genes for β-type chains are on chromosome 11, and those for α-type chains on chromosome 16. Each of these genes is turned on and then off during fetal life, until α and β genes, which direct the production of adult hemoglobin A1, are permanently activated.

The timing of production of each of these early hemoglobins corresponds to the site of hemoglobin production. Fetal blood is first produced in the yolk sac, where hemoglobins Gower 1, Gower 2, and Portland are made. Erythropoiesis then moves to the liver, where fetal hemoglobin F is produced. When hemopoiesis finally moves to the bone marrow, adult-type hemoglobin A1 appears in fetal red blood cells and is present in progressively greater amounts as the fetus matures (Lessard, 2018).

The final adult version of the α chain is produced exclusively by 6 weeks. After this, there are no functional alternative versions, and the gene for the zeta (ζ) globin chain is downregulated. If the gene coding the α globin chain undergoes mutation, no alternate α-type chain can be substituted to form functional hemoglobin. In contrast, at least two versions of the β chain—δ and γ—remain in production throughout fetal life and beyond. With a mutation in the gene coding the β globin chain, these two other versions of the β chain often continue to be produced, resulting in either hemoglobin A2 ($\alpha_2\delta_2$) or

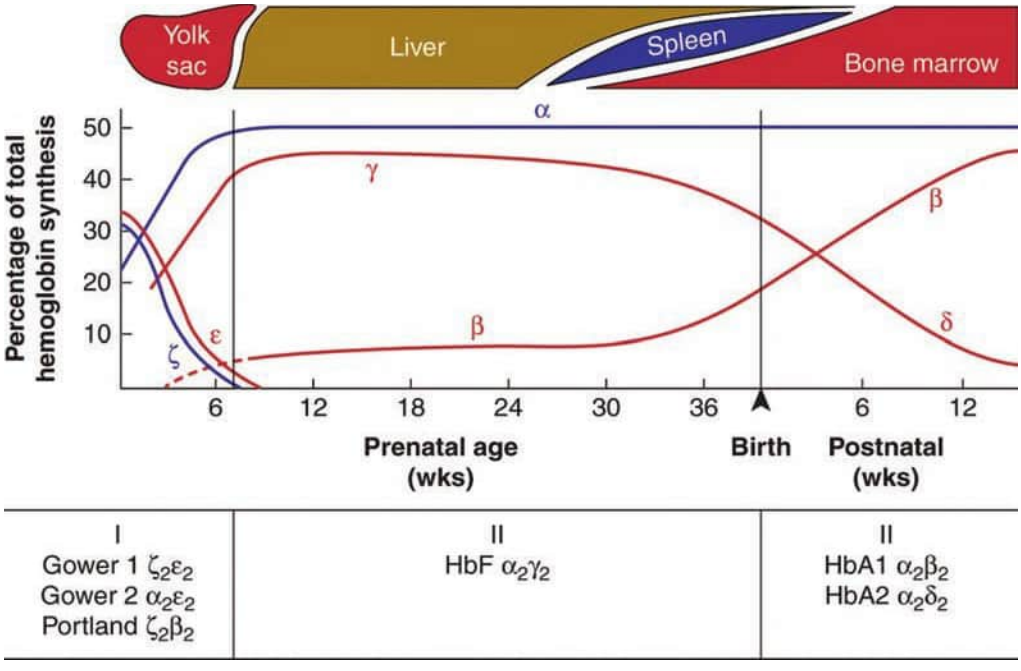

FIGURE 7-11 Hemoglobin types transition throughout pregnancy. Alpha (α) and zeta (ζ) globin chains are interchangeable. The beta (β) globin chain can be replaced by epsilon (ε), gamma (γ), or delta (δ) globin chains. In embryonic life (stage I), ζ and ε globin chain production is gradually replaced by α and γ globin chain production. Hemoglobin F is the main type in fetal life (stage II). After birth (stage III), HbA1 predominates.

hemoglobin F ($\alpha_2\gamma_2$), which substitute for the abnormal or missing hemoglobin A1.

Genes are turned off by methylation of their control region, which is discussed in Chapter 13 (p. 322). In some situations, methylation does not occur. For example, in newborns of diabetic women, hemoglobin F may persist due to hypomethylation of the γ gene (Perrine, 1988). With sickle-cell anemia, the γ gene remains unmethylated, and large quantities of fetal hemoglobin continue to be produced. As discussed in Chapter 59 (p. 1053), elevated hemoglobin F levels are associated with fewer sickle-cell disease symptoms, and pharmacological modification of these levels by hemoglobin F–inducing drugs is one treatment approach (Pasricha, 2018).

Hemoglobins A and F function differently. At any given oxygen tension and at identical pH, fetal erythrocytes that contain mostly hemoglobin F bind more oxygen than do those that contain nearly all hemoglobin A (Fig. 50-2, p. 886). This is because hemoglobin A binds 2,3-diphosphoglycerate (2,3-DPG) more avidly than does hemoglobin F. Remember that 2,3-DPG is an intraerythrocyte phosphate, and hemoglobin has a reciprocal affinity for 2,3-DPG and oxygen (Benesch, 1968). Thus, hemoglobin A's greater 2,3-DPG binding lowers its oxygen affinity compared with hemoglobin F. Moreover, during pregnancy, maternal 2,3-DPG levels are greater, and because fetal erythrocytes have lower concentrations of 2,3-DPG, fetal cells have increased oxygen affinity.

The amount of hemoglobin F in fetal erythrocytes begins to decrease in the last weeks of pregnancy. At term, approximately three fourths of total hemoglobin levels are hemoglobin F. During the first 6 to 12 months of life, the hemoglobin F proportion continues to decline and eventually reaches the low levels found in adult erythrocytes (Pasricha, 2018).

Coagulation Factors

With the exception of fibrinogen, other hemostatic proteins do not exist in embryonic forms. The fetus starts producing normal, adult-type procoagulant, fibrinolytic, and anticoagulant proteins by 12 weeks. Because they do not cross the placenta, their concentrations at birth are markedly below the levels that develop within a few weeks of life (Corrigan, 1992). In normal neonates, the levels of factors II, VII, IX, X, and XI, and of protein S, protein C, antithrombin, and plasminogen, all approximate 50 percent of adult levels. In contrast, levels of factors V, VIII, XIII, and fibrinogen are closer to adult values (Saracco, 2009). Maternal vitamin K deficiency has been associated with fetal cerebral hemorrhage (Goto, 2018). Without prophylactic treatment, the levels of vitamin K–dependent coagulation factors usually drop even further during the first few days after birth. This decline is amplified in breastfed infants and may lead to newborn hemorrhage (Chap. 33, p. 606). Schott (2018) and Konstantinidi (2019) and their colleagues have provided thromboelastographic parameters for both healthy and sick term newborns.

Fetal fibrinogen, which appears as early as 5 weeks, has the same amino acid composition as adult fibrinogen but different properties (Klagsbrun, 1988). It forms a less compressible clot, and the fibrin monomer has a lower degree of aggregation (Heimark, 1988). Although plasma fibrinogen levels at birth are less than those in nonpregnant adults, the protein is functionally more active than adult fibrinogen (Ignjatovic, 2011). Neonates have higher cord plasma levels and fibronectin-fibrinogen complexes compared with maternal levels (Lis-Kuberka, 2018).

Levels of functional fetal factor XIII (fibrin stabilizing factor) are significantly reduced compared with those in adults (Henriksson, 1974). Nielsen (1969) described low levels of plasminogen and elevated fibrinolytic activity in cord plasma compared with that of maternal plasma. Platelet counts in cord blood are in the normal range for nonpregnant adults.

Despite this relative reduction in procoagulants, the fetus appears to be protected from hemorrhage, and fetal bleeding is rare. Even after invasive fetal procedures such as cordocentesis, excessive bleeding is uncommon. Ney and coworkers (1989) have shown that amnionic fluid thromboplastins and a factor(s) in Wharton jelly combine to aid coagulation at the umbilical cord puncture site.

Various *thrombophilias* may cause thromboses and pregnancy complications in adults (Chap. 55, p. 976). If the fetus inherits one of these mutations, thrombosis and infarction can develop in the placenta or fetal organs. This is usually seen with homozygous inheritance. One example is homozygous protein C mutation, which causes *purpura fulminans*.

Plasma Proteins

Liver enzymes and other plasma proteins are produced by the fetus, and these levels do not correlate with maternal levels (Weiner, 1992). Concentrations of plasma proteins, which include albumin, lactic dehydrogenase, aspartate and alanine aminotransferases, and γ-glutamyl transpeptidase, all rise. Conversely, prealbumin levels decline with gestational age (Fryer, 1993). At birth, mean total plasma protein and albumin concentrations in fetal blood are similar to maternal levels. This is important because albumin binds unconjugated bilirubin to prevent *kernicterus* in the newborn (Chap. 33, p. 606).

■ Respiratory System

Lung maturation and biochemical indices of functional fetal lung maturity are important predictors of early neonatal outcome. Morphological or functional immaturity at birth leads to the development of the *respiratory distress syndrome* (Chap. 34, p. 615). A sufficient amount of surface-active materials—collectively referred to as *surfactant*—in the amnionic fluid is evidence of fetal lung maturity (Warburton, 2017). As Liggins (1994) emphasized, however, the structural and morphological maturation of fetal lung also is extraordinarily important to proper lung function.

Anatomical Maturation

Like the branching of a tree, lung development proceeds along an established timetable. As with other organ systems, gene activation and deactivation control these functions (Miller, 2019). The lung primordium is an outgrowth from foregut endoderm at approximately 20 days' gestation. The lung bud arises at 25 days and within this framework, four essential lung

development stages are described by Moore (2020). First, the *pseudoglandular stage* entails growth of the intrasegmental bronchial tree between the 5th and 17th weeks. The microvasculature begins to develop, and the lung looks microscopically like a gland. Second, during the *canalicular stage*, from 16 to 25 weeks, the bronchial cartilage plates extend peripherally. Each terminal bronchiole gives rise to several respiratory bronchioles, and each of these in turn divides into multiple saccular ducts. Third, the *terminal sac stage* begins after 25 weeks. During this stage, primordial alveoli give rise to primitive pulmonary alveoli, that is, the terminal sacs. Simultaneously, an extracellular matrix develops from proximal to distal lung segments until term. The fourth *alveolar stage* begins during the late fetal period and continues well into childhood. An extensive capillary network is built, the lymphatic system forms, and type II pneumocytes begin to produce surfactant. At birth, only approximately 15 percent of the adult number of alveoli is present. Thus, the lung continues to grow and add more alveoli for up to 8 years.

Various insults can upset this process, and their timing determines the sequelae. During the embryonic phase, abnormalities in lung development include esophageal and tracheal atresia, tracheoesophageal fistula, and pulmonary agenesis. Another example is fetal renal agenesis in which amnionic fluid is absent at the beginning of lung growth, and major defects occur in all four developmental stages. Similarly, the fetus with membrane rupture and subsequent oligohydramnios before 20 weeks usually exhibits nearly normal bronchial branching and cartilage development but has immature alveoli. In contrast, membrane rupture after 24 weeks may have minimal long-term effect on pulmonary structure. Last, vitamin D is thought to be important for several aspects of lung development (Hart, 2015; Ustun, 2020).

Pulmonary Surfactant

After the first breath, the terminal sacs must remain expanded despite the pressure imparted by the tissue-to-air interface, and surfactant keeps them from collapsing. Surfactant is formed in type II pneumocytes that line the alveoli. These cells are characterized by multivesicular bodies that produce the lamellar bodies in which surfactant is assembled. During late fetal life, at a time when the alveolus is characterized by a water-to-tissue interface, the intact lamellar bodies are secreted from the lung and swept into the amnionic fluid during respiratory-like movements that are termed fetal breathing. At birth, with the first breath, an air-to-tissue interface is established in the lung alveolus. Surfactant uncoils from the lamellar bodies and spreads to line the alveolus to prevent alveolar collapse during expiration. Thus, the fetal lungs' capacity to produce surfactant establishes lung maturity.

Surfactant Composition. Gluck (1972) and Hallman (1976) and their coworkers approximated that 90 percent of surfactant dry weight is lipid, specifically glycerophospholipids. Proteins account for the other 10 percent. Nearly 80 percent of the glycerophospholipids are phosphatidylcholines (lecithins). The principal active component that constitutes half of surfactant is a specific lecithin, which is dipalmitoyl phosphatidylcholine (DPPC or PC). Phosphatidylglycerol (PG) accounts for another 8 to 15 percent. Its precise role is unclear because newborns without PG usually do well. The other major constituent is phosphatidylinositol (PI).

Surfactant Synthesis. Biosynthesis takes place in the type II pneumocytes. The apoproteins are produced in the endoplasmic reticulum, and the glycerophospholipids are synthesized by cooperative interactions of several cellular organelles. Phospholipid is the primary surface tension–lowering component of surfactant, whereas the apoproteins aid the forming and reforming of a surface film.

The major apoprotein is surfactant A (SP-A), which is a glycoprotein with a molecular weight of 28,000 to 35,000 Da. It is synthesized in the type II cells, and its content in amnionic fluid increases with gestational age and fetal lung maturity. *SP-A* gene expression is demonstrable by 29 weeks (Mendelson, 2005). Specifically, *SP-A1* and *SP-A2* are two separate genes on chromosome 10, and their regulation is distinctive and different (McCormick, 1994).

Corticosteroids and Fetal Lung Maturation. Since Liggins (1969) observed accelerated lung maturation in lamb fetuses given glucocorticosteroid prior to preterm delivery, many suggested that fetal cortisol stimulates lung maturation and surfactant synthesis. It is unlikely, however, that corticosteroids are the only stimulus for augmented surfactant formation. But, when these are administered at certain critical times, they may improve preterm fetal lung maturation. Antenatal betamethasone and dexamethasone for lung maturation and neonatal replacement surfactant therapy are discussed in Chapter 34 (p. 617).

Breathing

Fetal respiratory muscles develop early, and chest wall movements are detected sonographically as early as 11 weeks (Koos, 2014). Breathing is essential for normal lung growth and development. From the beginning of the fourth month, the fetus engages in respiratory movement sufficiently intense to move amnionic fluid in and out of the respiratory tract. Some extrauterine events have effects on fetal breathing, for example, maternal exercise stimulates it (Sussman, 2016).

■ Digestive System

After its embryogenic formation from the yolk sac as the primordial gut, the digestive system forms the intestines and various appendages. The foregut gives rise to the pharynx, lower respiratory system, esophagus, stomach, proximal duodenum, liver, pancreas, and biliary tree. The midgut gives rise to the distal duodenum, jejunum, ileum, cecum, appendix, and the right colon. The hindgut develops into the left colon, rectum, and the superior portion of the anal canal that empties into the cloaca (Kruepunga, 2018). Numerous malformations develop in these structures from improper rotation, fixation, and partitioning. A common example is one of the several types of intestinal atresias (Moore, 2020; Stoll, 2017).

Swallowing begins at 10 to 12 weeks, coincident with the ability of the small intestine to undergo peristalsis and

to actively transport glucose (Koldovsky, 1965). As a correlate, neonates born preterm may have swallowing difficulties because of immature gut motility (Singendonk, 2014). Much of the water in swallowed fluid is absorbed, and unabsorbed matter is propelled to the lower colon. Gitlin (1974) demonstrated that late in pregnancy, approximately 800 mg of soluble protein is ingested daily by the fetus. The stimulus for swallowing is unclear, but the fetal neural analogue of thirst, gastric emptying, and change in the amnionic fluid composition are potential factors (Boyle, 1992). The fetal taste buds may play a role because saccharin injected into amnionic fluid increases swallowing, whereas injection of a noxious chemical inhibits it (Liley, 1972).

Fetal swallowing appears to have little effect on amnionic fluid volume early in pregnancy because the volume swallowed is small compared with the total. However, term fetuses swallow between 200 and 760 mL per day—an amount comparable to that of the term neonate (Pritchard, 1966). Thus at term, amnionic fluid volume regulation can be substantially altered by fetal swallowing. For example, as discussed in Chapter 14 (p. 256), if swallowing is inhibited, hydramnios is common.

Hydrochloric acid and some digestive enzymes are present in the stomach and small intestine in minimal amounts in the early fetus. Intrinsic factor is detectable by 11 weeks, and pepsinogen by 16 weeks. The preterm neonate, depending on its gestational age, may have transient deficiencies of these enzymes. The small intestinal histological appearance is normal (Meier, 2018).

Stomach emptying appears to be stimulated primarily by volume. A dilated stomach suggests obstruction (McCormick, 2021). Movement of amnionic fluid through the gastrointestinal system may enhance growth and development of the alimentary canal. That said, other regulatory factors likely are involved. For example, anencephalic fetuses, in which swallowing is limited, often have normal amnionic fluid volume and normal-appearing gastrointestinal tract.

Meconium

Fetal bowel contents consist of various products of secretion, such as glycerophospholipids from the lung, desquamated fetal cells, lanugo, scalp hair, and vernix. It also contains undigested debris from swallowed amnionic fluid. The dark greenish-black color forms from bile pigments, especially biliverdin. Meconium can pass from normal bowel peristalsis in the mature fetus or from vagal stimulation. It can also pass when hypoxia stimulates arginine vasopressin (AVP) release from the fetal pituitary gland. AVP stimulates colonic smooth muscle to contract, resulting in intraamnionic defecation (Rosenfeld, 1985). Meconium is toxic to the respiratory system, and its inhalation can result in *meconium aspiration syndrome*.

Liver

The hepatic diverticulum is an outgrowth of the endodermal lining of the foregut. Epithelial liver cords and primordial cells differentiate into hepatic parenchyma. By 9 weeks, the liver accounts for 10 percent of fetal weight (Moore, 2020). Serum liver enzyme levels increase with gestational age. As noted, in early gestation, fetal hepatic hemopoiesis is a key source of blood and immune cells (p. 125) (Popescu, 2019).

The fetal liver has a gestational-age-related capacity to conjugate bilirubin, which forms from hemoglobin breakdown (Morioka, 2015). Because of hepatic immaturity, the preterm newborn is at particular risk for unconjugated hyperbilirubinemia (Chap. 33, p. 606). And because the life span of normal fetal macrocytic erythrocytes is shorter than that of the adult, relatively more unconjugated bilirubin is produced. Of this unconjugated form, only a small fraction is conjugated by the fetal liver, and this is excreted into the intestine and ultimately oxidized to biliverdin. Instead, most of the unconjugated bilirubin is excreted into the amnionic fluid after 12 weeks and transferred across the placenta (Bashore, 1969). Importantly, placental bilirubin transfer is bidirectional. Thus, a woman with severe hemolysis has excess unconjugated bilirubin that readily passes to the fetus and then into the amnionic fluid. Conversely, conjugated bilirubin is not exchanged to any significant degree between mother and fetus.

Most fetal cholesterol derives from hepatic synthesis, which satisfies the large demand for low-density lipoprotein (LDL) cholesterol by the fetal adrenal glands. However, an estimated 20 to 50 percent of fetal cholesterol originates from the mother, is transferred through the placenta, and released to circulating fetal apolipoproteins (Baardman, 2012; Pecks, 2014). Fetuses with growth restriction have lower cholesterol levels due to diminished fetal synthesis rather than diminished maternal supply (Pecks, 2019).

Hepatic glycogen is present in low concentration during the second trimester, but near term, levels rise rapidly and markedly to reach concentrations that are two- to threefold higher than those in the adult liver. After birth, glycogen content falls precipitously.

Pancreas

This gland arises from dorsal and ventral pancreatic buds from the endoderm of the foregut (Moore, 2020). Gene regulation of its development has been reviewed (Jennings, 2015). Insulin-containing granules can be identified by 9 to 10 weeks, and insulin is detectable in fetal plasma at 12 weeks (Adam, 1969). Between 19 and 36 weeks, Kivilevitch and associates (2017) were able to visualize the pancreas sonographically in 60 percent of fetuses.

The fetal pancreas responds to hyperglycemia by secreting insulin (Obenshain, 1970). Islets of Langerhans are enlarged in fetuses of mothers with metabolic abnormalities (Avagliano, 2019). These fetuses likely can be identified by sonographic pancreatic hyperechogenicity (Akkaya, 2018). Glucagon has been identified in the fetal pancreas at 8 weeks. Although hypoglycemia does not cause an increase in fetal glucagon levels, similar stimuli do so by 12 hours after birth (Chez, 1975).

Most pancreatic enzymes are present by 16 weeks. Trypsin, chymotrypsin, phospholipase A, and lipase are found in the 14-week fetus, and their concentrations increase with gestational age (Werlin, 1992). Amylase has been identified in amnionic fluid at 14 weeks (Davis, 1986). The exocrine function of the fetal pancreas is limited. Physiologically important

secretion occurs only after stimulation by a secretagogue such as acetylcholine, which is released locally after vagal stimulation (Werlin, 1992). Cholecystokinin normally is released only after protein ingestion and thus ordinarily is not found in the fetus.

Urinary System

Renal development involves interaction between pluripotential stem cells, undifferentiated mesenchymal cells, and epithelial components (Fanos, 2015). Two primitive urinary systems—the pronephros and the mesonephros—precede development of the metanephros, which forms the final kidney. The pronephros involutes by 2 weeks, and the mesonephros produces urine at 5 weeks and degenerates by 11 to 12 weeks. Failure of these two structures either to form or to regress may result in anomalous urinary system development. Between 9 and 12 weeks, the ureteric bud and the nephrogenic blastema interact to produce the metanephros. Glomeruli develop and filtration begins by week 9 (Moore, 2020). The kidney and ureter develop from intermediate mesoderm. The bladder and urethra develop from the urogenital sinus. The bladder also develops in part from the allantois. Urogenital embryology is a focus of Chapter 3.

By week 14, the loop of Henle is functional and reabsorption occurs (Smith, 1992). New nephrons continue to be formed until 36 weeks (Lindström, 2018). In preterm neonates, their formation continues after birth. Although the fetal kidneys produce urine, their ability to concentrate and modify the pH is limited even in the mature fetus. Fetal urine is hypotonic with respect to fetal plasma and has low electrolyte concentrations.

Renal vascular resistance is high, and the filtration fraction is low compared with adult values (Smith, 1992). Fetal renal blood flow and thus urine production are controlled or influenced by the renin-angiotensin system, the sympathetic nervous system, prostaglandins, kallikrein, and atrial natriuretic peptide. The glomerular filtration rate increases with gestational age from less than 0.1 mL/min at 12 weeks to 0.3 mL/min at 20 weeks. In later gestation, the rate remains constant when corrected for fetal weight (Smith, 1992). Hemorrhage or hypoxia generally decreases renal blood flow, glomerular filtration rate, and urine output.

Urine usually is found in the bladder even in small fetuses. The fetal kidneys start producing urine at 12 weeks. By 18 weeks, they are producing 7 to 14 mL/d, and at term, this increases to 650 mL/d (Wladimiroff, 1974). Maternally administered furosemide augments fetal urine formation, whereas uteroplacental insufficiency, fetal-growth restriction, and other fetal disorders can lower it. Obstruction of the urethra, bladder, ureters, or renal pelves can damage renal parenchyma and distort fetal anatomy (Müller Brochut, 2014). Pathological correlates and prenatal therapy of urinary tract obstruction are discussed in Chapter 19 (p. 376).

Kidneys are not essential for survival in utero but influence control of amnionic fluid composition and volume. Thus, abnormalities that cause chronic fetal anuria are usually accompanied by oligohydramnios and pulmonary hypoplasia (Cotton, 2017).

Endocrine Gland Development

The fetal endocrine system is functional for some time before the central nervous system reaches maturity (Mulchahey, 1987).

Pituitary Gland

The anterior pituitary gland develops from oral ectoderm—the *Rathke pouch*—whereas the posterior pituitary gland derives from neuroectoderm. Embryonic development involves a complex and highly spatiotemporally regulated network of signaling molecules and transcription factors (Bancalari, 2012; Montenegro, 2019).

Anterior and Intermediate Lobes. The adenohypophysis, or anterior pituitary, differentiates into five cell types that secrete six protein hormones. Of these types, lactotropes produce prolactin (PRL), somatotropes produce growth hormone (GH), corticotropes produce adrenocorticotropic hormone (ACTH), thyrotropes produce thyroid-stimulating hormone (TSH), and gonadotropes produce luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

ACTH is first detected in the fetal pituitary gland at 7 weeks, and GH and LH have been identified by 13 weeks. By the end of the 17th week, the fetal pituitary gland synthesizes and stores all pituitary hormones. Moreover, the fetal pituitary is responsive to tropic hormones and is capable of secreting these early in gestation (Grumbach, 1974). The fetal pituitary secretes β-endorphin, and cord blood levels of β-endorphin and β-lipotropin rise with fetal arterial partial pressure of carbon dioxide ($Paco_2$) (Browning, 1983).

The intermediate lobe in the fetal pituitary gland is well developed. The cells of this structure begin to disappear before term and are absent from the adult pituitary.

Neurohypophysis. The posterior pituitary gland or neurohypophysis is well developed by 10 to 12 weeks, and oxytocin and arginine vasopressin are demonstrable. Both hormones probably function in the fetus to conserve water by actions directed largely at the lung and placenta rather than kidney. Vasopressin levels in umbilical cord plasma are strikingly higher than maternal levels (Chard, 1971).

Thyroid Gland

The thyroid primordium arises from the endoderm of the primordial pharynx (Moore, 2020). The thyroid migrates to its final position, and the obliterated thyroglossal duct connects to the foramen cecum of the tongue.

The pituitary–thyroid system is functional by the end of the first trimester. By 10 to 12 weeks, the thyroid gland is able to synthesize hormones, and thyrotropin, thyroxine, and thyroid-binding globulin (TBG) have been detected in fetal serum as early as 11 weeks (Bernal, 2007). Thyroid follicles have formed and colloid is present. The placenta actively concentrates iodine on the fetal side, and by 12 weeks and throughout pregnancy, the fetal thyroid concentrates iodine more avidly than does the maternal thyroid. Thus, maternal administration of either radioiodine or appreciable amounts of ordinary iodine is hazardous after this time (Chap. 66, p. 1174). Normal fetal levels of free thyroxine (T_4), free triiodothyronine (T_3), and TBG rise

steadily throughout gestation (Ballabio, 1989). Compared with adult levels, by 36 weeks, fetal serum concentrations of TSH are higher, total and free T_3 concentrations are lower, and T_4 is similar. This suggests that the fetal pituitary may not become sensitive to feedback until late pregnancy.

Fetal thyroid hormone plays a role in the normal development of virtually all fetal tissues, especially the brain (Andersen, 2018; Jansen, 2019). Congenital hypothyroidism is a heterogenous disorder for which several candidate genes have been identified (Moore, 2020). With hypothyroidism, it was previously believed that normal fetal growth and development provided evidence that T_4 was not essential for fetal growth. It is now known, however, that growth proceeds normally because small quantities of maternal T_4 prevent antenatal cretinism in fetuses with thyroid agenesis (Forhead, 2014; Vulsma, 1989). As discussed in Chapter 61 (p. 1098), the fetus with congenital hypothyroidism typically does not develop stigmata of cretinism until after birth (Abduljabbar, 2012). Because administration of thyroid hormone will prevent this, by state law, all newborns are tested for high serum levels of TSH (Chap. 32, p. 594).

The placenta prevents substantial passage of maternal thyroid hormones to the fetus by rapidly deiodinating maternal T_4 and T_3 to form reverse T_3, a relatively inactive thyroid hormone. Several antithyroid antibodies cross the placenta when present in high concentrations (Pelag, 2002). Those include the long-acting thyroid stimulators (LATS), LATS-protector (LATS-P), and thyroid-stimulating immunoglobulin (TSI). Congenital hyperthyroidism develops when maternal thyroid-stimulating antibody crosses the placenta to stimulate the fetal gland to secrete thyroxine (Donnelley, 2015). These fetuses develop large goiters as shown in Figure 61-3 (p. 1092). They also display tachycardia, hepatosplenomegaly, hematological abnormalities, craniosynostosis, and growth restriction. As children, they have perceptual motor difficulties, hyperactivity, and reduced growth (Johns, 2018).

Immediately after birth, thyroid function and metabolism undergo major change. Cooling to room temperature evokes a sudden and marked increase in TSH secretion. This in turn causes a progressive increase in serum T_4 levels that are maximal 24 to 36 hours after birth. There are nearly simultaneous elevations of serum T_3 levels.

Adrenal Glands

These glands develop from two separate tissues. The medulla derives from neural crest ectoderm, whereas the fetal and adult cortex arise from intermediate mesoderm. The gland grows rapidly through cell proliferation and angiogenesis, cellular migration, hypertrophy, and apoptosis (Ishimoto, 2011). Expression of the *Kiss1R* gene, alone or in concert with corticotropin-releasing hormone, stimulates fetal adrenal growth (Katugampola, 2017). Fetal glands are enormous in relation to body size and are 10 to 20 times larger than adult glands (Karsli, 2019; Moore, 2020). The bulk is made up of the inner or fetal zone of the adrenal cortex and involutes rapidly after birth. This zone is scant to absent in rare instances in which the fetal pituitary gland is congenitally absent. The function of the fetal adrenal glands is discussed in Chapter 5 (p. 102).

Immunological System

Infections in utero have provided an opportunity to examine mechanisms of the fetal immune response (Chap. 67, p. 1182). Evidence of immunological competence has been reported as early as 13 weeks (Stabile, 1988). In cord blood at or near term, the average level for most components approximates half that of the adult values.

B cells differentiate from pluripotent hemopoietic stem cells that migrate to the liver (Berthault, 2017; Melchers, 2015). Despite this, in the absence of a direct antigenic stimulus such as infection, fetal plasma immunoglobulins consist almost totally of transferred maternal immunoglobulin G (IgG). Thus, antibodies in the newborn most often reflect maternal immunological experiences (American College of Obstetricians and Gynecologists, 2019). The interaction between maternal and fetal T cells is described in Chapter 5 (p. 93).

Immunoglobulin G

Maternal IgG transport correlates with placental Fc receptor expression (Lozano, 2018). Fetal transport begins at approximately 16 weeks and increases thereafter. Because the bulk of IgG is acquired during the last 4 weeks, preterm neonates are poorly endowed with protective maternal antibodies. Newborns begin to slowly produce IgG, and adult values are not attained until age 3 years. In certain situations, the transfer of IgG antibodies from mother to fetus can be harmful rather than protective. The classic example is hemolytic disease of the fetus and newborn resulting from Rh-antigen alloimmunization (Chap. 18, p. 353).

Immunoglobulins M and A

In the adult, production of immunoglobulin M (IgM) in response to an antigenic stimulus is superseded in a week or so predominantly by IgG production. Similarly, very little IgM is produced by normal fetuses not exposed to infection, but with infection, the IgM response predominates and remains so for weeks to months in the newborn. And, because IgM is not transported from the mother, any IgM in the fetus or newborn is that which it produced. Thus, specific IgM levels in umbilical cord blood may be elevated in those with congenital infection. According to the American College of Obstetricians and Gynecologists (2019), elevated IgM levels are usually found in newborns with congenital infection such as rubella, cytomegalovirus infection, or toxoplasmosis. In infants, adult levels of IgM are normally attained by age 9 months.

Immunoglobulin A (IgA) ingested in colostrum provides mucosal protection against enteric infections. There is only a small amount of fetal secretory IgA found in amnionic fluid (Quan, 1999).

Lymphocytes and Monocytes

The immune system develops early, and B lymphocytes are derived from primordial stem cells and appear in fetal liver by 9 weeks and in blood and spleen by 12 weeks (Moore, 2020). T lymphocytes begin to leave the thymus at approximately 14 weeks. Despite this, the newborn responds poorly to immunization, and especially poorly to bacterial capsular

polysaccharides. This immature response may stem from a deficient response of newborn B cells to polyclonal activators or from a lack of T cells that proliferate in response to specific stimuli (Hayward, 1983). In the newborn, monocytes are able to process and present antigen when tested with maternal antigen-specific T cells. DNA methylation patterns are developmentally regulated during monocyte-macrophage differentiation and contribute to the antiinflammatory phenotype in macrophages (Kim, 2012).

■ Musculoskeletal System

The origin of most muscles and bones is mesodermal. MYOD is a member of the family of myogenic regulatory factors that activates transcription of muscle-specific genes (Moore, 2020). The limb buds appear by the fourth week. Most skeletal muscle derives from myogenic precursor cells in the somites. The skeleton arises from condensed mesenchyme—embryonic connective tissue—which eventually forms hyaline cartilage models of the bones. Osteoclasts arise from erythro-myeloid progenitors (Jacome-Galarza, 2019). By the end of the embryonic period, ossification centers have developed, and bones harden by endochondral ossification.

ENERGY AND NUTRITION

Because of the small amount of yolk in the human ovum, growth of the embryofetus is dependent on maternal nutrients during the first 2 months. During the first few days after implantation, blastocyst nutrition comes from the interstitial fluid of the endometrium and the surrounding maternal tissue.

Maternal adaptations to store and transfer nutrients to the fetus are discussed in Chapter 4 and summarized here. Three major maternal storage depots are the liver, muscle, and adipose tissue. These maternal depots and the storage hormone insulin are intimately involved in the metabolism of the nutrients absorbed from the gut. Maternal insulin secretion is sustained by increased serum levels of glucose and amino acids. The net effect is maternal storage of glucose as glycogen primarily in liver and muscle, retention of some amino acids as protein, and storage of the excess as fat (Abeysekera, 2016). Storage of maternal fat peaks in the second trimester and then declines as fetal energy demands rise in the third trimester (Pipe, 1979). Interestingly, the placenta appears to act as a nutrient sensor, altering transport based on the maternal supply and environmental stimuli (Jansson, 2006b, Wesolowski, 2017).

During times of fasting, glucose is released from glycogen, but maternal glycogen stores cannot provide an adequate amount of glucose to meet requirements for maternal energy and fetal growth. Augmentation is provided by cleavage of triacylglycerols, stored in adipose tissue, which results in free fatty acids and activation of lipolysis.

■ Glucose and Fetal Growth

Although dependent on the mother for nutrition, the fetus also actively participates in providing its own nutrition. At midpregnancy, fetal serum glucose concentration is independent of maternal levels and may exceed them. Glucose is the major nutrient for fetal growth and energy. Logically, mechanisms exist to minimize maternal glucose use so that the limited maternal supply is available to the fetus. As one example, human placental lactogen (hPL) is a hormone normally abundant in the mother but not the fetus and has an insulin antagonist effect. It blocks the peripheral uptake and use of glucose, while instead promoting mobilization and use of free fatty acids by maternal tissues (Chap. 5, p. 98). This hormone is also diabetogenic as discussed in Chapter 60 (p. 1068). Last, intrinsic epigenetic changes play a role (Hansen, 2017). For example, nonalcoholic fatty liver disease (NAFLD) is associated with fetal macrosomia (Lee, 2019).

Glucose Transport

The transfer of D-glucose across cell membranes is accomplished by a carrier-mediated, stereospecific, nonconcentrating process of facilitated diffusion. There are 14 glucose transport proteins (GLUTs) encoded by the *SLC2A* gene family and characterized by tissue-specific distribution (Joshi, 2021). Several of these are expressed by trophoblast (Stanirowski, 2017). GLUT-1, GLUT-3, and GLUT-4 primarily aid glucose uptake by the placenta and are located in the plasma membrane of the syncytiotrophoblast microvilli (Acosta, 2015; James-Allan, 2019). DNA methylation regulates expression of placental *GLUT* genes, with epigenetic modification across gestation (Novakovic, 2013). Methylation increases as pregnancy advances and is induced by almost all growth factors.

In addition to its transport role, the placenta uses glucose for its metabolic functions. Fetal and placental glucose consumption are inversely related. Thus, placental glucose use is a key modulator of maternal-fetal transfer (Michelsen, 2019).

Lactate is a product of glucose metabolism and transported across the placenta also by facilitated diffusion. By way of cotransport with hydrogen ions, lactate is probably transported as lactic acid.

Fetal Macrosomia

The precise biomolecular events in the pathophysiology of fetal macrosomia are not defined. Nonetheless, fetal hyperinsulinemia is clearly one driving force (Luo, 2012). As discussed with fetal-growth disorders in Chapter 47 (p. 824), insulin-like growth factor and leptin and other adipokines are important regulators of placental development and function (Gao, 2012). Maternal obesity begets fetal macrosomia. In addition, theories suggest that maternal obesity affects fetal cardiomyocyte growth that may result in fetal cardiomyopathy or even congenital heart disease (Roberts, 2015).

■ Leptin

This polypeptide hormone was originally identified as a product of adipocytes and a regulator of energy homeostasis by curbing appetite. It also contributes to angiogenesis, hemopoiesis, osteogenesis, pulmonary maturation, and neuroendocrine, immune, and reproductive functions (Briffa, 2015). Leptin is produced by the mother, fetus, and placenta. It is expressed in syncytiotrophoblast and fetal vascular endothelial cells. Of

placental production, 5 percent enters the fetal circulation, whereas 95 percent is transferred to the mother (Hauguel-de Mouzon, 2006).

Leptin concentrations peak in amnionic fluid at midpregnancy (Scott-Finley, 2015). Fetal serum leptin levels begin increasing at approximately 34 weeks and are correlated with fetal weight. This hormone is involved in the development and maturation of the heart, brain, kidneys, and pancreas, and its levels are decreased with fetal-growth restriction (Briffa, 2015; Yalinbas, 2019). Abnormal levels are associated with fetal-growth disorders, gestational diabetes, and preeclampsia, but not maternal obesity (Allbrand, 2018; Gurugubelli, 2018). Postpartum, leptin levels decline in both the newborn and mother. Perinatal leptin is associated with the development of metabolic syndromes later in life (Briffa, 2015).

Free Fatty Acids and Triglycerides

The term newborn has a large proportion of fat, which averages 15 percent of body weight (Kimura, 1991). Thus, late in pregnancy, a substantial part of the substrate transferred to the human fetus is stored as fat. Although maternal obesity raises placental fatty acid uptake and fetal fat deposition, it does not appear to affect fetal organ growth (Dubé, 2012). Neutral fat in the form of triglycerides does not cross the placenta, but glycerol does. Despite this, evidence supports that abnormal maternal concentrations of triglycerides—both low and high levels—are associated with major congenital anomalies (Nederlof, 2015).

There is preferential placental-fetal transfer of long-chain polyunsaturated fatty acids (Fonseca, 2018). Lipoprotein lipase is present on the maternal but not on the fetal side of the placenta. This arrangement favors hydrolysis of triacylglycerols in the maternal intervillous space yet preserves these neutral lipids in fetal blood. Fatty acids transferred to the fetus can be converted to triglycerides in the fetal liver.

The placental uptake and use of LDL is an alternative mechanism for fetal assimilation of essential fatty acids and amino acids (Chap. 5, p. 100). LDL binds to specific receptors in the coated-pit regions of the syncytiotrophoblast microvilli. The large LDL particle, measuring about 250,000 Da, is taken up by a process of receptor-mediated endocytosis. The apoprotein and cholesterol esters of LDL are hydrolyzed by lysosomal enzymes in the syncytium to yield: (1) cholesterol for progesterone synthesis; (2) free amino acids, including essential amino acids; and (3) essential fatty acids, primarily linoleic acid. Interestingly, maternal cholesterol is obligatory for steroid hormone synthesis, but increasing levels are associated with fetal aortic atherogenesis (de Nigris, 2018).

Amino Acids

The placenta concentrates many amino acids in the syncytiotrophoblast, which are then transferred to the fetal side by diffusion. In cordocentesis blood samples, the amino acid concentration in umbilical cord plasma is greater than in maternal venous or arterial plasma. DNA methylation serves to regulate transporter gene expression (Simner, 2017). Transport system activity is influenced by gestational age and environmental factors. These include heat stress, hypoxia, under- and overnutrition, and hormones such as glucocorticoids, growth hormone, and leptin (Briffa, 2015). Trophoblastic mammalian target of rapamycin complex 1 (mTORC1) regulates placental amino acid transporters and modulates transfer across the placenta (Jansson, 2012). In vivo studies suggest an upregulation of transport for certain amino acids and a greater delivery rate of these to the fetuses of women with gestational diabetes associated with fetal overgrowth (Jansson, 2006a).

Proteins

Placental transfer of larger proteins is limited, but there are exceptions. As discussed, IgG crosses the placenta in large amounts via endocytosis and trophoblast Fc receptors. IgG transfer depends on maternal levels of total IgG, gestational age, placental integrity, IgG subclass, and antigenic potential (Palmeira, 2012). Conversely, the larger immunoglobulins—IgA and IgM—of maternal origin are effectively excluded from the fetus.

Ions and Trace Metals

Calcium and phosphorus are actively transported from mother to fetus. Calcium is transferred for fetal skeletal mineralization (Olausson, 2012). A calcium-binding protein is produced in placenta. Parathyroid hormone–related protein (PTH-rP), as the name implies, acts as a surrogate PTH in many systems (Chap. 5, p. 99). PTH is not found in fetal plasma, but PTH-rP is present, suggesting that PTH-rP is the fetal parathormone (Martin, 2016). The expression of PTH-rP in cytotrophoblasts is modulated by the extracellular concentration of Ca^{2+} (Hellman, 1992). It seems possible that PTH-rP synthesized in decidua, placenta, and other fetal tissues is important in fetal Ca^{2+} transfer and homeostasis.

Another example is the unidirectional transfer of iron. Typically, maternal plasma iron concentration is much lower than that in her fetus. Even with severe maternal iron-deficiency anemia, the fetal hemoglobin mass is normal.

Iodine transport is clearly attributable to a carrier-mediated, energy-requiring active process. And, as discussed in Chapter 61 (p. 1097), the placenta concentrates iodine (Velasco, 2018). The concentrations of zinc in the fetal plasma also are greater than those in maternal plasma. Conversely, copper levels in fetal plasma are less than those in maternal plasma. This fact is of particular interest because important copper-requiring enzymes are necessary for fetal development.

Placental Sequestration of Heavy Metals

The heavy metal–binding protein metallothionein-1 is expressed in human syncytiotrophoblast. This protein binds and sequesters a host of heavy metals, including zinc, copper, lead, and cadmium. Despite this, fetal exposure is variable (Caserta, 2013). For example, lead enters the fetal environment at a level 90 percent of maternal concentrations. In contrast, placental transfer of cadmium is limited (Kopp, 2012).

The most common source of environmental cadmium is cigarette smoke.

Metallothionein also binds and sequesters copper in placental tissue. This accounts for the low copper levels in cord blood (Iyengar, 2001). It is possible that cadmium provokes metallothionein synthesis in the amnion. This may cause copper sequestration, a pseudocopper deficiency, and in turn, diminished amnion tensile strength.

Vitamins

The concentration of vitamin A (retinol) is greater in fetal than in maternal plasma and is bound to retinol-binding protein and to prealbumin. Retinol-binding protein is transferred from the maternal compartment across the syncytiotrophoblast. The transport of vitamin C—ascorbic acid—from mother to fetus is accomplished by an energy-dependent, carrier-mediated process. As a result, the concentration of ascorbic acid is two to four times higher in fetal plasma than in maternal plasma (Morriss, 1994). Levels of principal vitamin D metabolites, including 1,25-dihydroxycholecalciferol, are greater in maternal plasma than in fetal plasma. The 1β-hydroxylation of 25-hydroxyvitamin D_3 is known to take place in placenta and in decidua.

PLACENTAL ROLE IN EMBRYOFETAL DEVELOPMENT

The placenta is the organ of transfer between mother and fetus. Within this bidirectional maternal-fetal interface, maternal oxygen and nutrients transfer to the fetus, whereas CO_2 and metabolic wastes are directed back to the mother. Fetal blood, which is contained in the fetal capillaries of the chorionic villi, has no direct contact with maternal blood, which remains in the intervillous space. Instead, bidirectional transfer depends on processes that allow or aid the transport through the syncytiotrophoblast that lines chorionic villi (Michelsen, 2017).

With this system, breaks in the chorionic villi permit escape of fetal/placental cells and other blood-borne material into the maternal circulation. This leakage is the mechanism by which some D-negative women become sensitized by the erythrocytes of their D-positive fetus (Chap. 18, p. 353). The escape of fetal cells can also lead to fetal microchimerism from entrance of allogeneic fetal cells, including trophoblast, into maternal blood and other organs (Rijnink, 2015). Volumes are estimated to range from 1 to 6 cells/mL at midpregnancy. Some fetal cells become "immortal" in that they persist in the maternal circulation and organs following pregnancy. As discussed in Chapter 61 (p. 1109), the clinical corollary is that some maternal autoimmune diseases such as Hashimoto thyroiditis may be provoked by such microchimerism.

Last, cell-free DNA (cfDNA) is released from syncytiotrophoblast during normal physiological cell turnover. After 10 weeks, 10 to 15 percent of all cfDNA in maternal plasma is trophoblastic DNA (Norton, 2015; Shaffer, 2018). This phenomenon underlies one maternal-serum screening method for fetal aneuploidy, which is discussed in Chapters 16 and 17 (pp. 327 and 335).

The Intervillous Space

Maternal blood within the intervillous space is the primary source of maternal–fetal transfer. Blood from the maternal spiral arteries directly bathes the trophoblast layer that surrounds the villi. Substances transferred from mother to fetus first enter the intervillous space and are then transported to the syncytiotrophoblast. As such, the chorionic villi and intervillous space function together as the fetal lung, gastrointestinal tract, and kidney.

Circulation within the intervillous space is described in Chapter 5 (p. 92). Intervillous and uteroplacental blood flow increases throughout pregnancy, and at term, the residual volume of the intervillous space approximates 140 mL. Moreover, uteroplacental blood flow near term ranges from 700 to 900 mL/min, and most of this blood apparently goes to the intervillous space (Pates, 2010).

Placental Transfer

In the terminal villi, substances that pass from maternal to fetal blood must first traverse the syncytiotrophoblast, the attenuated cytotrophoblast layer, the thinned villous stroma, and finally, the fetal capillary wall. Although this histological barrier separates maternal and fetal circulations, it is not a simple physical barrier. First, throughout pregnancy, syncytiotrophoblast actively or passively permits, facilitates, and adjusts the amount and rate of substance transfer to the fetus. As discussed in Chapter 5 (p. 92), the maternal-facing syncytiotrophoblast surface is characterized by a complex microvillus structure. The fetal-facing basal cell membrane is the site of transfer to the intravillous space. Finally, the villous capillaries are an additional site for transport from the intravillous space into fetal blood, or vice versa. In determining the effectiveness of the human placenta as an organ of transfer, several variables are important and shown in Table 7-2. Epigenetic placental changes brought about by methylation of genes engaged in nutrient transfer also play a role (Kerr, 2018).

Mechanisms of Transfer

Most substances with a molecular mass <500 Da pass readily through placental tissue by simple diffusion. These include

TABLE 7-2. Variables of Maternal-Fetal Substance Transfer

Maternal plasma concentration
Maternal carrier-protein binding
Maternal blood flow rate through the intervillous space
Trophoblast surface area size available for exchange
Physical trophoblast properties to permit simple diffusion
Trophoblast biochemical machinery for active transport
Substance metabolism by the placenta during transfer
Fetal intervillous capillary surface area size for exchange
Fetal blood concentration of the substance
Fetal carrier-protein binding
Villous capillary blood flow rate
DNA methylation of transporter genes

oxygen, CO_2, water, most electrolytes, and anesthetic gases (Carter, 2009). Some low-molecular-weight compounds undergo transfer facilitated by syncytiotrophoblast. These are usually those that have low concentrations in maternal plasma but are essential for normal fetal development.

Insulin, steroid hormones, and thyroid hormones cross the placenta, but very slowly. The hormones synthesized in situ in the syncytiotrophoblast enter both the maternal and fetal circulations, but not equally (Chap. 5, p. 86). Examples are hCG and hPL concentrations, which are much lower in fetal plasma than in maternal plasma. High-molecular-weight substances usually do not traverse the placenta, but there are important exceptions. As discussed, one is IgG—molecular weight 160,000 Da—which is transferred by way of a specific trophoblast receptor–mediated mechanism (Stach, 2014).

Although simple diffusion is an important method of placental transfer, the trophoblast and chorionic villus unit demonstrate enormous selectivity in transfer. As discussed, important in this regard is DNA methylation of transporter genes (Kerr, 2018; Simner, 2017). The net results are different metabolite concentrations on the two sides of the villus.

Transfer of Oxygen and Carbon Dioxide

Placental oxygen transfer is blood flow limited. Using estimated uteroplacental blood flow, Longo (1991) calculated oxygen delivery to be approximately 8 mL O_2/min/kg of fetal weight. Because of the continuous passage of oxygen from maternal blood in the intervillous space to the fetus, its oxygen saturation resembles that in maternal capillaries. The average oxygen saturation of intervillous blood is estimated to be 65 to 75 percent, with a partial pressure (Pao_2) of 30 to 35 mm Hg. The oxygen saturation of umbilical vein blood is similar but has a somewhat lower oxygen partial pressure (Ramsay, 1996). As noted earlier, fetal hemoglobin has a higher oxygen affinity than adult hemoglobin.

The placenta is highly permeable to CO_2, which traverses the chorionic villus by diffusion more rapidly than oxygen. Near term, the partial pressure of carbon dioxide ($Paco_2$) in the umbilical arteries averages 50 mm Hg, which is approximately 5 mm Hg higher than in the maternal intervillous blood. Fetal blood has less affinity for CO_2 than does maternal blood, thereby favoring CO_2 transfer from fetus to mother. Also, mild maternal hyperventilation results in a fall in $Paco_2$ levels, favoring a transfer of CO_2 from the fetal compartment to maternal blood.

SECTION 4

PRECONCEPTIONAL AND PRENATAL CARE

CHAPTER 8

Teratology, Teratogens, and Fetotoxic Agents

Birth defects are common. Of all newborns, 2 to 3 percent have a major congenital abnormality detectable at birth (Cragan, 2009; Dolk, 2010). Some medications undoubtedly pose significant risk to the developing embryo or fetus (Table 8-1). However, 80 percent of birth defects do not have an obvious etiology, and of those with an identified cause, nearly 95 percent of cases have chromosomal or genetic origins (Feldkamp, 2017). The U.S. Food and Drug Administration (FDA) (2018) estimates that <1 percent of all birth defects are caused by medications (Fig. 8-1).

That said, significant concern surrounds medication use in pregnancy. This is because many pregnant women are prescribed medications and because safety data are often lacking. Investigators from the National Birth Defects Prevention Study found that women take an average of two to three medications per pregnancy and that 70 percent use medication in the first trimester (Mitchell, 2011). A population-based review from Canada found that 65 percent of women fill ≥1 prescription during pregnancy (Leong, 2019). Between 2010 and 2019, the FDA approved 290 new drugs, and only 11 percent had human data related to pregnancy (Byrne, 2020).

TERATOLOGY

The study of birth defects and their etiology is termed teratology, derived from the Greek *teratos,* meaning monster. A *teratogen* may be broadly defined as any agent that acts during embryonic or fetal

TABLE 8-1. Selected Teratogenic and Fetotoxic Agents

Acitretin	Methotrexate
Alcohol	Mycophenolate
Angiotensin-converting enzyme inhibitors	Nitrofurantoin
Angiotensin-receptor blockers	Non-steroidal anti-inflammatory drugs
Bexarotene	Paroxetine
Carbamazepine	Phenobarbital
Cocaine	Phenytoin
Corticosteroids	Radioactive iodine
Cyclophosphamide	Ribavirin
Endothelin-receptor antagonists[a]	Sulfonamides
Fluconazole	Tamoxifen
Isotretinoin	Tetracyclines
Lead	Thalidomide and analogues[b]
Leflunomide	Tobacco
Lithium	Toluene
Marijuana	Topiramate
Mercury	Trastuzumab
Methamphetamine	Valproic acid
Methimazole	Warfarin

[a]Includes ambrisentan, bosentan, and macitentan.
[b]Includes lenalidomide and pomalidomide.

development to produce a permanent alteration of form or function. Thus, a teratogen may be a medication or other chemical substance, a physical or environmental factor such as heat or radiation, a maternal metabolite as in diabetes or phenylketonuria, or an infection such as cytomegalovirus.

Strictly defined, a teratogen causes structural abnormalities. A *hadegen*—after the god Hades—is an agent that interferes with normal maturation and function of an organ. A *trophogen* is an agent that alters growth. Substances in the latter two groups typically affect development in the fetal period or postnatally and are thus fetotoxins rather than teratogens.

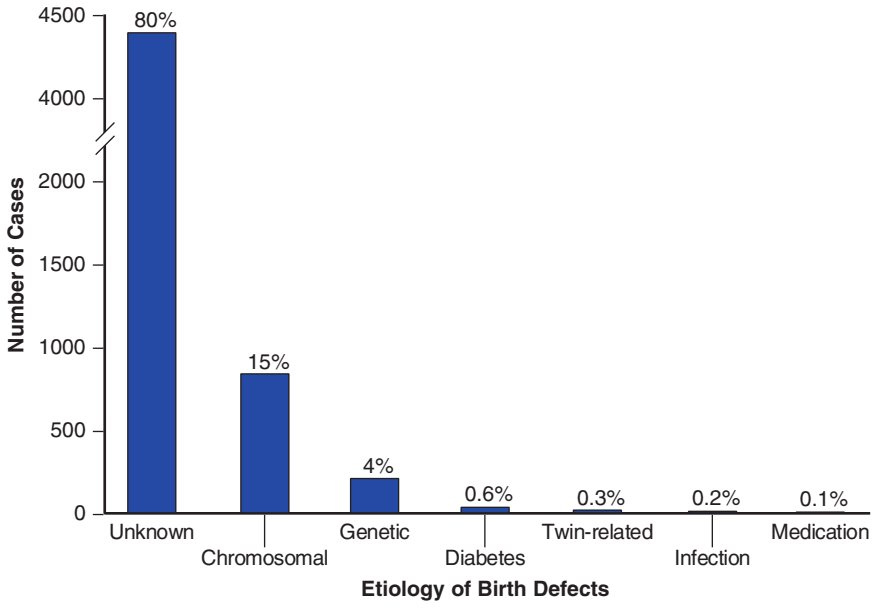

FIGURE 8-1 Etiology of birth defects. Known and unknown causes of 5504 birth defects from a population-based review of 270,878 births.

Criteria for Determining Teratogenicity

The guidelines shown in Table 8-2 were proposed by Shepard (1994) as a framework for discussion and have proved useful for nearly 30 years. Although each individual criterion is not required to establish teratogenicity, the following tenets should be considered (Shepard, 2002a):

- The abnormality has been completely characterized. This is preferably done by a geneticist or dysmorphologist because different genetic and environmental factors may produce similar defects. It is easiest to prove causation when a rare exposure produces a rare anomaly, when at least three cases with the same exposure have been identified, and when the defect is severe.
- The agent must cross the placenta. Although almost all drugs cross the placenta, transport must be of sufficient quantity to directly influence embryonic or fetal development or to alter maternal or placental metabolism to exert an indirect effect. Placental transfer depends on maternal metabolism; on specific characteristics of the drug, such as protein binding and storage, molecular size, electrical charge, and lipid solubility; and on placental metabolism, such as by the cytochrome P_{450} enzyme system. In early pregnancy, the placenta also has a relatively thick membrane that slows diffusion.
- Exposure must occur during a critical developmental period.
  - The *preimplantation period* is the 2 weeks between fertilization and implantation and is known as the "all or none" period. As the zygote undergoes cleavage, an insult damaging a large number of cells typically causes embryonic death. However, if only a few cells are injured, compensation may be possible and allow normal development.
  - The *embryonic period* extends from the second through the eighth week postconception. It encompasses organogenesis and is thus the most crucial period with regard to structural malformations. Critical developmental periods for each organ system are illustrated in Figure 7-2 (p. 122).
  - The *fetal period*, which is beyond 8 weeks postconception, is characterized by continued maturation and functional development. During this time, certain organs remain vulnerable.
- A biologically plausible association is supportive. Because birth defects and medication exposures are both common, they may be temporally but not causally related.
- Epidemiological findings must be consistent. Because initial evaluation of teratogen exposure is often retrospective, it may be hampered by recall bias, inadequate reporting, and

TABLE 8-2. Criteria for Determining Teratogenicity

Essential Criteria:

1. Careful delineation of clinical cases, particularly if there is a specific defect or syndrome
2. Proof that exposure occurred at a critical time during development (see Fig. 7-2, p. 122)
3. Consistent findings by at least two epidemiological studies with:
   a. exclusion of bias,
   b. adjustment for confounding variables,
   c. adequate sample size (power),
   d. prospective ascertainment if possible, and
   e. relative risk (RR) of 3.0 or greater, some recommend RR of 6.0 or greater

   or

   For a rare environmental exposure associated with a rare defect, at least three reported cases. This is easiest if the defect is severe.

Ancillary Criteria:

4. The association is biologically plausible
5. Teratogenicity in experimental animals is important but not essential
6. The agent acts in an unaltered form in an experimental model

incomplete assessment of the exposed population. Potential confounding factors include varying dosages, concomitant drug therapy, and comorbid maternal disease(s). Familial and environmental variables also can influence development of birth defects. Thus, an important criterion for teratogenicity is that two or more high-quality epidemiological studies report similar findings. Last, a relative risk of *3.0 or greater* is generally considered necessary to support the hypothesis, whereas a lesser risk is interpreted with caution (Khoury, 1992).

- The suspected teratogen causes a defect in animal studies. This criterion is not obligatory, and for litigation purposes, establishment of a causal relationship between an exposure and an outcome in humans requires human data (Teratology Society Public Affairs Committee, 2005).

Failure to employ these tenets and criteria has contributed to erroneous conclusions regarding the safety of some widely used drugs. The poster child for this is the medicolegal fiasco surrounding Bendectin. This antiemetic was a combination of doxylamine and pyridoxine, with or without dicyclomine. More than 30 million women used this drug worldwide, and it was safe and effective for nausea and vomiting in early pregnancy. The 3-percent congenital anomaly rate among exposed fetuses was not different from the background rate (McKeigue, 1994). Despite considerable evidence that this combination of an antihistamine and a B-vitamin is not teratogenic, Bendectin was the target of numerous lawsuits, and the financial burden of defending these forced its withdrawal from the marketplace in 1983. Consequently, hospitalization rates for hyperemesis doubled (Koren, 1998). Ironically, the combination of doxylamine and pyridoxine was subsequently remarketed under the brand name Diclegis and was approved by the FDA in 2013.

Studies in Pregnant Women

The study of medication safety—or teratogenicity—in pregnant women is fraught with complications. First, animal studies are necessary but insufficient. For example, thalidomide was considered harmless in several animal species but resulted in phocomelia in thousands of children born across Europe in the late 1950s and early 1960s. Second, medications are rarely approved by the FDA for a pregnancy-related indication. Despite the Common Rule's removal of pregnant women as a vulnerable population, pregnant women are routinely excluded from research (Health and Human Services, 2017; Spong, 2018). Last, drug concentration and thus embryo-fetal exposure are affected by pregnancy physiology. This includes changes in volume of distribution, cardiac output, gastrointestinal absorption, hepatic metabolism, and renal clearance. In the absence of research trials, counseling is based on case reports or series, case-control studies, cohort studies, and pregnancy registry data.

Case Reports and Series

Many major teratogens were first described by clinicians who observed a rare defect occurring after a rare exposure. This has been termed the "astute clinician model" (Carey, 2009). Congenital rubella syndrome was identified in this way by Gregg (1941), an Australian ophthalmologist whose observations challenged the view that the uterine environment was impervious to noxious agents. Other teratogens identified through case series include thalidomide and alcohol (Jones, 1973; Lenz, 1962). Shepard (2002a) recommended that establishment of teratogenicity in this way requires proven exposure at a critical time in development and at least three such cases. Unfortunately, teratogens are less likely to be identified if the exposure is uncommon, if the defects are relatively nonspecific, or if abnormalities develop in only a small proportion of exposed fetuses. A major limitation of case series is their lack of a control group.

Case-control Studies

These studies begin with groups of affected infants (cases) and unaffected controls and are structured to allow retrospective assessment of prenatal exposure to particular substances. Case-control studies are an efficient way to study rare outcomes (Alwan, 2015). These permit investigators to evaluate associations and generate useful hypotheses. However, case-control studies have inherent potential for *recall bias.* Namely, parents of an affected infant are often more likely to recall exposure than those whose child is not ill. Confounding by indication is another concern, that is, the indication for the medication may be the cause of the birth defect. And importantly, birth defect registries have statistical power to detect small differences that may not be clinically meaningful. Grimes and Schulz (2012) have cautioned that unless odds ratios in case-control studies are above three- to fourfold, the observed associations may not be correct.

The National Birth Defects Prevention Study. Funded by Congress and coordinated by the National Center on Birth Defects and Developmental Disabilities, the National Birth Defects Prevention Study (NBDPS) took place between 1997 and 2013 across ten states with active birth defects surveillance programs. It is an excellent example of a population-based case-control study. The study involved approximately 32,000 cases and nearly 12,000 controls. Live births, stillbirths, and terminated pregnancies were included. Clinical geneticists reviewed each potential case, and standardized telephone interviews were conducted with women whose pregnancies were affected or unaffected to obtain information regarding medication exposure and risk factors (Mitchell, 2011; Reefhuis, 2015).

The NBDPS identified novel—although often small—associations between individual birth defects and several classes of medications. These include antibiotics, antidepressants, antiemetics, antihypertensives, asthma medications, nonsteroidal antiinflammatory drugs (NSAIDs), and opioids (Ailes, 2016; Broussard, 2011; Fisher, 2018; Hernandez, 2012; Lin, 2012; Munsie, 2011). Pregestational diabetes was significantly associated with 46 of 50 different abnormalities studied (Tinker, 2020). The NBDPS also found associations between birth defects and exposures such as secondhand smoke, pesticides, and nitrogen oxide, which is a marker of traffic-related air pollution (Hoyt, 2016; Rocheleau, 2015; Stingone, 2017).

The NBDPS had several key limitations related to study design. First, interviews were conducted 6 weeks to 2 years following delivery, which raised the likelihood of recall bias. For example, 25 percent of women could not remember which

antibiotic they had taken (Ailes, 2016). Additionally, only two thirds of women agreed to participate, and there were differences in ethnicity and socioeconomic status between cases and controls. These factors may have contributed to selection bias (Reefhuis, 2015). Further, medical records were not reviewed to verify dosage, and this precluded assessment of dose-response relationships. Last, a major limitation was that because the NBDPS included only a small number of cases of each birth defect and analyzed them for many different maternal exposures, it was not possible to adjust for multiple comparisons. As a result, some of the observed associations were likely due to chance (Alwan, 2015). As one example, the study of antibiotics and birth defects included 43 comparisons and identified four significant associations, but chance alone predicted that two associations would be identified (Ailes, 2016).

Importantly, the NBDPS was able to identify statistically significant odds ratios for which the absolute risk was quite low. Such findings have the potential to complicate counseling and prenatal management. In many instances, the risk identified by the NBDPS was as low as 1 case per 1000 exposed pregnancies.

Cohort Studies

These studies begin with cohorts of pregnant women who are exposed or unexposed to a particular medication. The percentage of infants or children affected with birth defects is examined in each cohort. Because individual birth defects are rare, cohort studies require a *very* large sample size. Medicaid datasets and private insurance claims databases are commonly used for cohort studies of teratogenicity in the United States (Ehrenstein, 2010). Inability to adjust for confounding variables—such as the indication for which the medication was needed—is an important limitation of this study design.

Pregnancy Registries

Potentially harmful agents may be monitored by clinicians who prospectively enroll exposed pregnancies in a registry. The FDA (2021) maintains an active webpage of Pregnancy Exposure Registries. As of 2021, this included registries for 115 individual medications and for medication groups used to treat asthma, attention deficit hyperactivity disorder, autoimmune diseases, cancer, diabetes, epilepsy, hepatitis B and C, human immunodeficiency virus infection, hypercholesterolemia, inborn errors of metabolism, inflammatory bowel disease, multiple sclerosis, narcolepsy, psychiatric illness, and transplant rejection. Similar to case series, exposure registries are hampered by lack of a control group. The prevalence of an abnormality identified through a registry requires knowledge of the baseline prevalence of that anomaly in the population. Investigators typically use a birth defect registry to assess population prevalence. One example is the Metropolitan Atlanta Congenital Defects Program, which is an active surveillance program established in 1967 for fetuses and infants with birth defects.

COUNSELING FOR MEDICATION EXPOSURE

Questions regarding medication and illicit drug use should be part of routine preconceptional and prenatal care. Misinformation is common. Individuals tend to underestimate the background risk for birth defects in the general population and exaggerate potential risks associated with medication exposure. In one population-based study of more than 270,000 births from Utah that included 5500 fetuses and infants with major birth defects, only 4 cases were attributed to medication exposure (see Fig. 8-1) (Feldkamp, 2017). And yet, Koren and colleagues (1989) reported that a fourth of women exposed to nonteratogenic drugs thought they had a 25-percent risk for fetal anomalies. Misinformation may be amplified by inaccurate reports in the lay press. Knowledgeable counseling may allay anxiety considerably and may even avert pregnancy termination.

Several sources are available to assist providers with accurate and updated risk information. With recent changes to the FDA labeling requirements, discussed next, the manufacturer's prescribing information has become increasingly helpful. We recommend using this content for initial counseling. Published research studies can be identified using PubMed, a free database tool from the National Center for Biomedical Information. Additionally, online databases such as Reprotox, TERIS, and Shepard's Online Catalog of Teratogenic Agents offer detailed reviews of medication risks. Lactmed, a database from the National Library of Medicine, specifically deals with medication use by breastfeeding women. Its entries on specific medications describe levels in breast milk and potential effects on the infant.

Ultimately, it is the responsibility of the clinician to interpret risk information. Medication dosage and route, timing of exposure during pregnancy, other medications used, and underlying medical condition(s) are considered in this analysis. Last, the risk from lack of treatment also is weighed.

Labeling Requirements

In 1979, the FDA developed a letter classification system (A, B, C, D, X) to provide therapeutic guidance for prescribing medications in pregnancy. These letter categories were intended to simplify risk-benefit data using summary statements regarding available evidence from human or animal studies of embryonic–fetal risk. Unfortunately, information regarding medication risk was often incomplete and led to an overreliance on the category definition.

To address these deficiencies, new FDA (2014, 2020b) labeling requirements were created and went into effect in 2015. The label provides a framework to aid prescribing decisions by more clearly communicating risks and benefits. Information about each medication now incorporates a detailed summary of risks, clinical considerations, and available data (Table 8-3). Registry information is included when available. For each medication, a lactation subsection is provided, and a section addressing potential risks in females and males of reproductive potential is presented. In addition to risks associated with specific medications, the label is required to include the background risk of major birth defects and miscarriage in the general population. Because of the level of detail in the new labels, the information can be indispensable for counseling.

Presenting Risk Information

Counseling should cover not only the embryonic and fetal risks from drug exposure, but also the risks and/or genetic

TABLE 8-3. Food and Drug Administration Pregnancy Labeling Requirements

Label Subsection	Categories	Selected Specific Content
8.1 Pregnancy	Pregnancy exposure registry	Presence of a registry and contact information
	Risk summary	Structural abnormalities, embryo-fetal and/or infant mortality information, functional impairments, and alterations to growth
		Human data, animal data, and pharmacology information as an integrated summary
		Incidence of adverse outcomes, including dose effects, exposure duration, and gestational age
	Clinical considerations	Disease-associated maternal and embryo-fetal risks; dose adjustments (pregnancy or postpartum); maternal, fetal or neonatal adverse reactions; effects on labor or delivery
	Data	Content from human and animal studies and their findings and limitations
8.2 Lactation	Risk summary	Presence of a drug or its metabolite(s) in human milk, effects on the breastfed child, and effects on milk production
	Clinical considerations	Summary of available data and information about minimizing exposure
	Data	Includes content from human and animal studies that inform clinical considerations
8.3 Males and females of reproductive potential	Pregnancy testing	Testing requirement or recommendation before, during, or after drug use
	Contraception	Contraception requirement or recommendation before, during, or after drug use
	Infertility	Effects on fertility, potential reversibility, mutagenesis data, and pre-implantation loss effects

From Food and Drug Administration, 2020b.

implications of the condition for which the drug is administered. Risks associated with not treating the condition also are described. Even the manner in which information is presented affects perception. For example, women given negative information—such as a 2-percent chance of a malformed newborn—are more likely to perceive an exaggerated risk than women given positive information—such as a 98-percent chance of an unaffected infant (Jasper, 2001). Instead of citing a higher odds ratio, it may be helpful to provide the *absolute risk* for a particular defect or the *attributable risk*, which is the difference between prevalence in exposed and unexposed individuals (Conover, 2011). The association between oral corticosteroid medications and cleft lip sounds far more concerning when presented as a tripling or 200-percent increase in risk than when described as an increase from 1 to 3 cases per 1000 or as a 99.7-percent likelihood of no cleft development following exposure.

With a few notable exceptions, most commonly prescribed drugs and medications can be used with relative safety during pregnancy. Many drugs discussed in this chapter are *low-risk teratogens*, which are medications that produce defects in fewer than 10 per 1000 maternal exposures (Shepard, 2002a). Because risks conferred by low-risk teratogens are so close to the population background rate of fetal anomalies, they may not be a major factor in deciding whether to discontinue treatment for an important condition (Shepard, 2002b). All women have an approximate 3-percent chance of having a fetus or newborn with a major anomaly. Although exposure to a confirmed teratogen may elevate this risk, the magnitude of the increase is usually only 1 or 2 percent or at most, doubled or tripled. The concept of risk versus benefit is often central to counseling. Some untreated diseases pose a more serious threat to both mother and fetus than medication exposure risks.

TERATOGENIC AND FETOTOXIC AGENTS

Considering the thousands of compounds available, relatively few medications and other substances are considered to be major human teratogens or to have significant fetotoxicity. The most common examples are listed in Table 8-1. With few exceptions, in every clinical situation potentially requiring therapy with a known teratogen, alternative drugs can be given with relative safety. Realizing limitations in available evidence, pregnant women should be advised to take any medication only when it is clearly needed. Detailed sonography is generally indicated if the fetus has been exposed to any major teratogen during the embryonic period.

Alcohol

Ethanol is a potent and prevalent teratogen. It is considered the leading cause of preventable developmental disabilities

worldwide (Hoyme, 2016). In the United States, alcohol use is reported by 10 percent of pregnant women (England, 2020). Nearly 10 percent of such women admit to binge drinking in the first trimester, and 1 percent report binge drinking in the second and third trimesters.

The fetal effects of alcohol abuse have been recognized since the 1800s. Lemoine (1968) and Jones (1973) and their coworkers are credited with describing the spectrum of alcohol-related fetal defects known as *fetal alcohol syndrome.* Criteria are shown in Table 8-4 (Hoyme, 2016). For every child with the syndrome, many more are born with neurobehavioral deficits from alcohol exposure. *Fetal alcohol spectrum disorder (FASD)* is an umbrella term that includes five conditions attributed to prenatal alcohol damage: (1) fetal alcohol syndrome, (2) partial fetal alcohol syndrome, (3) alcohol-related birth defects, (4) alcohol-related neurodevelopmental disorder, and (5) neurobehavioral disorder associated with prenatal alcohol exposure (Williams, 2015). The prevalence of FASD exceeds 1 percent in 76 countries, and 1 in 13 women who consume alcohol in pregnancy has a child with FASD (Lange, 2017). The birth prevalence of fetal alcohol syndrome is estimated to be as high as 1 percent in the United States (Centers for Disease Control, 2015; Guerri, 2009). Further, studies of school-aged children have identified FASD in 2 to 5 percent (May, 2009, 2014).

TABLE 8-4. Criteria for Prenatal Alcohol Exposure, Fetal Alcohol Syndrome, and Alcohol-Related Birth Defects

Documented Prenatal Alcohol Exposure—One or More Required

1. ≥6 drinks per week for ≥2 weeks
2. ≥3 drinks per occasion for ≥2 occasions
3. Risk identified with a validated screening questionnaire
4. Laboratory testing indicating alcohol intoxication or positive alcohol-exposure biomarker
5. Documentation of an alcohol-related legal or social problem

Fetal Alcohol Syndrome Diagnostic Criteria—All Required

1. Dysmorphic facial features (≥2 required)
   a. Short palpebral fissures
   b. Thin vermilion border of the upper lip
   c. Smooth philtrum
2. Prenatal and/or postnatal growth impairment, ≤10th percentile
3. Abnormal brain growth, morphogenesis, or physiology (≥1 required)
   a. Head circumference ≤10th percentile
   b. Structural brain abnormalities
   c. Recurrent nonfebrile seizures
4. Neurobehavioral impairment (defined as >1.5 SD below mean)
   a. Child <3 years: developmental delay
   b. Child ≥3 years: global cognitive impairment, or cognitive deficit in at least 1 neurobehavioral domain, or behavioral deficit in at least 1 domain

Alcohol-Related Birth Defects

Cardiac: atrial or ventricular septal defect, aberrant great vessels, conotruncal heart defects
Skeletal: radioulnar synostosis, vertebral segmentation defects, joint contractures, scoliosis
Renal: aplastic or hypoplastic kidneys, dysplastic kidneys, horseshoe kidney, ureteral duplication
Eyes: strabismus, ptosis, retinal vascular abnormalities, optic nerve hypoplasia
Ears: conductive or neurosensory hearing loss

SD = standard deviation.

Criteria

Fetal alcohol syndrome has specific criteria (see Table 8-4). These include central nervous system (CNS) abnormalities, pre- or postnatal growth impairment, and a characteristic pattern of minor facial abnormalities (Fig. 8-2). Similar criteria have been established for the other conditions that make up FASD (Hoyme, 2016). Prenatal alcohol exposure criteria also are available to assist with assessment.

Alcohol-related birth defects include cardiac and renal anomalies, orthopedic problems, and abnormalities of the eyes and ears (see Table 8-4). An association has further been reported between periconceptional alcohol use and omphalocele and gastroschisis (Richardson, 2011). There are no established sonographic criteria for prenatal diagnosis of fetal alcohol syndrome. At Parkland Hospital, we reserve detailed sonography for pregnancies that have met the exposure criteria listed in Table 8-4. Third-trimester assessment of fetal growth also should be considered.

Fetal vulnerability to alcohol is modified by genetic and environmental factors, nutritional status, coexisting maternal disease, and maternal age (Abel, 1995). Binge drinking, however, is believed to pose particularly high risk for alcohol-related birth

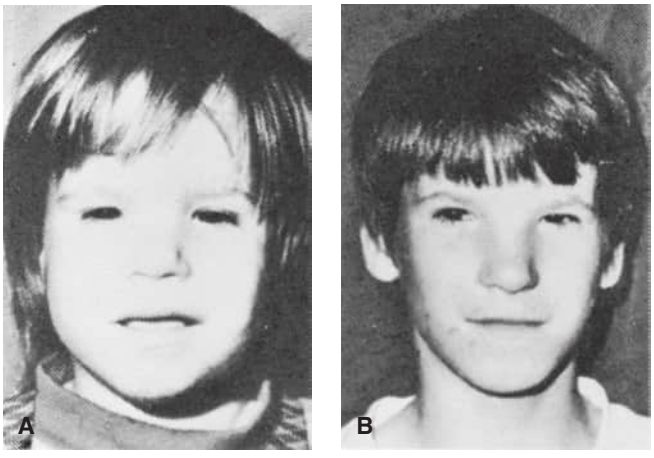

FIGURE 8-2 Fetal alcohol syndrome. **A.** At 2½ years. **B.** At 12 years. Note persistence of short palpebral fissures, epicanthal folds, flat midface, hypoplastic philtrum, and thin upper vermilion border. (Reproduced with permission from Streissguth AP, Clarren, SK, Jones KL. Natural history of fetal alcohol syndrome: a 10-year follow-up of eleven patients, Lancet. 1985 Jul 13;2(8446):85–91.)

defects and has also been linked to a greater risk for stillbirth (Centers for Disease Control, 2015; Strandberg-Larsen, 2008). The American College of Obstetricians and Gynecologists, Centers for Disease Control and Prevention (CDC), and the American Academy of Pediatrics have stressed that *no* amount of alcohol can be considered safe in pregnancy (American College of Obstetricians and Gynecologists, 2020a; Williams, 2015).

Antiepileptic Medications

Traditionally, women with epilepsy requiring treatment with medication were informed that their risk for fetal malformations was increased. More recent data suggest that the risk may not be as great as once thought, particularly for newer agents. The most frequently reported anomalies are orofacial clefts, cardiac malformations, and neural-tube defects.

Of agents in current use, valproic acid confers the highest risk (Vajda, 2016). The North American Antiepileptic Drug (NAAED) Pregnancy Registry reported that major malformations developed in 9 percent of fetuses with first-trimester valproate exposure. This included a 4-percent risk for neural-tube defects (Hernandez-Diaz, 2012). School-aged children with prior in utero exposure to valproic acid have poorer cognitive development—including significantly lower intelligence quotient (IQ) scores—than children exposed to other antiepileptic drugs (Bromley, 2014; Meador, 2009).

Regarding other specific anticonvulsants, one metaanalysis identified increased malformation rates among exposed children compared with rates among children born to women with untreated epilepsy. Rates were twofold higher among children exposed to carbamazepine or phenytoin, threefold higher among those exposed to phenobarbital, and fourfold higher among those exposed to topiramate as monotherapy (Weston, 2016). The risk for fetal malformations is approximately doubled if multiple agents are required (Vajda, 2016). Several older anticonvulsants may produce a constellation of findings similar to the *fetal hydantoin syndrome*. The syndrome is characterized by distinctive features such as hypertelorism, low nasal bridge, and midface hypoplasia; hypoplasia of the distal phalanges and nails; growth impairment; and intellectual disability.

Importantly, evidence to date suggests that these risks do not appear to hold for the newer agents levetiracetam and lamotrigine (Mølgaard-Nielsen, 2011; Weston, 2016). A review of 208 pregnancies with first-trimester lamotrigine exposure from the Israeli Teratology Information Service found no increase in the rate of major malformations and no case of oral cleft (Diav-Citrin, 2017). Similarly, the International Lamotrigine Pregnancy Registry followed more than 1500 pregnancies with first trimester exposure and observed no effect on the rate of major malformations (Cunnington, 2011). The Motherisk Program reviewed eight studies of levetiracetam and concluded that monotherapy was associated with a 2-percent major malformation rate, no different from that for the general population (Chaudhry, 2014). More recently, a review of 465 pregnancies reported to the Levetiracetam Pregnancy Registry found no evidence of teratogenicity (Scheuerle, 2019).

Providers are encouraged to enroll pregnant women treated with antiepileptic medication in the NAAED Pregnancy Registry. Management of epilepsy in pregnancy is discussed in Chapter 63 (p. 1128).

Angiotensin-converting Enzyme Inhibitors and Receptor Blocking Drugs

These medications may result in *angiotensin-converting enzyme (ACE)-inhibitor fetopathy*. Normal renal development depends on the fetal renin-angiotensin system. ACE-inhibitor medication may cause fetal hypotension and renal hypoperfusion, with subsequent ischemia and anuria (Guron, 2000; Pryde, 1993). Reduced perfusion can result in fetal-growth restriction and calvarium maldevelopment, and oligohydramnios may lead to pulmonary hypoplasia and limb contractures (Barr, 1991). Because angiotensin-receptor blockers have a similar mechanism of action, concerns regarding fetotoxicity have been generalized to include this entire medication class. A recent review of nearly 200 pregnancies from teratology information services found a 30-percent fetopathy risk with angiotensin-receptor blockers compared with a 3-percent risk with ACE-inhibitor exposure beyond 20 weeks' gestation (Weber-Schoendorfer, 2020).

Concerns about ACE-inhibitor embryotoxicity have largely been disproven. In 2006, a review of 29,000 infants from the Tennessee Medicaid database identified a two- to threefold greater risk for neonatal cardiac and CNS abnormalities among the 209 that had prenatal ACE-inhibitor exposure (Cooper, 2006). Subsequent larger studies have not corroborated these observations. In a retrospective cohort study of more than 460,000 pregnancies, risks for birth defects were not higher with ACE inhibitors than with other antihypertensive medications (Li, 2011). Similarly, a review of 1.3 million pregnancies from the Medicaid Analytic eXtract found no increased risk for any malformation with ACE-inhibitor exposure after adjusting for confounding factors such as diabetes (Bateman, 2017). Thus, women with inadvertent first-trimester exposure to these medications may be reassured. Importantly, given the many therapeutic options for treating hypertension during pregnancy, discussed in Chapter 53 (p. 949), ACE inhibitors and angiotensin receptor-blocking drugs should be avoided in pregnancy.

Antifungal Medications

From this class of drugs, fluconazole has been associated with a pattern of congenital malformations resembling the autosomal recessive *Antley-Bixler syndrome*. Abnormalities include oral clefts, abnormal facies, and cardiac, skull, long-bone, and joint abnormalities. Such findings have been reported only with chronic, first-trimester, high-dose treatment at doses of 400 to 800 mg daily.

Regarding low-dose treatment of vulvovaginal candidiasis, the Motherisk Program conducted a systematic review of pregnancies with first-trimester oral fluconazole exposure of 150 or 300 mg in total (Alsaad, 2015). The overall risk for birth defects was not greater, although a small increase in rates of cardiac malformations could not be excluded. A population-based cohort study from Denmark identified a threefold greater

risk for tetralogy of Fallot following exposure to low-dose fluconazole (Mølgaard-Nielsen, 2013). The birth prevalence of tetralogy of Fallot rose from 3 to 10 cases per 10,000. Notably, investigators did not identify increased risks for 14 other birth defects previously associated with exposure to high-dose azole antifungal agents (Mølgaard-Nielsen, 2013). A subsequent review of more than 37,000 pregnancies with first-trimester fluconazole exposure did not identify an association with cardiac abnormalities (Zhu, 2020). Based on reported risks, we do not perform detailed sonography or fetal echocardiography following low-dose fluconazole exposure.

Antiinflammatory Agents

Nonsteroidal Antiinflammatory Drugs

This drug class includes both aspirin and traditional NSAIDs such as ibuprofen and indomethacin. They exert their effects by inhibiting prostaglandin synthesis. In a report from the NBDPS, at least 20 percent of pregnant women recall first-trimester NSAID use, particularly ibuprofen and aspirin, and such exposure is not a major risk factor for birth defects (Hernandez, 2012).

When taken in late pregnancy, however, indomethacin may cause constriction of the fetal ductus arteriosus and subsequent pulmonary hypertension. Fetal ductal constriction is more likely with third trimester use that exceeds 72 hours. The drug also may decrease fetal urine production and amnionic fluid volume (Rasanen, 1995; van der Heijden, 1994; Walker, 1994). In one systematic review, indomethacin tocolysis was associated with a 1.5-fold risk for bronchopulmonary dysplasia, intraventricular hemorrhage, and necrotizing enterocolitis (Hammers, 2015a,b).

Based on a review of 35 cases of oligohydramnios or neonatal kidney problems reported to the FDA Adverse Event Reporting System database, the FDA recommends that pregnant women ≥20 weeks' gestation avoid NSAID use (Food and Drug Administration, 2020a). If NSAIDs are needed for more than 48 hours, ultrasound evaluation of amnionic fluid should be considered. Oligohydramnios usually resolves within 6 days of discontinuing NSAIDs, but there are cases in which infants have died of renal failure.

With aspirin, a low dosage of 100 mg daily or less does *not* confer a greater risk for constriction of the ductus arteriosus or for adverse infant outcomes (Grab, 2000). As with other NSAIDs, however, high-dose aspirin use should be avoided, particularly in the third trimester.

Leflunomide

This is a pyrimidine-synthesis inhibitor used to treat rheumatoid arthritis. Leflunomide is considered contraindicated in pregnancy. In rats and rabbits, leflunomide results in hydrocephalus, eye anomalies, skeletal anomalies, and embryo death when given at or below human-equivalent doses (Sanofi-Aventis, 2016). The active metabolite, teriflunomide, is detectable in plasma for up to 2 years following discontinuation of the medication. Women who become pregnant while taking leflunomide, and even those of childbearing potential who have discontinued it, are recommended to undergo an accelerated drug elimination procedure with either cholestyramine or activated charcoal (Sanofi-Aventis, 2016).

Reassuringly, studies of exposed human pregnancies have not confirmed these teratogenic effects (Berard, 2018; Chambers, 2010). In a cohort of 60 women with first-trimester leflunomide exposure who completed cholestyramine washout, the rate of birth defects was not increased (Chambers, 2010). A recent review of more than 500 exposed pregnancies found that the rate of major birth defects was 3 percent, similar to the general population (Henson, 2020). The rate of spontaneous abortion also was not increased.

Antimicrobial and Antiviral Drugs

Medications used to treat infections are among those most frequently administered during pregnancy. Over the years, experience has accrued regarding their general safety. With few exceptions, commonly used antimicrobial agents are without embryo-fetal safety concerns.

Nitrofurantoin

From NBDPS results, first-trimester nitrofurantoin exposure is linked to a twofold risk for cleft lip (Ailes, 2016). Considering that the birth prevalence of clefts approximates 1 case per 1000, the likelihood that a nitrofurantoin-exposed fetus would *not* have a cleft would thus be 998 per 1000. For other birth defects, initial associations with this antibiotic did not persist in the final NBDPS cohort (Ailes, 2016).

In one systematic review of nitrofurantoin exposure in pregnancy, results of cohort and case-control studies differed (Goldberg, 2015). Five cohort studies included 9275 exposed pregnancies and nearly 1.5 million unexposed pregnancies, and the review found no higher risk for any malformation. However, among three case-control studies that had nearly 40,000 cases matched with 130,000 controls, the rate of hypoplastic left heart syndrome was threefold greater (Goldberg, 2015). For context, this increase in risk would result in a birth prevalence of fewer than 1 case per 1000 exposed infants. Nitrofurantoin is considered contraindicated in pregnant women with known or suspected glucose-6-phosphate dehydrogenase (G6PD) deficiency because of risk for hemolytic anemia and other hematologic abnormalities. In the absence of G6PD deficiency, the There are no concerns with second- or third-trimester nitrofurantoin use, and first-trimester use is appropriate if no suitable alternatives are available.

Sulfonamides

These drugs are often combined with trimethoprim and used to treat infections during pregnancy. One indication is treatment of methicillin-resistant *Staphylococcus aureus (MRSA)* infection. The NBDPS, which included 107 pregnancies with periconceptional trimethoprim-sulfamethoxazole exposure and birth defects, identified a fivefold greater risk to have offspring with esophageal atresia or diaphragmatic hernia (Ailes, 2016). Similar to findings with nitrofurantoin exposure, this degree of increase would confer a risk of approximately 1 case per 1000 exposed infants for these selected birth defects. However, these findings have not been corroborated by other reports. One review from the Medication Exposure in Pregnancy Risk Evaluation Program included more than 7500 infants with first-trimester exposure

to trimethoprim-sulfamethoxazole (Hansen, 2016). Compared with either unexposed infants or those exposed to penicillins or cephalosporins, no higher risk for any congenital abnormality was identified. Given this reassuring data, we consider sulfonamides appropriate for first-trimester use if suitable alternatives are lacking.

Sulfonamides are considered contraindicated in pregnant women with known or suspected G6PD deficiency because of risk for hemolytic anemia and other hematologic abnormalities. Additionally, sulfonamides displace bilirubin from protein-binding sites. Thus, if given near the time of preterm delivery, these agents theoretically might worsen neonatal hyperbilirubinemia. However, a population-based review of more than 800,000 births from Denmark found no association between exposure to sulfamethoxazole in late pregnancy and neonatal jaundice (Klarskov, 2013).

Tetracyclines

These drugs are not commonly used in pregnant women. They have been associated with yellowish-brown discoloration of the deciduous teeth when used after 25 weeks' gestation. The risk for subsequent dental caries is not increased (Billings, 2004; Kutscher, 1966). Doxycycline has a reduced ability to chelate calcium orthophosphate compared with other tetracyclines and is preferred if needed. A systematic review of doxycycline-exposed pregnancies identified no higher rates of either birth defects or staining of deciduous teeth (Cross, 2016).

Ribavirin

This antiviral nucleoside analogue is a component of therapy for hepatitis C infection, discussed in Chapter 58 (p. 1038). Ribavirin causes birth defects in multiple animal species at doses significantly lower than those recommended for human use. Reported malformations include skull, palate, eye, skeleton, and gastrointestinal abnormalities. The drug has a half-life of 12 days and persists in extravascular compartments following therapy discontinuation. Treated women must use two forms of contraception and have monthly pregnancy tests while on therapy and for 6 months following drug discontinuation (Merck, 2020). Ribavirin use is also contraindicated in men whose partners are pregnant.

■ Antineoplastic Agents

Cancer management in pregnancy includes many chemotherapeutic agents generally considered to be at least potentially toxic to the embryo, fetus, or both. For the many novel polyclonal antibody therapies designated as antineoplastics, there is little information concerning safety. The National Toxicology Program (2013) conducted a review of 300 pregnancies with first-trimester exposure and identified major malformations in 14 percent. Treatment of cancer in pregnancy is discussed in Chapter 66 (p. 1163). Risks associated with selected agents for which experience in pregnancy has accrued are considered next.

Cyclophosphamide

This alkylating agent inflicts a chemical insult on developing fetal tissues and leads to cell death and heritable DNA alterations in surviving cells. Pregnancy loss rates are greater, and reported fetal abnormalities include skeletal anomalies, limb defects, cleft palate, and eye abnormalities (Enns, 1999; Kirshon, 1988). The risk for a major abnormality is estimated to be 18 percent (National Toxicology Program, 2013). Surviving infants may have growth abnormalities and developmental delays. Environmental exposure among health-care workers is associated with a higher risk for spontaneous abortion.

Methotrexate

This folic-acid antagonist is a potent teratogen. It is used for cancer chemotherapy, immunosuppression of autoimmune diseases and psoriasis, nonsurgical treatment of ectopic pregnancy, and medical abortion. It acts similarly to aminopterin, which is no longer used clinically, and can cause defects known collectively as the fetal *methotrexate-aminopterin syndrome*. Associated craniofacial abnormalities include craniosynostosis with a "clover-leaf" skull, wide nasal bridge, low-set ears, and micrognathia (Del Campo, 1999). Exposure has also been linked to central nervous system abnormalities, cardiac defects, and limb anomalies (Cumberland Pharmaceuticals, 2020). Intellectual impairment has been described. The embryo is thought to be most vulnerable at 8 to 10 weeks postconception and at dosages of at least 10 mg/week. However, this is not universally accepted (Feldkamp, 1993). Because of its distribution, methotrexate can remain in the body for prolonged periods. Thus, preconceptional exposure is not without risk.

The standard 50-mg/m^2 dose given to treat ectopic pregnancy or to induce abortion exceeds the 10-mg/week threshold dose. Reports describe cardiac anomalies, particularly conotruncal defects, in intrauterine pregnancies inadvertently treated with methotrexate for suspected ectopic pregnancy (Dawson, 2014; Hyoun, 2012).

Tamoxifen

This nonsteroidal selective estrogen-receptor modulator (SERM) is used as an adjuvant to treat breast cancer. In animal studies, tamoxifen has been associated with malformations similar to those caused by diethylstilbestrol (DES) exposure in rodents, including vaginal adenosis. One review of 167 pregnancies reported a fetal abnormality in 13 percent but emphasized that evidence was limited (Schuurman, 2019). Abnormalities have included ambiguous genitalia and craniofacial anomalies.

Trastuzumab

This is a recombinant monoclonal antibody directed to the human epidermal growth factor receptor 2 (HER2) protein. Used to treat breast and gastric cancers that express HER2 protein, this drug has not been associated with fetal malformations. However, postmarketing surveillance identified cases of oligohydramnios sequence resulting in pulmonary hypoplasia, renal failure, skeletal abnormalities, and neonatal death (Genentech, 2020). Surveillance for these complications is recommended for exposed pregnancies and for those treated at any time in the 7 months prior to conception. A trastuzumab pregnancy exposure registry and a pregnancy pharmacovigilance program have been established to monitor pregnancy outcomes. These warnings also apply to those treated with ado-trastuzumab emtansine.

Endothelin-receptor Antagonists

Bosentan, ambrisentan, and macitentan are three endothelin-receptor antagonists used to treat pulmonary arterial hypertension (Chap. 52, p. 930). The endothelin-receptor signaling pathway is important for neural-crest development. Mice deficient in endothelin receptors develop neural-crest cell defects that include craniofacial and cardiac outflow tract abnormalities (de Raaf, 2015). Each of these three agents has been found to cause similar birth defects in multiple animal species (Janssen, 2019a,b). No human data are available. Endothelin-receptor antagonists may be obtained only through restricted access programs, each of which has stringent requirements that include contraception and monthly pregnancy testing (Gilead, 2019; Janssen, 2019a,b).

Immunosuppressant Medications

Selected autoimmune diseases and their treatment are reviewed in Chapter 62 (p. 1109).

Corticosteroids

Glucocorticoids and mineralocorticoids have antiinflammatory and immunosuppressive actions. They are used to treat serious disorders such as asthma and autoimmune disease. Corticosteroids have been associated with orofacial clefts in animal studies, but the absolute risk is small. In a metaanalysis of case-control studies by the Motherisk Program, systemic corticosteroid exposure was associated with a threefold rate increase, conferring an absolute risk of 3 clefts per 1000 exposed fetuses (Park-Wyllie, 2000). A 10-year prospective cohort study by the same group, however, did not identify an increased overall risk for major malformations. Based on these findings, corticosteroids are not considered to represent a major teratogenic risk.

Potential risks associated with prednisone or methylprednisolone are considered to be lower than those with other corticosteroids. Prednisolone, the active metabolite of prednisone, is itself metabolized and rendered inactive by the placental enzyme 11β-hydroxysteroid dehydrogenase 2 (Murphy, 2007). Thus, it is thought to reach the fetus less effectively.

Mycophenolate Mofetil

This inosine monophosphate dehydrogenase inhibitor, and a related agent, mycophenolic acid, are immunosuppressants. They are used to prevent rejection in organ-transplant recipients and to treat autoimmune disease (Chap. 62, p. 1112). Mycophenolate is a potent teratogen. From the National Transplantation Pregnancy Registry, of pregnancies in which mycophenolate was not discontinued until after the first trimester, birth defects complicated 30 percent, and another 30 percent spontaneously aborted (King, 2017). One prospective review by the European Network of Teratology Information Services similarly identified a spontaneous loss rate of nearly 30 percent in exposed pregnancies. More than 20 percent of liveborn infants had major anomalies (Hoeltzenbein, 2012).

Many affected infants have a pattern of defects termed *mycophenolate embryopathy*. This includes microtia, auditory canal atresia, clefts, coloboma and other eye anomalies, short fingers with hypoplastic nails, and cardiac defects (Anderka, 2009; Merlob, 2009). A Risk Evaluation and Mitigation Strategy (REMS) has been developed for mycophenolate prescribers who treat women with reproductive potential. REMS are safety strategies mandated by the FDA to help manage known risks associated with a medicine yet still allow patients to have access to the benefits of a given drug.

Lead

Lead crosses the placenta via passive diffusion. Prenatal lead exposure is associated with fetal-growth impairment and with childhood neurodevelopmental delays. According to the CDC (2010), no level of lead exposure is considered safe in pregnancy. Although routine testing is not recommended, risk factors should be assessed in all pregnancies (American College of Obstetricians and Gynecologists, 2019a). Care and testing for at-risk pregnancies is discussed in Chapter 10 (p. 188).

Mercury

The developing nervous system is particularly susceptible to mercury. In the 1950s and early 1960s, children born near Minamata Bay, Japan were found to have congenital Minamata disease—severe neurological abnormalities from methylmercury exposure in utero (Yorifuji, 2020). Prenatal exposure causes disturbances in neuronal cell division and migration. This leads to a range of defects from microcephaly to intellectual disability, choreo-athetoid movement abnormalities, motor delays, and behavioral abnormalities (Grandjean, 2011).

The principal concern for prenatal mercury exposure is the consumption of certain species of large fish and seafood (Chap. 10, p. 188). Methylmercury cannot be eliminated by cooking. It crosses the placenta and can accumulate in the fetus. The FDA (2019) advises that pregnant women and breastfeeding mothers avoid consumption of king mackerel, marlin, orange roughy, shark, swordfish, tilefish, and bigeye tuna.

Psychiatric Medications

Treatment of psychiatric illness in pregnancy, including a discussion of the risks and benefits of various psychiatric medications, is described in Chapter 64 (p. 1142).

Antipsychotic Medications

No antipsychotic medications are considered teratogenic. Exposed neonates can manifest abnormal extrapyramidal muscle movements and withdrawal symptoms that include agitation, abnormally enhanced or diminished muscle tone, tremor, agitation, somnolence, respiratory abnormalities, and feeding difficulty. Such findings are nonspecific and transient. An FDA (2017) alert cited all medications in this class. Included are older medications like haloperidol and chlorpromazine and newer medications such as aripiprazole, olanzapine, quetiapine, and risperidone.

Lithium

This medication has been associated with Ebstein anomaly, a rare cardiac abnormality that otherwise complicates only 1

per 20,000 births. Ebstein anomaly is characterized by apical displacement of the tricuspid valve, often resulting in severe tricuspid regurgitation and marked right atrial enlargement. A report from the Lithium Baby Registry initially suggested that the risk for Ebstein anomaly was as high as 3 percent. However, subsequent series have identified an attributable risk for Ebstein anomaly and co-occurring right-sided cardiac anomalies of only 1 to 4 cases per 1000 exposed pregnancies (Patorno, 2017; Yacobi, 2008). The NBDPS found that just 1 of 135 cases of Ebstein anomaly occurred in the setting of lithium exposure (Downing, 2019).

Neonatal lithium toxicity stems from exposure near delivery. The manufacturer recommends that if possible, the dosage should be decreased or drug discontinued 2 to 3 days prior to delivery to reduce this risk (West-Ward, 2020). Findings may persist for up to 2 weeks and may include cardiac arrhythmias, hypoglycemia, nephrogenic diabetes insipidus, and a "floppy infant syndrome" (American College of Obstetricians and Gynecologists, 2019f). The latter may include hypotonia, respiratory distress or apnea, bradycardia, cyanosis, and feeding difficulties (West-Ward, 2020).

Selective Serotonin- and Norepinephrine-reuptake Inhibitors

These medications have been studied more than almost any other, apart from Bendectin (p. 146). As a class, they are not considered major teratogens (American College of Obstetricians and Gynecologists, 2019f). The one exception is paroxetine, which has been associated with a slightly higher risk for cardiac anomalies, particularly atrial and ventricular septal defects. Metaanalyses have identified a pooled odds ratio of just 1.3 for paroxetine and cardiac abnormalities (Berard, 2016; Wurst, 2010). However, a review of nearly 1 million pregnancies from the nationwide Medicaid Analytic eXtract identified no significant association between paroxetine use in the first trimester and fetal cardiac abnormalities (Huybrechts, 2014). The American College of Obstetricians and Gynecologists (2019f) recommends that women planning pregnancy avoid paroxetine. Fetal echocardiography should be considered for those with first-trimester paroxetine exposure.

Neonatal effects have been associated with prenatal exposure to selective serotonin-reuptake inhibitors (SSRIs) and selective norepinephrine-reuptake inhibitors (SNRIs). Approximately 25 percent of neonates exposed to SSRIs in late pregnancy manifest one or more nonspecific findings considered to represent poor neonatal adaptation (Costei, 2002; Jordan, 2008). Collectively termed the *neonatal behavioral syndrome*, findings can include jitteriness, irritability, hyper- or hypotonia, feeding abnormalities, vomiting, hypoglycemia, thermoregulatory instability, and respiratory abnormalities. Fortunately, these neonatal behaviors are typically mild and self-limited and last approximately 2 days. Jordan and coworkers (2008) reported that affected newborns were not more likely to require a higher level of care, to experience respiratory abnormalities, or to have prolonged hospitalization. Rarely, neonates exposed to SSRIs in late pregnancy have demonstrated more severe adaptation abnormalities (Ornoy, 2017).

Another concern with late-pregnancy exposure is the possible association of SSRI medications with *persistent pulmonary hypertension of the newborn (PPHN)*. The baseline incidence approximates 2 cases per 1000 term newborns. PPHN is characterized by elevated pulmonary vascular resistance with right-to-left shunting and resultant hypoxemia. Two population-based cohort studies—together involving more than 5 million pregnancies—identified an attributable risk of only 1 to 2 cases per 1000 births (Huybrechts, 2015; Kieler, 2012). Moreover, cases of PPHN associated with SSRI medication have not been severe (Ornoy, 2017).

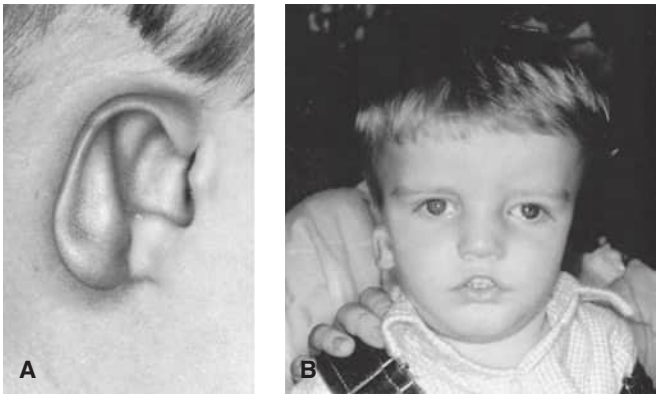

FIGURE 8-3 Retinoic acid embryopathy. **A.** Bilateral microtia or anotia with stenosis of external ear canal. **B.** Flat, depressed nasal bridge and ocular hypertelorism. (Reproduced with permission from permission from Dr. Edward Lammer.)

■ Retinoids

Vitamin A derivatives are among the most potent human teratogens. By inhibiting neural-crest cell migration during embryogenesis, they create a pattern of cranial neural-crest defects—termed *retinoic acid embryopathy*—that involve the CNS, face, heart, and thymus (Fig. 8-3). Specific anomalies may include ventriculomegaly, maldevelopment of the facial bones or cranium, microtia or anotia, micrognathia, cleft palate, conotruncal heart defects, and thymic aplasia or hypoplasia.

Acitretin

This retinoid is used to treat severe psoriasis. It was introduced to replace etretinate, a lipophilic retinoid with such a long half-life (120 days) that birth defects resulted more than 2 years after therapy was discontinued. Although acitretin has a short half-life, it is metabolized to etretinate, and thus remains in the body for prolonged periods (Stiefel Laboratories, 2017). To obviate exposure, the manufacturer of acitretin has developed a pregnancy risk management program. Called "Do Your P.A.R.T"—pregnancy prevention actively required during and after treatment, this program promotes a delay of conception for at least 3 years following therapy discontinuation.

Bexarotene

This retinoid is used to treat refractory cutaneous T-cell lymphoma. When given to rats in doses comparable to those for human therapy, fetuses developed eye and ear abnormalities, cleft palate, and incomplete ossification. For a woman to receive bexarotene, the manufacturer requires two forms of contraception that are initiated 1 month before therapy and continued

for 1 month after it is discontinued. This is coupled with monthly pregnancy testing during treatment (Bausch Health, 2020). Males who have partners who could become pregnant are advised to use condoms during sexual intercourse while taking bexarotene and for 1 month after discontinuing therapy.

Isotretinoin

13-*cis*-Retinoic acid is a vitamin A isomer that stimulates epithelial cell differentiation. It is primarily used to treat recalcitrant nodular acne. First-trimester exposure is associated with a high rate of pregnancy loss, and up to a third of infants have malformations (Lammer, 1985). The iPLEDGE program is an FDA-mandated REMS for isotretinoin and is found at www.ipledgeprogram.com. This web-based, restricted-distribution program requires participation for all patients, physicians, and pharmacies to help eliminate embryo–fetal exposure. Other countries have instituted similar programs, however, inadvertent exposure remains a global concern (Autret-Leca, 2010; Crijns, 2011).

Topical Retinoids

These compounds, initially used to treat acne, have become so popular for sun-damage treatment that they are called *cosmeceuticals* (Panchaud, 2012). The most commonly used topical agents are tretinoin, isotretinoin, and adapalene. Systemic absorption is low, and this argues against plausible teratogenicity.

Isolated case reports have described malformations following topical tretinoin, and it is unknown whether this is due to variability in absorption or perhaps potential individual susceptibility (Kaplan, 2015). A prospective study by the European Network of Teratology Information Services found no higher rates of birth defects or spontaneous losses, and no case of retinoid embryopathy (Panchaud, 2012). A systematic review of 635 pregnancies exposed to topical retinoids identified no higher risk for congenital malformations, spontaneous abortion, stillbirth, low birthweight, or preterm delivery (Kaplan, 2015). Notably, the manufacturer of tazarotene cautions that application over a sufficient body surface area could be comparable to oral treatment. Accordingly, its use in pregnancy is not recommended (Allergan, 2019).

Vitamin A

There are two natural forms of vitamin A. First, *provitamin A carotenoids*, which include beta-carotene, alpha-carotene, and beta-cryptoxanthin, are precursors found in fruits and vegetables. The body converts carotenoids into vitamin A. They have never been shown to cause birth defects (Oakley, 1995).

Second, *preformed vitamin A*, also called retinol, has been associated with cranial neural-crest defects when more than 10,000 IU per day is consumed in the first trimester (Rothman, 1995). Preformed vitamin A is present in liver, fish oils, milk, eggs, and in vitamin pills and dietary supplements. It seems reasonable to avoid doses of preformed preparations that exceed the recommended 3000 IU daily allowance (American Academy of Pediatrics, 2017).

Sex Hormones

Selected functions and effects of male and female hormones on the developing fetus are reviewed in Chapter 3 (p. 31). Androgen exposure may cause varying degrees of virilization in female fetuses and may result in ambiguous genitalia (Fig. 3-3, p. 34).

Thalidomide and Analogues

Possibly the most notorious human teratogen, thalidomide causes malformations in 20 percent of fetuses exposed between 34 and 50 days menstrual age. The characteristic malformation is *phocomelia*—an absence or underdevelopment of one or more long bones. As a result, hands or feet may attach to the trunk, occasionally by a small rudimentary bone. Cardiac defects, gastrointestinal abnormalities, external ear and eye malformations, and other limb-reduction defects also are common following thalidomide exposure. The manufacturer reports that up to 40 percent of affected newborns do not survive the neonatal period (Celgene, 2021).

Thalidomide was marketed outside the United States from 1956 to 1960, before its teratogenicity was appreciated. The ensuing disaster, with thousands of affected children, was instructive of several important teratological principles. First, the placenta is not an effective barrier to the transfer of toxic substances from mother to embryo (Dally, 1998). Second, different species manifest considerable variability in their susceptibility to drugs and chemicals. Namely, thalidomide produced no defects in multiple rodent species and was assumed to be safe for humans. Last, timing of exposure may be closely related to the type of defect (Vargesson, 2015). For example, upper-limb amelia may develop with thalidomide exposure during days 24 to 30 postconception, upper-limb phocomelia with exposure during days 24 to 33, and lower-limb phocomelia with exposure during days 27 to 33.

Thalidomide was first approved in the United States in 1999 and currently is used to treat erythema leprosum nodosum and multiple myeloma (Celgene, 2021). The FDA has mandated a web-based, restricted-distribution program for thalidomide, called THALOMID REMS, which is required before patients, physicians, and pharmacies can access the medication.

Lenalidomide and *pomalidomide* are analogues of thalidomide. Both cross the placenta in animal species. Lenalidomide is used to treat some types of myelodysplastic syndrome and multiple myeloma. It has been found to cause thalidomide-like limb abnormalities in monkeys (Celgene, 2019). Pomalidomide is used to treat refractory multiple myeloma and acquired immunodeficiency syndrome (AIDS)-related Kaposi sarcoma. It is teratogenic in rats and rabbits (Celgene, 2020). Restricted-distribution programs similar to those used for thalidomide have been developed for these analogues.

Thyroid Medications

Methimazole

This thionamide drug is used to treat hyperthyroidism. Methimazole has been associated with a 2-fold increased risk for aplasia cutis congenita, as well as choanal atresia and esophageal atresia (Yoshihara, 2012). This constellation of findings has been termed *methimazole embryopathy*. Aplasia cutis is a rare abnormality characterized by a full-thickness skin defect, usually the scalp,

occasionally with a defect of underlying bone. In a study of more than 1000 methimazole-treated pregnancies, Yoshihara and colleagues (2015) identified the embryopathy in 1 to 2 percent. Treatment of hyperthyroidism in pregnancy is reviewed in Chapter 61.

Radioiodine

Radioactive iodine-131 is used for treatment of thyroid cancer and thyrotoxicosis and for diagnostic thyroid scanning. It is also a component of iodine-131 tositumomab therapy, which is employed to treat a type of non-Hodgkin lymphoma. Radioiodine is contraindicated during pregnancy because it readily crosses the placenta and is concentrated in the fetal thyroid gland by 12 weeks' gestation. It may cause severe or irreversible fetal and neonatal hypothyroidism, which can lead to decreased mental capacity and delayed skeletal maturation. Pregnancy testing should be performed before administration of radioiodine-131, and it is recommended that pregnancy be avoided for 6 to 12 months following treatment (Haugen, 2016). A review of more than 3000 pregnancies in which women delayed conception for at least 6 months after receiving radioactive iodine treatment identified no increase in pregnancy losses or congenital malformations (Kim, 2020). Concerns for the breastfeeding mother stem from breast exposure to the radioisotope.

Warfarin

This anticoagulant is a vitamin K antagonist with a long half-life. Because of its low molecular weight, it readily crosses the placenta and may cause embryotoxic and fetotoxic effects. It is considered contraindicated in pregnancy with one important exception. As discussed in Chapter 52 (p. 922), warfarin is used to treat women with mechanical heart valves who are at high risk for thromboembolism (Bristol-Myers Squibb, 2019).

Warfarin embryopathy is characterized by stippled epiphyses and nasal hypoplasia (Fig. 8-4). In one review of 63 cases attributed to warfarin exposure, 80 percent displayed characteristic findings, which include depressed nasal bridge with nasal hypoplasia and choanal atresia, along with stippled epiphyses of the femur, humerus, calcanei, and distal phalanges (Van Driel, 2002). The embryopathy may result from exposure between 6 and 9 weeks' gestation (Hall, 1980). Prevalence following exposure during this critical period is estimated to be 6 percent. One metaanalysis of cases in which the warfarin dosage was ≤5 mg/d identified embryopathy in 1 percent of exposed fetuses. This suggests that risk may be dose dependent (Hassouna, 2014).

If used beyond the first trimester, warfarin may lead to hemorrhage into fetal structures, which can cause abnormal growth and deformation from scarring (Warkany, 1976). Nearly 50 percent of reported embryopathy cases also have CNS anomalies (van Driel, 2002). Abnormalities can include agenesis of the corpus callosum; cerebellar vermian agenesis, which is the Dandy-Walker malformation; microphthalmia; and optic atrophy. Affected infants are also at risk for blindness, deafness, and developmental delays.

Tobacco

Cigarette smoking is the leading preventable cause of perinatal mortality. At least 7 percent of women report smoking cigarettes during pregnancy (Drake, 2018). Cigarette smoke contains a complex mixture of nicotine, cotinine, cyanide, thiocyanate, carbon monoxide, cadmium, lead, and various hydrocarbons (Stillerman, 2008). In addition to being fetotoxic, many of these substances have vasoactive effects or reduce oxygen levels.

Although tobacco is not considered a major human teratogen, selected birth defects have been reported to occur with greater frequency following exposure. Cigarette smoking and exposure to second-hand smoke have been associated with up to a 1.5-fold risk for orofacial clefts (Kummet, 2016; Sabbagh, 2015). This equates to an attributable risk of approximately 1 case per 2000 births. It is plausible that the vasoactive properties of tobacco smoke could produce congenital defects related to vascular disturbances. For example, the prevalence of Poland sequence, which is caused by an interruption in the vascular supply to one side of the fetal chest and ipsilateral arm, has been reported to occur two times more commonly among cigarette smokers (Martinez-Frias, 1999). The NBDPS similarly found an association between active or passive cigarette smoking and limb reduction defects, and an overall increase in risk of 25 percent (Caspers, 2013). A small increased risk for fetal cardiac anomalies also has been reported and may be dose related (Alverson, 2011; Malik, 2008; Sullivan, 2015).

The most prevalent obstetrical complication from smoking is a dose-dependent reduction in fetal growth. Newborns of mothers who smoke weigh on

FIGURE 8-4 Warfarin embryopathy or fetal warfarin syndrome: nasal hypoplasia and depressed nasal bridge seen in a fetal sonographic image **(A)** and in the same newborn **(B)**.

average 200 g less than newborns of nonsmokers (D'Souza, 1981). Smoking doubles the risk of low birthweight and raises the risk of fetal-growth restriction two- to threefold (Werler, 1997). As such, cigarette smoking accounts for 15 percent of low-birthweight neonates (Dietz, 2010). Even secondhand smoke increases the risk for low birthweight. Other adverse pregnancy outcomes associated with cigarette smoking include preterm birth, prelabor rupture of membranes, placenta previa, and placenta abruption (American College of Obstetricians and Gynecologists, 2020b). Approximately one third of cases of sudden infant death syndrome have been attributed to cigarette smoking (Anderson, 2019; Dietz, 2010). Risks of childhood asthma and obesity also are increased.

When inquiring about tobacco use, providers should include alternative nicotine delivery products. All forms of nicotine cross the placenta. None is considered safe in pregnancy. Vaping or e-cigarette products heat an "e-liquid" containing nicotine—and often additional contaminants—along with a flavoring agent. Nicotine is associated with adverse effects on fetal brain and lung development (American College of Obstetricians and Gynecologists, 2020b; Spindel, 2016). In adults, vaping has been linked to serious lung injury known as EVALI—e-cigarette or vaping-associated lung injury (Krishnasamy, 2020). Animal studies of hookah use, in which tobacco smoke is filtered through a water bowl, demonstrate lower birthweight and increased markers of cardiac stress (Khabour, 2016).

Smoking cessation should be strongly encouraged. Counseling includes avoidance of secondhand smoke and all nicotine-replacement products, such as patches, gum, and lozenges. A hotline is available from the Centers of Disease Control and Prevention and can be accessed by calling 1-800-QUIT-NOW. The U.S. Preventive Services Task Force has recommended that behavioral interventions be offered at the initial visit and continued throughout pregnancy (Siu, 2015).

■ Herbal Medicinal Products

In large survey studies from North America and Europe, 30 to 60 percent of women report using herbal remedies during pregnancy (Kennedy, 2016; Pallivalapila, 2015). These products are not regulated by the FDA, and there is a paucity of controlled studies assessing their safety and efficacy. The identity, quantity, and purity of each ingredient are usually unknown. Authors of a recent systematic review that included more than 1 million pregnancies concluded that in the absence of more safety data, the use of herbal medicinal products in pregnancy should be discouraged (Munoz Balbontin, 2019). Selected herbal remedies and their reported adverse effects are shown in Table 8-5.

■ Drugs of Abuse

Substance abuse is not uncommon in pregnancy. Assessment of outcomes attributable to illicit drug use is often confounded by factors such as poor maternal health, malnutrition, and infectious disease. Polysubstance abuse further complicates assessment of outcomes associated with any one drug. Moreover, illegal substances may contain toxic contaminants such as lead, cyanide, herbicides, and pesticides. Impurities added as diluents may independently have serious adverse perinatal effects. As noted on page 149, alcohol is a significant teratogen. Because it is legally obtained and ubiquitous, its use confounds the study of illicit drug teratogenicity. Similarly, tobacco use confounds the effect of drugs on fetal growth.

Cocaine

With this CNS stimulant, most adverse outcomes result from its vasoconstrictive and hypertensive effects. Serious potential maternal complications are cerebrovascular hemorrhage, myocardial damage, and placental abruption. Studies of congenital abnormalities and cocaine exposure have yielded conflicting results, but associations with cleft palate, cardiovascular abnormalities, and urinary tract anomalies have been reported (Chasnoff, 1988; Lipshultz, 1991; van Gelder, 2009). Cocaine use is also associated with fetal-growth restriction and preterm delivery. Children exposed as fetuses have risks for behavioral abnormalities and cognitive impairments (Bada, 2011; Gouin, 2011).

Marijuana

This is the recreational drug most commonly used in pregnancy (American College of Obstetricians and Gynecologists, 2019b). Based on data from the National Survey on Drug Use and Health, nearly 4 percent of pregnant women reported using marijuana in 2014 (Brown, 2017). Among women diagnosed with nausea and vomiting of pregnancy, the prevalence of marijuana use increased from 7 to 11 percent from 2009 to 2016 (Young-Wolff, 2019). Of concern is that the increase in prevalence is related to perceived safety and efficacy. In a study of 400 cannabis dispensaries, nearly 70 percent advised a caller posing as a pregnant woman with nausea at 8 weeks' gestation to use marijuana (Dickson, 2018). However, no data support efficacy of marijuana for nausea and vomiting of pregnancy, and there are indeed safety concerns (Metz, 2018).

Cannabinoids are not considered to be major teratogens, but they cross the placenta, and endogenous cannabinoids play key roles in brain development. In animals, cannabinoids are involved in neuronal proliferation, migration, and differentiation (Campolongo, 2011). Adverse developmental outcomes reported in exposed children include decreased attention span and lower scores on tests of visual problem solving and visual-motor coordination (Fried, 2003; Willford 2010).

Pregnancy outcome data are somewhat limited by the confounding risks of concomitant tobacco use. In one metaanalysis of nearly 8000 exposed pregnancies, only those with concomitant tobacco use had increased rates of preterm birth and low-birthweight neonates (Conner, 2016). The American College of Obstetricians and Gynecologists (2019b) has stated that the effects of marijuana may be as serious as those of cigarette smoking or alcohol consumption. Because of neurodevelopmental concerns, women who are pregnant or contemplating pregnancy should avoid marijuana use.

Methamphetamine

This sympathomimetic amine is derived from dextroamphetamine. It enhances dopamine release and blocks its reuptake. Methamphetamine is prescribed to treat attention deficit

TABLE 8-5. Pharmacological Actions and Adverse Effects of Some Herbal Medicines

Herb and Common Name	Potential Pharmacological Effects	Concerns
Aloe (oral ingestion)	Smooth-muscle stimulant	May cause uterine contractions
Almond oil (topical)	Smooth-muscle stimulant	Increase in preterm births
Black cohosh	Smooth-muscle stimulant	Causes uterine contractions; also has an estrogenic compound
Blue cohosh	Smooth-muscle stimulant	Causes uterine contractions; contains compounds teratogenic in multiple animal species
Echinacea: *purple coneflower root*	Activates cell-mediated immunity	Allergic reactions; decreases immunosuppressant effectiveness; possible immunosuppression with long-term use
Ephedra: *ma huang*	Direct and indirect sympathomimetic; tachycardia and hypertension	Hypertension, arrhythmias, myocardial ischemia; stroke; depletes endogenous catecholamines; life-threatening interaction with monoamine oxidase inhibitors
Evening primrose oil	Contains linoleic acids, a prostaglandin precursor	Possible complications if used for labor induction
Garlic: *ajo*	Inhibits platelet aggregation; increased fibrinolysis; antihypertensive activity	Risk of bleeding when combined with other platelet aggregation inhibitors
Ginger	Cyclooxygenase inhibitor, thromboxane synthetase inhibitor; lowers blood glucose	Increased risk of bleeding; hypoglycemia
Ginkgo biloba	Anticoagulant	Risk of bleeding; interferes with monoamine oxidase inhibitors
Ginseng	Lowers blood glucose; inhibition of platelet aggregation	Hypoglycemia; hypertension; risk of bleeding
Kava: *awa, intoxicating pepper, kawa*	Sedation, anxiolysis	Sedation; tolerance and withdrawal
Licorice (glycyrrhizin)	Inhibits cortisol and prostaglandin metabolism	Increased risk of preterm birth
Raspberry leaf	Smooth-muscle stimulant	Increased risk of cesarean when used in late pregnancy or in labor
Valerian: *all heal, garden heliotrope, vandal root*	Sedation	Sedation; hepatotoxicity; benzodiazepine-like acute withdrawal
Yohimbe		Hypertension, arrhythmias

Data from Ang-Lee, 2001; Facchinetti, 2012; Hall, 2012; Munoz Balbontin, 2019; Nordeng, 2011; Strandberg, 2002; Wiesner, 2017.

hyperactivity disorder and narcolepsy. Abuse has been rising in the United States since the late 1980s (American College of Obstetricians and Gynecologists, 2019c). Methamphetamine is not considered teratogenic. However, use in pregnancy is consistently associated with small-for-gestational age newborns, and children are at risk for developmental delays and behavioral abnormalities (Derauf, 2012; Eze, 2016; Gabrhelik, 2021; O'Connor, 2020). Behavioral abnormalities have been described in both infants and school-aged children (Eze, 2016). Hypertensive complications, placental abruption, preterm birth, and stillbirth are other associated adverse outcomes (Gorman, 2014).

Opioids

The dramatic rise in narcotic use among nonpregnant and pregnant individuals has been aptly termed an epidemic. Opioids are not major teratogens. However, the NBDPS did identify a slightly greater risk for spina bifida, gastroschisis, and cardiac abnormalities with periconceptional opioid exposure (Broussard, 2011). The American College of Obstetricians and Gynecologists (2019d) stresses that this potential, small increase in birth defects with maintenance therapy should be weighed against the risks associated with uncontrolled opioid abuse. Heroin addiction is associated with adverse pregnancy outcomes from the effects of repeated narcotic withdrawal on the fetus and placenta. These include preterm birth, placental abruption, fetal-growth restriction, and fetal death.

Neonatal narcotic withdrawal, called the *neonatal abstinence syndrome*, may manifest in 40 to 90 percent of exposed newborns (Blinick, 1973; Creanga, 2012; Dashe, 2002; Zelson, 1973). As discussed in Chapter 33 (p. 605), CNS irritability may progress to seizures if untreated and may be accompanied by tachypnea, apneic episodes, poor feeding, and failure to thrive. At-risk neonates are closely monitored using a scoring

system, and those severely affected are treated with opioids (Finnegan, 1975). The proportion of exposed newborns developing neonatal abstinence syndrome has risen significantly in recent years (Creanga, 2012; Lind, 2015).

The American College of Obstetricians and Gynecologists (2019d) recommends that pregnant women with opioid-use disorder be maintained on opioid-agonist therapy to reduce the risks associated with illicit opioid abuse and associated behaviors. Treatment includes either buprenorphine, which may be given in an office-based setting by a licensed buprenorphine prescriber, or methadone, usually through a licensed outpatient opioid treatment program. A multidisciplinary treatment program is recommended to reduce the likelihood of additional opioid abuse while on maintenance therapy. Withdrawal from methadone during pregnancy is discouraged because of high relapse rates (American College of Obstetricians and Gynecologists, 2019d). At Parkland Hospital, pregnant opioid users who decline maintenance therapy are offered inpatient hospitalization for controlled methadone taper. The goal is to reduce the likelihood of neonatal abstinence syndrome (Dashe, 2002; Stewart, 2013).

Miscellaneous Drugs

Phencyclidine (PCP) or angel dust is not associated with congenital anomalies. More than half of exposed newborns, however, experience withdrawal symptoms characterized by tremors, jitteriness, and irritability. *Toluene* is a common solvent used in paints and glue. Occupational exposure is reported to have significant fetal risks (Wilkins-Haug, 1997). When abused by women in early pregnancy, it is associated with *toluene embryopathy*, which is phenotypically similar to fetal alcohol syndrome. Abnormalities include pre- and postnatal growth deficiency, microcephaly, midface hypoplasia, short palpebral fissures, and wide nasal bridge (Pearson, 1994). Up to 40 percent of exposed children have developmental delays (Arnold, 1994).

CHAPTER 9

Preconceptional Counseling

The Centers for Disease Control and Prevention (CDC) defines preconceptional health to encompass the overall health of nonpregnant women during their reproductive years (Robbins, 2018). The American College of Obstetricians and Gynecologists (2019b) and the Society for Maternal–Fetal Medicine (2014, 2021) attest to the importance of preconceptional care and promote the following objectives to advance it:

1. Improve knowledge, attitudes, and behaviors of men and women related to preconceptional health
2. Assure that all childbearing-aged women receive preconceptional care services—including evidence-based risk screening, health promotion, and interventions—that will enable them to enter pregnancy in optimal health
3. Implement interconceptional interventions to prevent or minimize recurrent adverse outcomes
4. Reduce the racial and socioeconomical disparities in adverse pregnancy outcomes

Table 9-1 lists the prevalence of many conditions often amenable to preconceptional intervention (Robbins, 2018). These are frequently encountered by generalist obstetrician–gynecologists, who can help optimize health entering pregnancy (Arluck, 2018). For example, by the time most women realize they are pregnant—usually 1 to 2 weeks after the first missed period—the embryo has already begun to form. Thus, many preventive steps—such as folic acid to avoid neural-tube defects—will be ineffective if initiated at this time. Moreover, 45 percent of all pregnancies in the United States are unplanned, and often these are at greatest risk (Finer, 2016). Last, a disproportionate number of indigent women receive less preconceptional care compared with their more affluent counterparts (Easter, 2017).

Few randomized trials evaluate preconceptional care efficacy, in part because withholding such counseling would be unethical.

TABLE 9-1. Preconceptional Health Indicators—United States, 2013–2015

Factor	Prevalence (%)
Diabetes	3.1
Unwanted pregnancy	6.1
Hypertension	10.9
Smoking	16.9
Depression	21.9
Multivitamin use	33.6
Normal weight	44.9
Physical activity	50.4
Effective contraception	56.9

Data from Centers for Disease Control and Prevention, Behavioral Risk Factor Surveillance System, and Pregnancy Risk Assessment Monitoring System.

Also, pregnancy outcomes are dependent on the interaction of various maternal, fetal, and environmental factors. Thus, ascribing a salutary outcome to a specific intervention is difficult (Temel, 2014; Tieu, 2017). However, prospective observational and case-control studies have demonstrated the successes of preconceptional counseling (Yamamoto, 2018). Therefore, routine pregnancy intention screening should be done (Manze, 2020).

COUNSELING SESSION

Obstetricians–gynecologists, internists, family practitioners, and pediatricians have the best opportunity to provide preventive counseling during periodic health maintenance examinations. The occasion of a negative pregnancy test is also an excellent time for education (Skogsdal, 2018). Jack and colleagues (1995) administered a comprehensive preconceptional risk survey to 136 such women, and almost 95 percent reported at least one problem that could affect a future pregnancy (see Table 9-1). Providers should be knowledgeable regarding relevant medical diseases, prior surgery, reproductive disorders, or genetic conditions and be able to interpret data and recommendations provided by other specialists (Simpson, 2014).

Women presenting specifically for preconceptional evaluation are advised that information collection may be time consuming, depending on the number and complexity of factors. The intake evaluation includes a thorough review of the medical, obstetrical, social, and family histories. Useful information is more likely to be obtained by asking specific questions regarding each of these histories and the health of each family member than by asking general, open-ended questions. Some important information can be obtained by questionnaires that address these topics. Answers are reviewed with the couple to ensure appropriate follow-up, including obtaining relevant medical records.

The Fourth Trimester

Another optimal time to begin preconceptional counseling is during the "fourth trimester." This was emphasized by the Presidential Task Force on Redefining the Postpartum Visit (American College of Obstetricians and Gynecologists, 2018e). Designed to optimize postpartum care and provide contraceptive counseling, it also sets the stage for any subsequent pregnancy and for the woman's long-term health. To assist the provider, the American College of Obstetricians and Gynecologists (2019b) has joined the Society of Maternal–Fetal Medicine to provide an Obstetric Care Consensus guide that emphasizes the interpregnancy period.

MEDICAL HISTORY

With specific medical conditions, general points include the pregnancy's effect on the condition and the disorder's influence on the fetus and pregnancy course. Some chronic conditions that may worsen pregnancy outcomes include treated or active cancer, prior peripartum cardiomyopathy, antiphospholipid antibodies, systemic lupus erythematosus, and congenital heart disease (Amant, 2015; Cunningham, 2019; Davis, 2021; Foeller, 2018; Gibbins, 2018; Hopkins, 2018). Importantly, psychological health also is considered (Barker, 2020; Lassi, 2014). Detailed preconceptional information regarding a few exemplary conditions is found in the next sections and in the other topic-specific chapters of this text.

Diabetes Mellitus

Because maternal and fetal pathology associated with hyperglycemia is well known, diabetes is the prototype of a condition for which preconceptional counseling is beneficial. Diabetes-associated risks to both mother and fetus are discussed in detail in Chapter 60 (p. 1068). If a patient maintains glucose levels close to normal, many of these complications can be avoided before conception. Another important aspect of counseling pertains to the frequent use of teratogenic angiotensin-converting enzyme inhibitors in this population (Podymow, 2015).

The American College of Obstetricians and Gynecologists (2018f) has concluded that preconceptional counseling for women with pregestational diabetes is beneficial and cost-effective and should be encouraged. The American Diabetes Association (2004) has promulgated consensus recommendations for preconceptional care for women with diabetes. These guidelines advise an inventory of disease duration and related complications and clinical and laboratory examination for end-organ damage. Perhaps most essential, they encourage a preconceptional hemoglobin A_{1c} level goal below 7 percent. In addition to assessing diabetic control, hemoglobin A_{1c} measurement can also forecast the risks for gestational diabetes and for major anomalies (Fig. 9-1) (Hinkle, 2018; Martin, 2020).

Although no randomized trials attest to the success of preconceptional counseling in women with diabetes, cohort studies do demonstrate its effectiveness (Tieu, 2017). In a prospective study of 5075 affected women, preconceptional counseling improved hemoglobin A_{1c} levels, folic acid compliance, and "optimal" pregnancy preparation (Yamamoto, 2018). Diabetic women who undergo preconceptional counseling also have improved glycemic control before pregnancy and in the first trimester and experience lower rates of adverse outcomes—defined as a perinatal death or major congenital anomaly (Tripathi, 2010). Despite

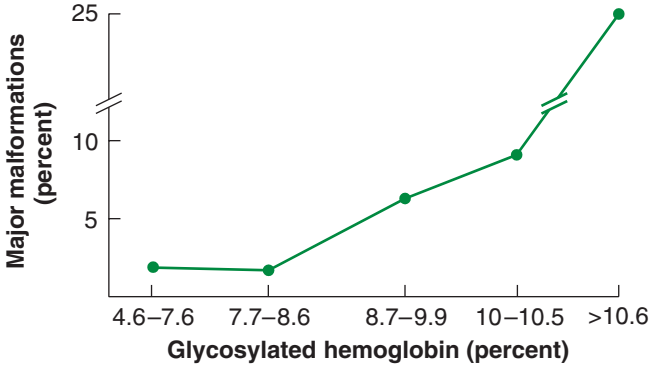

FIGURE 9-1 Relationship between first-trimester glycosylated hemoglobin values and risk for major congenital malformations in 320 women with insulin-dependent diabetes.

TABLE 9-2. First-Trimester Antiepileptic Monotherapy and the Associated Major Malformation Risk

Antiepileptic (n)	Malformations (%)[a]	Relative Risk (95% CI)[b]
Unexposed controls	1.1	Reference
Gabapentin	0.7	1.0 (0.5–1.9)
Lamotrigine	2.0	0.9 (0.7–1.3)
Oxcarbazepine	2.2	—
Levetiracetam	2.4	0.7 (0.4–1.2)
Phenytoin	2.9	1.7 (1.3–2.2)
Carbamazepine	3.0	1.4 (1.1–1.7)
Clonazepam	3.1	1.1 (0.6–2.0)
Topiramate	4.2	1.9 (1.2–2.9)
Phenobarbital	5.5	1.8 (1.4–2.5)
Valproate	9.3	2.9 (2.4–3.7)
Ethosuximide	—	3.0 (1.2–7.1)

Risk compared with that of the unexposed reference population of women without epilepsy.
CI = confidence interval.
Data from [a]Hernández-Díaz, 2012; [b]Veroniki, 2017.

such benefits, in one study of approximately 300 diabetic women in a managed-care plan, only approximately half received preconceptional counseling (Kim, 2005).

Epilepsy

Compared with unaffected women, those with a seizure disorder carry an augmented risk of neonates with structural anomalies. Some early reports indicated that epilepsy conferred an elevated a priori risk for congenital malformations that was independent of anticonvulsant treatment effects. More recent studies have largely failed to confirm this, but it is difficult to refute entirely because women who are controlled without medication generally have less severe disease (Cassina, 2013; Vajda, 2015). Polytherapy is associated with a higher malformation risk compared with monotherapy (Bromley, 2017). Last, in women using antiseizure medications, the risks for miscarriage and stillbirth in do not appear elevated (Aghajanian, 2015; Bech, 2014).

Ideally, medications are adjusted preconceptionally to minimize seizure frequency. From one national registry, the seizure risk during pregnancy was 50 to 70 percent lower in women without a seizure in the year preceding pregnancy compared with a group experiencing seizures in this preceding year (Vajda, 2008). No further advantages accrued if the seizure-free period exceeded a year.

Treatment goals attempt to control seizure frequency with monotherapy and with medications considered less teratogenic (Aguglia, 2009; Tomson, 2009). Discussed in Chapter 63 (p. 1129) and shown in Table 9-2, some one-drug regimens are more teratogenic than others. In particular, valproic acid is avoided if possible, as it has consistently been associated with a greater risk for major congenital malformations than other antiepileptic drugs (Jentink, 2010; Vajda, 2015). Information concerning the teratogenicity of newer antiepileptics is limited (Knight, 2021).

The American Academy of Neurology recommends consideration of antiseizure medication discontinuation before pregnancy in suitable candidates (Jeha, 2005). These include women who satisfy the following criteria: (1) have been seizure-free for 2 to 5 years, (2) display a single seizure type, (3) have a normal neurological examination and normal intelligence, and (4) show electroencephalogram results that have normalized with treatment.

Women with seizures should be advised to take a daily 4-mg oral folic acid supplement. Even so, the value of folate to reduce fetal malformation rates in pregnant women taking anticonvulsant therapy is not entirely clear. In one case-control study, the congenital abnormality risk was reduced by maternal folate supplementation in fetuses exposed to carbamazepine, phenobarbital, phenytoin, and primidone (Kjær, 2008). Conversely, Morrow and coworkers (2009) compared fetal outcomes of women who received preconceptional folic acid with those who did not receive it until later in pregnancy or not at all. In this study, a paradoxical *increase* in the number of major congenital malformations was observed in the group who received preconceptional folate. These investigators concluded that folate metabolism may be only a part of the mechanism by which malformations are induced in women taking these medications.

Immunizations

Preconceptional counseling includes assessment of immunity against common pathogens. Also, depending on health status, travel plans, and time of year, other immunizations may be indicated as discussed in Chapter 10 (p. 189). Several immunization resources are listed in Table 9-3. Vaccines that contain toxoids such as tetanus are suitable before or during gestation. Also, those containing killed bacteria or viruses—such as influenza, pneumococcus, hepatitis B, meningococcus, and rabies vaccines—are not associated with adverse fetal outcomes and are not contraindicated preconceptionally or during pregnancy. Conversely, live-virus vaccines are not recommended during pregnancy. Examples are vaccines against varicella-zoster, measles, mumps, rubella, polio, chickenpox, and yellow fever. Moreover,

TABLE 9-3. Immunization Resources

American College of Obstetricians and Gynecologists website: www.acog.org/programs/immunization-for-women
Centers for Disease Control and Prevention website: www.cdc.gov/vaccines/hcp/
Immunization Action Coalition: www.immunize.org

1 month or longer should ideally pass between vaccination and conception attempts. That said, inadvertent administration of measles, mumps, rubella (MMR) or varicella vaccines during pregnancy should not generally be considered indications for pregnancy termination. Most reports indicate that the fetal risk is only theoretical. Immunization to smallpox, anthrax, and other bioterrorism diseases is discussed if clinically appropriate (Chap. 67, p. 1200).

With some infections, vaccines are unavailable. One recent example is the Zika virus (Brasil, 2016). For this virus, during the 2016 epidemic, the CDC issued travel advisories for pregnant women (Petersen, 2016; Schuler-Faccini, 2016).

GENETIC DISEASES

The CDC (2016) estimates that 3 percent of neonates born each year in the United States will have at least one birth defect. Importantly, such defects are the leading cause of infant mortality and account for 20 percent of deaths. Ethics preclude randomized trials of preconceptional counseling for genetic risk (Hussein, 2018). Instead, the benefits of preconceptional counseling usually are measured by comparing the incidence of new cases before and after initiation of such a program. Specific congenital conditions that clearly benefit from patient education include neural-tube defects, phenylketonuria, thalassemias, and other genetic diseases more common in individuals of Eastern European Jewish descent (King, 2018). Other missed opportunities for genetic consultation were found for women with a personal or family history of birth defects, intellectual disability or autism, and a prior positive genetic carrier screening test (McClatchey, 2018).

Family History

Pedigree construction using the symbols shown in Figure 9-2 is the most thorough method for obtaining a family history as a part of genetic screening. The health and reproductive status of each "blood relative" are individually reviewed for medical illnesses, mental retardation, birth defects, infertility,

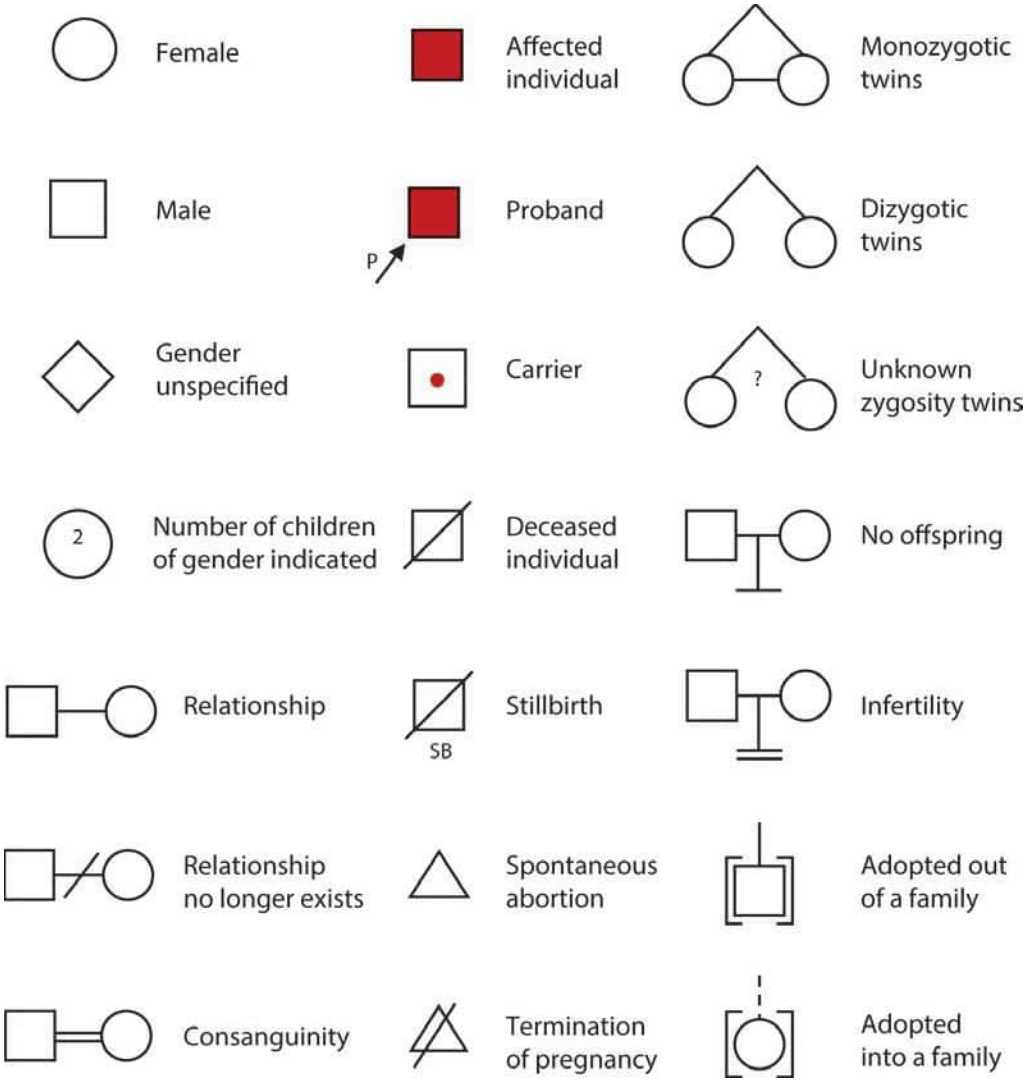

FIGURE 9-2 Symbols used for pedigree construction.

and pregnancy loss. Certain racial, ethnic, or religious backgrounds may indicate elevated risk for specific recessive disorders.

Although most women can provide information regarding their history, their understanding may be limited. Pregnant women may fail to communicate a birth defect in the family or may report it incorrectly. Thus, any disclosed defect or genetic disease is ideally confirmed by reviewing pertinent medical records or by contacting affected relatives for additional information.

Neural-Tube Defects

The incidence of neural-tube defects (NTDs) is 0.9 per 1000 live births, and they are second only to cardiac anomalies as the most frequent structural fetal malformation. Some of these malformations are associated with specific mutations. One example is the 677C → T substitution in the gene that encodes methylene tetrahydrofolate reductase. For this and similar gene defects, one seminal trial showed that preconceptional folic acid therapy significantly reduced the risk for a recurrent NTD by 72 percent (Medical Research Council Vitamin Study Research Group, 1991). More importantly, because more than 90 percent of neonates with NTDs are born to women at low risk, Czeizel and Dudas (1992) showed that universal supplementation reduced the a priori risk of a first NTD.

Because of these findings, all women who may become pregnant are recommended to take daily 400 to 800 μg of folic acid orally before conception and through the first trimester (U.S. Preventive Services Task Force, 2019). Folate fortification of cereal grains has been mandatory in the United States since 1998, and this practice has lowered neural-tube defect rates (Williams, 2015). Despite the demonstrated benefits of folate supplementation, only half of women take folic acid supplementation periconceptionally (de Jong-van den Berg, 2005; Goldberg, 2006).

Phenylketonuria

More than 600 mutations have been identified in the phenylalanine hydroxylase gene. The inherited defect in phenylalanine metabolism exemplifies diseases in which the fetus may not be at risk to inherit the disorder but may be damaged by maternal disease. Specifically, mothers with phenylketonuria (PKU) who eat an unrestricted diet have abnormally high blood phenylalanine levels. This amino acid readily crosses the placenta and can damage developing fetal organs, especially neural and cardiac tissues.

With appropriate preconceptional counseling and adherence to a phenylalanine-restricted diet before pregnancy, the incidence of fetal malformations is dramatically reduced (Camp, 2014; Vockley, 2014). Therefore, the phenylalanine concentration is ideally brought into normal range 3 months before conception and then maintained there throughout pregnancy (American College of Obstetricians and Gynecologists, 2020a). The target phenylalanine blood concentration is 120 to 360 μmol/L (Camp, 2014).

Thalassemias

These disorders of globin-chain synthesis are the most common single-gene disorders worldwide (Forget, 2013; Vichinsky, 2013). As many as 200 million people carry a gene for one of these hemoglobinopathies, and hundreds of mutations are known to cause thalassemia syndromes (Chap. 59, p. 1053). In endemic areas such as Mediterranean and Southeast Asian countries, counseling and other prevention strategies have reduced the incidence of new cases by up to 80 percent (Cao, 2013).

The American College of Obstetricians and Gynecologists (2018a) recommends that individuals of high-risk ancestry be offered carrier screening to allow them informed decision-making regarding reproduction and prenatal diagnosis. One method of early prenatal diagnosis for some thalassemia syndromes is *preimplantation genetic testing (PGT)*, which is coupled with assisted reproductive technology (Chap. 17, p. 348).

Individuals of Eastern European Jewish Descent

Most individuals of Jewish ancestry in North America are descended from Ashkenazi Jewish communities and are at greater risk for having offspring with one of several autosomal recessive disorders. These include Tay-Sachs disease, Gaucher disease, cystic fibrosis, Canavan disease, familial dysautonomia, mucolipidosis IV, Niemann-Pick disease type A, Fanconi anemia group C, and Bloom syndrome. The American College of Obstetricians and Gynecologists (2017a; 2019a) recommends preconceptional counseling and screening for these disorders in this population. Carrier frequency and features of these conditions are discussed in greater detail in Chapter 17 (p. 343).

REPRODUCTIVE HISTORY

During preconceptional screening, information is sought regarding infertility; abnormal pregnancy outcomes that may include miscarriage, ectopic pregnancy, molar pregnancy, and recurrent pregnancy loss; and obstetrical complications such as cesarean delivery, preeclampsia, placental abruption, and preterm delivery (Stubblefield, 2008).

As discussed in Chapter 35 (p. 626), details involving a prior stillbirth are especially important. For example, Korteweg and associates (2008) identified chromosomal abnormalities in 13 percent of stillborns who underwent karyotyping. And, Reddy and colleagues (2012) confirmed that chromosomal microarray analysis (CMA) yields better detection of genetic abnormalities than does standard karyotyping. This primarily stems from CMA's ability to assess nonviable tissue (Chap. 16, p. 325). Identification of a genetic abnormality in a stillborn can help to determine recurrence risk.

PARENTAL AGE

Maternal Age

Women at both ends of the reproductive-age spectrum have unique outcomes to consider. First, according to the CDC, 3.4 percent of births in the United States in 2010 were in women aged 15 to 19 years (Martin, 2012). An international study reported a rate of 11.9 percent for this age group globally (Althabe, 2015). These adolescents are at higher risk for anemia, preterm delivery, and preeclampsia compared with women aged 20 to 35 years (Usta, 2008). The incidence of sexually transmitted diseases—common in adolescents—is even higher during pregnancy (Niccolai, 2003). Unfortunately, because most of their pregnancies are unplanned, adolescents rarely seek preconceptional counseling.

Conceptions after age 35 currently constitute approximately 15 percent of pregnancies in the United States (Martin, 2012). By contrast, these women are more likely to request preconceptional counseling. Motivations may stem from a desire to optimize outcomes at their age or with infertility treatment or both. Some studies—including data from Parkland Hospital presented in Figure 9-3–indicate that risks for obstetrical complications and for perinatal morbidity and mortality rise after age 35 (Waldenström, 2015). The older woman who has a chronic illness or who is in poor physical condition usually has readily apparent risks. For the physically fit woman without medical problems, however, the risks are lower.

Overall, the maternal mortality rate is higher in women aged 35 and older (Chap. 1, p. 5). Creanga and coworkers (2017) analyzed pregnancy-related deaths in the United States for 2011 through 2013. Although women older than 35 years contributed less than 15 percent of all live births, they constituted 31 percent of maternal deaths. For the fetus, maternal age-related risks primarily originate from (1) indicated preterm delivery for maternal complications such as hypertension and diabetes, (2) spontaneous preterm birth, (3) fetal-growth disorders related to chronic maternal disease or multifetal gestation, (4) fetal aneuploidy, and (5) pregnancies resulting from assisted reproductive technology.

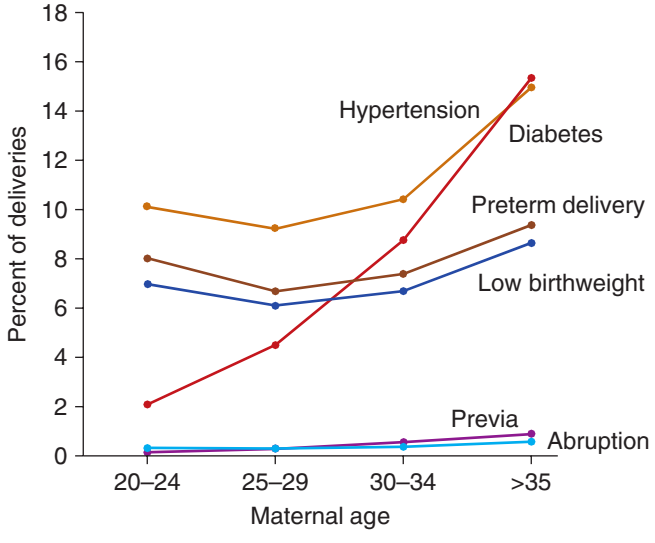

FIGURE 9-3 Incidence of selected pregnancy complications in relation to maternal age among 295,667 women delivered at Parkland Hospital.

Assisted Reproductive Technologies

Recall that older women have subfertility problems. And, although the incidence of dizygotic twinning rises with maternal age, the more important cause of multifetal gestation in older women follows the use of assisted reproductive technology (ART) and ovulation induction. Indeed, according to the CDC, 30 to 40 percent of all multifetal gestations in the United States in 2012 were conceived with the use of ART (Sunderan, 2015). Morbidity and mortality with multifetal pregnancies stem from preterm delivery and placentation complications, such as placenta previa and abruption (Qin, 2016).

With ART, transmission of infectious agents is a risk. For women without human immunodeficiency virus (HIV) infection who plan conception with their HIV-affected partners, the CDC has published prevention strategies (Kawwass, 2017). Also, Zika virus infection acquisition through in vitro fertilization (IVF) has been described (Washington Cross, 2017). Last, some data links ART to higher major congenital malformation rates. In a registry of 308,974 births, 8.3 percent of neonates conceived by ART had major birth defects, and intracytoplasmic injection was also associated with an elevated risk for malformations (Davies, 2012).

Paternal Age

Advanced paternal age has doubled in the United States over the past generation. It is associated with a higher risk of preterm birth and new autosomal-dominant mutations (Chap. 16, p. 320) (Khandwala, 2018). One example is the possible link between increasing paternal age and complex neuropsychiatric conditions (Malaspina, 2015). Parental history and experiences can also exert effects on progeny through epigenomic information not contained in the DNA sequence. Variations in sperm and oocyte cytosine methylation and noncoding RNAs are examples (Cedars, 2015; Lane, 2014).

SOCIAL HISTORY

Recreational Drugs and Smoking

Fetal risks associated with alcohol, marijuana, cocaine, amphetamines, and heroin are discussed in Chapters 8 (p. 148) and 64 (p. 1150). The first step in preventing drug-related fetal risk is an honest assessment of use by the patient (American College of Obstetricians and Gynecologists, 2017c). Toward this end, questioning should be nonjudgmental.

Several validated tools screen for at-risk drinking. One is the well-studied TACE questions (American College of Obstetricians and Gynecologists, 2019d). These four questions investigate having a *tolerance* to alcohol, being *annoyed* by comments about their drinking, attempting to *cut down*, and drinking early in the morning—the *eye opener*.

Of more than 1000 postpartum patients in one Canadian study, a high percentage reported alcohol use concurrent with conception attempts (Tough, 2006). Specifically, nearly half of those planning for pregnancy consumed a mean of 2.2 drinks daily during early gestation and before they recognized their pregnancy. This frequency and pattern clearly underscore the opportunity for preconceptional counseling.

In 2014 to 2015, 17 percent of reproductive-age women in the United States smoked cigarettes according to the CDC (Robbins, 2018). Smoking in pregnancy is consistently associated with numerous adverse perinatal outcomes (Chap. 8, p. 156). These risks are largely mitigated by cessation before pregnancy, highlighting the importance of screening for tobacco use prior to and during pregnancy (Chap. 10, p. 179).

Environmental Exposures

Only a few environmental agents have been shown to cause adverse pregnancy outcomes (McCue, 2019; Windham, 2008). For example, contact with some chemicals may impart significant maternal and fetal risks. Discussed in Chapter 8 (p. 153), excess exposure to methyl mercury or lead is associated with neurodevelopmental disorders. For lead, the American College of Obstetricians and Gynecologists (2018b) endorses guidelines that recommend blood lead testing only if a lead-exposure risk factor is identified. If the levels are >5 µg/dL, counseling is completed, and the lead source is sought and removed. Blood lead levels >45 µg/dL are consistent with lead poisoning, and women in this group may be candidates for chelation therapy (Centers for Disease Control and Prevention, 2019).

In contrast, everyday exposures to *electromagnetic fields* are not linked to adverse fetal outcomes (Robert, 1999). Examples include energy emanated by high-voltage power lines, electric blankets, microwave ovens, and cellular phones.

Diet

Pica is the craving for and consuming of ice, laundry starch, clay, dirt, or other nonfood items. It should be discouraged due to its inherent replacement of healthful food with nutritionally empty products (Chap. 10, p. 191). In some cases, it may represent an unusual physiological response to iron deficiency (Epler, 2017). Many *vegetarian diets* are protein deficient but can be corrected by increasing egg and cheese consumption. *Anorexia* and *bulimia* raise maternal risks of nutritional deficiencies, electrolyte disturbances, cardiac arrhythmias, and gastrointestinal pathology (American Psychiatric Association, 2013). Discussed in Chapter 64 (p. 1149), pregnancy-related complications with these eating disorders include greater risks of low birthweight, smaller head circumference, microcephaly, and small-for-gestational-age newborns.

Obesity is linked with several maternal complications. Discussed in Chapter 51 (p. 905), these include hypertension, preeclampsia, gestational diabetes, labor abnormalities, cesarean delivery, and operative complications (American College of Obstetricians and Gynecologists, 2018d). Obesity also appears to be associated with a range of structural fetal anomalies (Stothard, 2009).

Exercise

Conditioned pregnant women usually can continue to exercise throughout gestation (American College of Obstetricians and Gynecologists, 2020b). Discussed in Chapter 10, covering prenatal care (p. 187), no data suggest that exercise is harmful during pregnancy. However, as pregnancy progresses, balance problems and joint relaxation may predispose to orthopedic injury. During exercise, gravidas should avoid exhaustion, overheating, dehydration, and prolonged supine position.

Intimate-Partner Violence

Pregnancy can exacerbate interpersonal problems and is a time of elevated risk from an abusive partner. According to the American College of Obstetricians and Gynecologists (2012), approximately 324,000 pregnant women are abused each year. Intimate-partner violence (IPV) is associated with greater risk for several pregnancy-related complications that include hypertension, vaginal bleeding, hyperemesis, preterm delivery, and low-birthweight neonates (Chap. 50, p. 891) (Silverman, 2006). Because IPV can escalate during pregnancy, even to the point of homicide, the preconceptional period provides an ideal time for screening and intervention (Cheng, 2010). In support, the American College of Obstetricians and Gynecologists (2019c) provides recommendations and resources for screening both pregnant and nonpregnant women for IPV.

Lesbian, Gay, Bisexual, Transgender, and Queer Individuals

Preconceptional care has traditionally been based on the assumption of heterosexuality and has often excluded lesbian women (Bushe, 2017). The American College of Obstetricians and Gynecologists (2018c) endorses quality health care for all women regardless of sexual orientation. Indeed, in a study by Carpinello and colleagues (2016), three fourths of lesbian couples planned for one partner to conceive. Paradoxically, adolescent bisexual and lesbian women are at greater risk for undesired pregnancies (Charlton, 2018; Hodson, 2017). Of special risks in this group, lesbian and bisexual women have higher incidences of obesity, tobacco and alcohol use, depression, diabetes, and low parity compared with heterosexual women (Mravcak, 2006; O'Hanlan, 2007). In some of these groups, knowledge of surrogacy laws is imperative (Tsai, 2020).

SCREENING TESTS

Highlighted in Table 9-4, women with certain chronic medical diseases ideally would be evaluated before conception. With several of these, optimizing maternal condition will improve pregnancy outcomes.

TABLE 9-4. Selected Preconceptional Counseling Topics

Condition	Reference Chapter	Recommendations for Preconceptional Counseling
Environmental exposure	Chap. 10, p. 188	*Methyl mercury*: Avoid shark, swordfish, king mackerel, and tile fish. Ingest no more than 12 ounces or 2 servings of canned tuna and no more than 6 ounces of albacore per week. *Lead*: Blood lead testing if a risk factor is identified (p. 188); treat if indicated according to recommendations.
Obesity	Chap. 51, p. 902	Calculate BMI yearly from Figure 51-1, p. 903
Eating disorder	Chap. 64, p. 1149	*BMI* $\geq$*25 kg/m*^{2}: Counsel on diet. Test for diabetes and metabolic syndrome if indicated. Consider weight loss prior to conception. *BMI* $\leq$*18.5 kg/m*^{2}: Assess for eating disorder. *Bariatric surgery*: Fertility rate, obstetrical complications.
Physical activity	Chap. 10, p. 187	*Exercise:* Conditioned women may continue to exercise. Counsel on fall prevention. Avoid exhaustion and heat exposure.
Cardiovascular disease	Chap. 52, p. 918 Chap. 8, p. 150	Counsel on cardiac risks during pregnancy; discuss situations in which pregnancy is contraindicated. Optimize cardiac function. Discuss medication teratogenicity (warfarin, ACE inhibitor, ARB) and, if possible, switch to less dangerous agent when conception planned. Offer genetic counseling to those with congenital cardiac anomalies (Table 52-4, p. 920).
Chronic HTN	Chap. 53, p. 944 Chap. 8, p. 150	Counsel on specific risks during pregnancy. Assess those with long-standing HTN for ventricular hypertrophy, retinopathy, and renal disease. Optimize blood pressure control. Assess for teratogenic drug use.
Asthma	Chap. 54, p. 960	Counsel on asthma risks during pregnancy. Optimize pulmonary function preconceptionally. Treat women with pharmacological step therapy for chronic asthma.
Thrombophilia	Chap. 55, p. 976	Question for personal or family history of thrombotic events or recurrent poor pregnancy outcomes. If a thrombophilia is found or known, counsel and offer appropriate anticoagulation regimen.
Renal disease	Chap. 56, p. 1003 Chap. 8, p. 150	*Chronic renal disease:* Counsel on specific risks during pregnancy. Optimize blood pressure control before conception. Counsel women taking ACE inhibitors and ARBs about teratogenicity.
Gastrointestinal disease	Chap. 57, p. 1021 Chap. 8, p. 152	*Inflammatory bowel disease*: Counsel affected women on subfertility risks and risks of adverse pregnancy outcomes. Discuss teratogenicity of methotrexate and the other immunomodulators. Offer effective contraception during their use.
Hepatobiliary disease	Chap. 58, p. 1037	*Hepatitis B*: Vaccinate all high-risk women before conception (Table 10-7, p. 189). Counsel chronic carriers on transmission prevention to partners and fetus. Treat if indicated. *Hepatitis C*: Screen high-risk women. Counsel affected women on risks of disease and transmission. If nonpregnant treatment indicated, discuss ramifications and appropriateness of pregnancy.
Hematological disease	Chap. 59, p. 1048	*Iron-deficiency anemia*: Iron supplementation. *Sickle-cell disease*: Screen all black women. Counsel those with trait or disease. Test partner if desired. *Thalassemias*: Screen women of Southeast Asian or Mediterranean ancestry.
Diabetes	Chap. 60, p. 1070	Optimize glycemic control to minimize teratogenicity of hyperglycemia. Evaluate for end-organ damage such as retinopathy, nephropathy, hypertension, and others. Discontinue ACE inhibitors.
Thyroid disease	Chap. 61, p. 1089	Screen those with thyroid disease symptoms. Ensure iodine-sufficient diet. Treat overt hyper- or hypothyroidism. Counsel on risks to pregnancy outcome.
Connective tissue disease	Chap. 62, p. 1109 Chap. 8, p. 144	*Rheumatoid arthritis*: Counsel on flare risk after pregnancy. Discuss methotrexate and leflunomide teratogenicity, as well as possible effects of other immunomodulators. Switch these agents before conception. Stop NSAIDs by 27 weeks' gestation. *Lupus*: Counsel on risks during pregnancy. Assess renal involvement. Optimize disease before conception. Discuss mycophenolate mofetil and cyclophosphamide teratogenicity as well as possible effects of newer immunomodulators. Switch these agents before conception.

(*continued*)

TABLE 9-4. Continued

Condition	Reference Chapter	Recommendations for Preconceptional Counseling
Substance abuse	Chap. 64, p. 1150	*Opioid use disorder (OUD)*: codeine, oxycodone, heroin, and other opioids.
Psychiatric disorders	Chap. 64, p. 1143	*Depression*: Screen for symptoms of depression. Counsel on risks of treatment and of untreated illness and the high risk of exacerbation during pregnancy and the puerperium.
Neurological disorders	Chap. 63, p. 1128	*Seizure disorder*: Optimize seizure control using monotherapy if possible.
Dermatological disease	Chap. 8, p. 155	Discuss isotretinoin and etretinate teratogenicity and effective contraception during their use; switch agents before conception.
Cancer	Chap. 66, p. 1164	Counsel on fertility preservation options before cancer therapy and on decreased fertility following certain agents. Discuss appropriateness of pregnancy balanced with need for ongoing cancer therapy and prognosis of the disease state.
Infectious diseases	Chap. 67, p. 1183	*Influenza*: Vaccinate all women who will be pregnant during flu season. Vaccinate high-risk women prior to flu season. *COVID-19*: Vaccinate candidates. *Malaria*: Counsel to avoid travel to endemic areas during conception. If unable, offer effective contraception during travel or provide chemoprophylaxis for those planning pregnancy. *Zika virus*: See travel restrictions by CDC. *Rubella*: Screen for rubella immunity. If nonimmune, vaccinate and counsel on the need for effective contraception during the subsequent month. *Tdap*: *tetanus, diphtheria, pertussis:* Update vaccination in all reproductive-aged women. *Varicella*: Question regarding immunity. If nonimmune, vaccinate.
STIs	Chap. 68, p. 1206	*Gonorrhea, syphilis, chlamydial infection*: Screen high-risk women and treat as indicated. *Human immunodeficiency virus*: Screen at-risk women. Counsel affected women on risks during pregnancy and on perinatal transmission. Discuss initiation of treatment before pregnancy to decrease transmission risk. Offer effective contraception to those not desiring conception. *Human papilloma virus*: Provide Pap smear screening per guidelines (Chap. 66, p. 1164). Vaccinate candidate patients. *Herpes virus*: Provide serological screening to asymptomatic women with affected partners. Counsel affected women on risks of perinatal transmission and on preventative measures during the third trimester and labor.

ACE = angiotensin-converting enzyme; ARB = angiotensin-receptor blocker; BMI = body mass index; CDC = Centers for Disease Control and Prevention; HTN = hypertension; NSAID = nonsteroidal antiinflammatory drug; STI = sexually transmitted infection.

CHAPTER 10

Prenatal Care

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) define prenatal care as "A comprehensive antepartum program involves a coordinated approach to medical care, continuous risk assessment, and psychosocial support that optimally begins before pregnancy and extends throughout the postpartum and interpregnancy period." As promulgated by John Ballantyne, such care has been a bedrock to improve pregnancy outcomes for more than 100 years (Reiss, 2000).

PRENATAL CARE IN THE UNITED STATES

Almost a century after its introduction, prenatal care has become one of the most frequently used health services in the United States. According to the Centers for Disease Control and Prevention (CDC), only 1.6 percent of women who gave birth in 2016 received no prenatal care (Osterman, 2018). African-American and Hispanic women have high rates of inadequate or no prenatal care that reach 10 and 7.7 percent, respectively. This figure is greater for adolescents, particularly those younger than 15 years, compared with older age groups. These data highlight areas of potential improvement by the health-care system.

Prenatal Care Effectiveness

Care designed during the early 1900s focused on lowering the extremely high maternal mortality rate. Prenatal care undoubtedly contributed to the dramatic decline in maternal deaths from 690 per 100,000 births in 1920 to 50 per 100,000 by 1955 (Loudon, 1992). Data from 1998 to 2005 from the Pregnancy Mortality Surveillance System identified a fivefold increased risk for maternal death in women who received no prenatal care (Berg, 2010).

Goldenberg and McClure (2018) have emphasized the importance of prenatal care to reduce stillbirth rates as well. In a study of almost 29 million births, the risk for preterm birth, stillbirth, early and late neonatal death, and infant death rose linearly with decreasing prenatal care utilization (Partridge, 2012). Similarly, from Parkland Hospital, Leveno and associates (2009) found that a significant decline in preterm births correlated closely with any use of prenatal care by medically indigent women. And in women with diabetes, adherence to prenatal care resulted in lower rates of neonatal admissions to the intensive care unit (Sperling, 2018a).

Group prenatal care is acceptable and effective (American College of Obstetricians and Gynecologists, 2018g). Ickovics and coworkers (2016) compared this with individual prenatal care. Group care provided traditional pregnancy surveillance in a group setting with special focus on support, education, and active health-care participation. Women enrolled in group care had significantly better pregnancy outcomes. Carter and colleagues (2017) cited similar results. Childbirth education classes are also reported to result in better pregnancy outcomes (Afshar, 2017). Pregnancy in adolescents carries special risk, and guidelines have been developed that focus on this age group (Fleming, 2015).

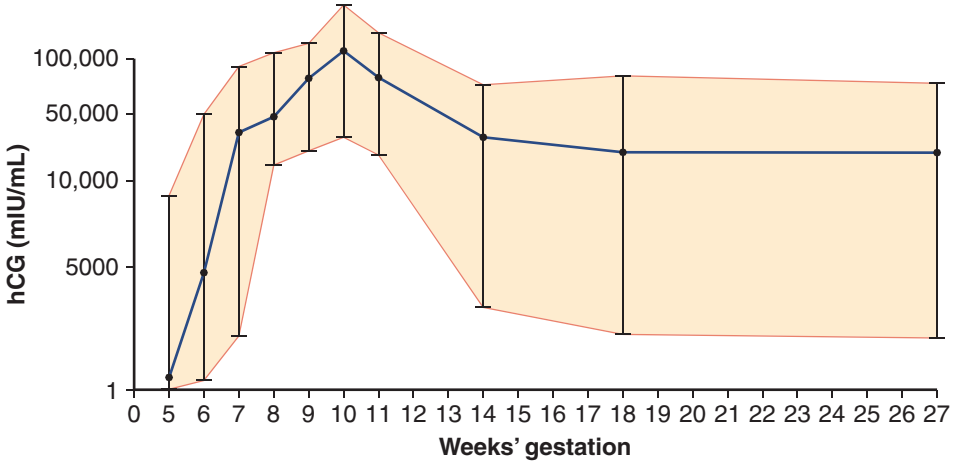

FIGURE 10-1 Mean concentration (95% CI) of human chorionic gonadotropin (hCG) in serum of women throughout normal pregnancy.

corpus luteum, which is the principal site of progesterone formation during the first 6 weeks of pregnancy.

With a sensitive test, the hormone can be detected in maternal serum or urine by 8 to 9 days after ovulation. The doubling time of serum hCG concentration is 1.4 to 2.0 days. As shown in Figure 10-1, serum levels range widely and increase from the day of implantation. Lower levels of hCG rise more rapidly than higher levels (Barnhart, 2016). Peak hCG levels are reached at 60 to 70 days. Thereafter, the concentration declines slowly to a plateau at approximately 16 weeks' gestation.

DIAGNOSIS OF PREGNANCY

Pregnancy is usually identified when a woman presents with symptoms and possibly a positive home urine pregnancy test result. Typically, these women receive confirmatory testing of urine or blood for human chorionic gonadotropin (hCG). Further, presumptive signs or diagnostic findings of pregnancy may be found during the clinical examination. Sonography is often used, especially if miscarriage or ectopic pregnancy is a concern.

Symptoms and Signs

Amenorrhea in a healthy reproductive-aged woman who previously has experienced spontaneous, cyclical, predictable menses is highly suggestive of pregnancy. Menstrual cycles vary appreciably in length among women and even in the same woman (Chap. 5, p. 83). Thus, amenorrhea is not a reliable pregnancy indicator until 10 or more days have passed after expected menses. Occasionally, uterine bleeding that mimics menstruation is noted after conception. During the first month of pregnancy, these episodes are likely the consequence of blastocyst implantation. Still, first-trimester bleeding should prompt evaluation for an abnormal pregnancy.

Of other symptoms, maternal perception of fetal movement depends on factors such as parity and habitus. In general, after a first successful pregnancy, a woman may first perceive fetal movements between 16 and 18 weeks' gestation. A primigravida may not appreciate fetal movements until approximately 2 weeks later. At about 20 weeks, depending on maternal habitus, an examiner can begin to detect fetal movements. Of pregnancy signs, changes in the lower reproductive tract, uterus, and breasts develop early.

Pregnancy Tests

Detection of hCG in maternal blood and urine is the basis for endocrine assays of pregnancy. Syncytiotrophoblast produces hCG in amounts that increase exponentially during the first trimester. hCG and luteinizing hormone (LH) share the same receptor in tissues. Thus, a main function of hCG is to prevent involution of the

Measurement of hCG

This hormone is a glycoprotein with high carbohydrate content. The general structure of hCG is a heterodimer composed of two dissimilar subunits, designated α and β, which are noncovalently linked. The α-subunit is identical to those of LH, follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH), but the β-subunit is structurally distinct. Thus, antibodies were developed with high specificity for the hCG β-subunit. This specificity allows its detection, and numerous commercial immunoassays are available for measuring serum and urine hCG levels. Each immunoassay detects a slightly different mixture of hCG variants, its free subunits, or its metabolites—however, all are appropriate for pregnancy testing (Braunstein, 2014). Depending on the assay used, the sensitivity for the laboratory detection limit of hCG in serum is 1.0 mIU/mL or even lower.

False-positive hCG test results are rare. A few women have circulating serum factors that may bind erroneously with the test antibody directed to hCG in a given assay. The most common factors are heterophilic antibodies. These are produced by an individual and bind to the animal-derived test antibodies used in a given immunoassay. Thus, women who have worked closely with animals are more likely to develop these antibodies, and alternative laboratory techniques are available (American College of Obstetricians and Gynecologists, 2017a). Elevated hCG levels may also reflect molar pregnancy and its associated neoplasms (Chap. 13, p. 238). Other rare causes of positive assays without pregnancy are (1) exogenous hCG injection used for weight loss, (2) renal failure with impaired hCG clearance, (3) physiological pituitary hCG, and (4) hCG-producing tumors that most commonly originate from gastrointestinal sites, ovary, bladder, or lung (McCash, 2017).

Home Pregnancy Tests

More than 60 different types of over-the-counter pregnancy test kits are available in the United States (Grenache, 2015). Unfortunately, many of these are not as accurate as advertised (Johnson, 2015). For example, Cole and associates (2011) found that a detection limit of 12.5 mIU/mL would be required to diagnose

95 percent of pregnancies at the time of missed menses. However, they reported that only one brand had this degree of sensitivity. Two other brands gave false-positive or invalid results. In fact, with an hCG concentration of 100 mIU/mL, clearly positive results were displayed by only 44 percent of brands. Accordingly, only approximately 15 percent of pregnancies could be diagnosed at the time of the missed menses. Some manufacturers of even newer home urine assays claim >99-percent accuracy for tests done on the day of—and some up to 4 days before—the expected day of menses. Again, careful analysis suggests that these assays are often not as sensitive as advertised.

■ Sonographic Recognition of Pregnancy

Transvaginal sonography is commonly used to accurately establish gestational age and confirm pregnancy location. A *gestational sac* is the first sonographic evidence of pregnancy, and it may be seen with transvaginal sonography by 4 to 5 weeks' gestation. It should not be confused with a *pseudogestational sac*. The latter, or *pseudosac*, is a fluid collection within the endometrial cavity, which can occur in the setting of ectopic pregnancy (Fig. 12-3, p. 223). Further evaluation may be warranted if this is the only sonographic finding, particularly in a woman with pain or bleeding. A normal gestational sac implants eccentrically in the endometrium, whereas a pseudosac is seen in the midline of the endometrial cavity. Other potential indicators of early intrauterine pregnancy are an anechoic center surrounded by a single echogenic rim—the *intradecidual sign*—or two concentric echogenic rings surrounding the gestational sac—the *double decidual sign* (Fig. 10-2). If sonography yields equivocal findings, the term *pregnancy of unknown location (PUL)* is applied (Bobdiwala, 2019). In these cases, serial serum hCG levels and transvaginal sonography can help differentiate a normal intrauterine pregnancy from an extrauterine pregnancy or an early miscarriage (Chap. 12, p. 222).

FIGURE 10-2 Transvaginal sonogram of a first-trimester intrauterine pregnancy. The double decidual sign is noted surrounding the gestational sac and is defined by the decidua parietalis (*white asterisk*) and the decidua capsularis (*yellow asterisk*). The arrow notes the yolk sac, and the crown-rump length of the embryo is marked with measuring calipers. (Reproduced with permission from Dr. Elysia Moschos.)

If the *yolk sac*—a brightly echogenic ring with an anechoic center—is seen within the gestational sac, an intrauterine location for the pregnancy is confirmed. The yolk sac can normally be seen by the middle of the fifth week. As shown in Figure 10-2, after 6 weeks, an embryo is seen as a linear structure immediately adjacent to the yolk sac. Cardiac motion is typically noted at this point.

INITIAL PRENATAL EVALUATION

Prenatal care is ideally initiated early. Major goals are to (1) define the health status of the mother and fetus, (2) estimate the gestational age, and (3) initiate a plan for continued obstetrical care. Typical components of the initial visit are summarized in Table 10-1. Subsequent care may range from relatively infrequent routine visits to prompt hospitalization because of serious maternal or fetal disease.

■ Prenatal Record

Use of a standardized record within a perinatal health-care system greatly aids antepartum and intrapartum management. Standardizing documentation allows communication and care continuity between providers and enables objective measures of care quality to be evaluated over time and across different clinical settings (Gregory, 2006). A prototype is provided by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) in their *Guidelines for Perinatal Care*, 8th edition.

Definitions

Several definitions are pertinent to establishment of an accurate prenatal record.

1. *Nulligravida*—a woman who currently is not pregnant and has never been pregnant.
2. *Gravida*—a woman who currently is pregnant or has been in the past, irrespective of the pregnancy outcome. With the establishment of the first pregnancy, she becomes a *primigravida*, and with successive pregnancies, a *multigravida*.
3. *Nullipara*—a woman who has never completed a pregnancy beyond 20 weeks' gestation. She may not have been pregnant or may have had a spontaneous or elective abortion(s) or an ectopic pregnancy.
4. *Primipara*—a woman who has been delivered only once of a fetus or fetuses born alive or dead with an estimated gestation duration of 20 or more weeks. In the past, a 500-g birthweight threshold was used to define parity. This threshold is now controversial. Namely, many states still use this weight to differentiate a stillborn fetus from an abortus, but the survival of neonates with birthweights <500 g is no longer uncommon (Chap. 1, p. 2).
5. *Multipara*—a woman who has completed two or more pregnancies with gestational ages at least 20 weeks. Parity is determined by the number of pregnancies reaching 20 weeks. It is not increased to a higher number if multiples are delivered in a given pregnancy. Moreover, stillbirth does not lower this number.

TABLE 10-1. Typical Components of Routine Prenatal Care

	Text Referral	First Visit	Weeks 15–20	Weeks 24–28	Weeks 29–41
History

Tuberculosis screening	Chap. 54, p. 966	**F**			

[a]First-trimester aneuploidy screening may be offered between 10 and 14 weeks.
A Performed at 28 weeks, if indicated.
B Test should be offered.
C High-risk women should be retested at the beginning of the third trimester.
D High-risk women should be screened at the first prenatal visit and again in the third trimester.
E Rectovaginal culture should be obtained between 35 and 37 weeks.
F High-risk women should be screened at the first prenatal visit.
HIV = human immunodeficiency virus.

In some locales, the obstetrical history is summarized by a series of digits connected by dashes. These refer to the number of term newborns, preterm neonates, abortuses younger than 20 weeks, and children currently alive. For example, a woman who is para 2–1–0–3 has had two term deliveries, one preterm delivery, no abortuses, and has three living children. Because these are nonconventional, it is helpful to specify the outcome of any pregnancy that did not end normally.

Normal Pregnancy Duration

The normal duration of pregnancy calculated from the first day of the last normal menstrual period is very close to 280 days or 40 weeks. A quick estimate of a pregnancy due date based on menstrual data can be made as follows: add 7 days to the first day of the last period and subtract 3 months. For example, if the first day of the last menses was October 5, the due date is 10-05 minus 3 (months) plus 7 (days) = 7–12 or July 12 of the following year. This calculation is the *Naegele rule*. However, menstrual cycle length varies among women and renders many of these calculations inaccurate. This, combined with the frequent use of first-trimester sonography, has changed the method of determining an accurate gestational age.

The American College of Obstetricians and Gynecologists (2017e), the American Institute of Ultrasound in Medicine, and the Society for Maternal-Fetal Medicine have emphasized that first-trimester ultrasound is the most accurate method to

establish or reaffirm gestational age. For pregnancies conceived by assisted reproductive technologies, embryo age or transfer date is used to assign gestational age. If available, the gestational ages calculated from the last menstrual period and from first-trimester ultrasound are compared, and this estimated date of delivery is recorded. Reconciling any discordance between these two values is discussed in Chapter 14 (p. 248).

Trimesters

It has become customary to divide pregnancy into three equal epochs or trimesters of approximately 3 calendar months. More recently a "fourth trimester" has been recognized to emphasize the need for comprehensive postpartum care (American College of Obstetricians and Gynecologists, 2018i). This is discussed in Chapter 36 (p. 634). Historically, the first trimester extends through completion of 14 weeks, the second through 28 weeks, and the third through 42 weeks. The fourth is the 12 weeks after delivery. Thus, prenatally, there are three periods of 14 weeks each. Certain major obstetrical problems tend to cluster in each of these three time periods. For example, most spontaneous abortions take place during the first trimester, whereas most women with hypertensive disorders due to pregnancy are diagnosed during the third trimester.

In modern obstetrics, the clinical use of trimesters to describe a specific pregnancy is imprecise. For example, it is inappropriate in cases of uterine hemorrhage to categorize the problem temporally as "third-trimester bleeding." Appropriate management for the mother and her fetus will vary remarkably depending on whether bleeding begins early or late in the third trimester (Chap. 42, p. 733). Because precise knowledge of fetal age is imperative for obstetrical management, the clinically appropriate unit is *weeks of gestation completed.* Clinicians designate gestational age using completed weeks and days. For example, $33^{4/7}$ weeks or 33 + 4 describes pregnancy duration of 33 completed weeks and 4 days.

Previous and Current Health Status

As elsewhere in medicine, history-taking begins with queries concerning medical or surgical disorders. Detailed information regarding previous pregnancies is essential, as many obstetrical complications tend to recur in subsequent pregnancies. The *menstrual* and *contraceptive histories* also are important. As noted earlier, gestational age may be less accurate for those with irregular menses. Moreover, some methods of birth control favor ectopic implantation following method failure (Chap. 38, p. 665).

Psychosocial Screening. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) define psychosocial issues as nonbiomedical factors that affect mental and physical well-being. Women should be screened regardless of social status, education level, race, or ethnicity. Such screening should seek barriers to care, communication obstacles, nutritional status, unstable housing, desire for pregnancy, safety concerns that include intimate-partner violence, depression, stress, and use of substances such as tobacco, alcohol, and illicit drugs. This screening is performed on a regular basis, at least once per trimester, to identify important issues and reduce adverse pregnancy outcomes. Coker and colleagues (2012) compared pregnancy outcomes in women before and after implementation of a universal psychosocial screening program and found that screened women were less likely to have preterm or low-birthweight newborns, as well as other adverse outcomes. Specific screens for depression are presented in Chapter 64 (p. 1143).

Cigarette Smoking. These data are included on the birth certificate, and the number of pregnant women who smoke continues to decline. From 2000 to 2010, the prevalences were 12 to 13 percent (Tong, 2013). By 2016, the incidence was 7.2 percent according to the National Center for Health Statistics (Drake, 2018). Concurrent with the decline in cigarette use, there has been an increase in electronic cigarettes/vaping with a reported prevalence of 0.6 to 15 percent (Whittington, 2018). In a survey of more than 3000 mothers in Oklahoma and Texas, 7 percent reported using electronic vapor products prior to conception and in the postpartum period. Of these women, according to the CDC, 1.4 percent used them during the last 3 months of pregnancy (Kapaya, 2019).

According to the American Society for Reproductive Medicine (2018), smoking is associated with subfertility. Higher rates of miscarriage, stillbirth, low birthweight, and preterm delivery also are linked to smoking during pregnancy (Dahlin, 2016; Luke, 2018; Tong, 2013). Compared with nonsmokers, risks of placenta previa, placental abruption, and premature membrane rupture are increased twofold. Potential teratogenic effects are reviewed in Chapter 8 (p. 156). Thus, the U.S. Preventive Services Task Force recommends that clinicians offer counseling and effective intervention options to pregnant smokers at the first and subsequent prenatal visits (Siu, 2015). Although benefits are greatest if smoking ceases early in pregnancy or preferably preconceptionally, quitting at any stage of pregnancy can improve perinatal outcomes (Soneji, 2019).

Compared with simple counseling to quit, person-to-person psychosocial interventions are significantly more successful in achieving smoking abstinence in pregnancy (Fiore, 2008). One example is a brief counseling session covering the "5As" of smoking cessation (Table 10-2). This approach can be accomplished in 15 minutes or less and is effective when initiated by health-care providers (American College of Obstetricians and Gynecologists, 2020b).

Behavioral interventions and nicotine replacement products are successful in reducing smoking rates (Patnode, 2015). However, nicotine replacement has not been sufficiently evaluated to determine its effectiveness and safety in pregnancy. Trials evaluating such therapy have yielded conflicting evidence (Coleman, 2015; Spindel, 2016). Two randomized trials also produced inconclusive results. In the Smoking and Nicotine in Pregnancy (SNAP) trial, Cooper and associates (2014) reported that a temporary cessation of smoking may have been associated with improved infant development. In the Study of Nicotine Patch in Pregnancy (SNIPP) trial, no differences in smoking cessation rates or birthweights were found (Berlin, 2014). Similar preliminary results were reported for sustained-release bupropion (Nanovskaya, 2017). Olson and colleagues (2019) reported that financial incentives were helpful to encourage smoking cessation.

TABLE 10-2. Five A's of Smoking Cessation

ASK about smoking at the first and subsequent prenatal visits.
ADVISE with clear, strong statements that explain the risks of continued smoking to the woman, fetus, and newborn.
ASSESS the patient's willingness to attempt cessation.
ASSIST with pregnancy-specific, self-help smoking cessation materials. Offer a direct referral to the smokers' quit line (1-800-QUIT NOW) to provide ongoing counseling and support.
ARRANGE to track smoking abstinence progress at subsequent visits.

Adapted from American College of Obstetricians and Gynecologists, 2020b; Fiore, 2008.

Because of limited available evidence to support pharmacotherapy for smoking cessation in pregnancy, the American College of Obstetricians and Gynecologists (2020b) recommends that if nicotine replacement therapy is used, it should be done with close supervision and after careful consideration of the risks of smoking versus nicotine replacement.

Alcohol. Ethyl alcohol or ethanol is a potent teratogen that causes the *fetal alcohol spectrum disorders.* Fetal alcohol syndrome, the most severe form of these disorders, is characterized by growth restriction, facial abnormalities, and central nervous system dysfunction. The estimated prevalence of these disorders is 11 to 50 per 1000 (May, 2018).

As discussed in Chapter 8 (p. 150), women who are pregnant or considering pregnancy should abstain from drinking any alcoholic beverages (Sarman, 2018). The CDC analyzed data from the Behavioral Risk Factor Surveillance System from 2015 to 2017 and estimated that 12 percent of pregnant women used alcohol (Denny, 2019). The American College of Obstetricians and Gynecologists (2021a) in collaboration with the CDC has developed the *Fetal Alcohol Spectrum Disorders (FASD) Prevention Program*, which provides resources for providers and is available at www.acog.org/alcohol.

Illicit Drugs. An estimated 10 percent of fetuses are exposed to one or more illicit drugs. Agents may include heroin and other opiates, cocaine, amphetamines, barbiturates, and marijuana (American Academy of Pediatrics, 2017). As discussed in Chapter 8 (p. 157), chronic use of large quantities is harmful to the fetus (Metz, 2015). Well-documented sequelae include fetal-growth restriction, low birthweight, and drug withdrawal soon after birth. Adverse effects of marijuana are less convincing. Women who use such drugs frequently do not seek prenatal care, which in itself is associated with risks for preterm and low-birthweight neonates (Eriksen, 2016).

For women who abuse heroin, methadone maintenance can be initiated within a registered methadone treatment program to reduce complications of illicit opioid use and narcotic withdrawal, to encourage prenatal care, and to avoid drug culture risks (American College of Obstetricians and Gynecologists, 2017g). Available programs can be found through the treatment locator of the Substance Abuse and Mental Health Services Administration at www.samhsa.gov. Methadone dosages usually are initiated at 10 to 30 mg orally daily and titrated as needed. In some women, careful methadone taper may be an appropriate option (Stewart, 2013). Buprenorphine alone or in combination with naloxone also may be offered and managed by physicians with specific credentialing. These therapeutic options are considered in greater detail in Chapter 64 (p. 1150).

Intimate-Partner Violence. This term refers to a pattern of assault and coercive behavior that may include physical injury, psychological abuse, sexual assault, progressive isolation, stalking, deprivation, intimidation, and reproductive coercion (Miller, 2019). Such violence is recognized as a major public health problem. Unfortunately, most abused women continue to be victimized during pregnancy. With the possible exception of preeclampsia, intimate-partner violence (IPV) is more prevalent than any major medical condition detectable through routine prenatal screening (American Academy of Pediatrics, 2017). The estimated prevalence during pregnancy lies between 4 and 8 percent. IPV is associated with an increased risk of several adverse perinatal outcomes that include preterm delivery, fetal-growth restriction, and perinatal death (Chap. 50, p. 891).

The American College of Obstetricians and Gynecologists (2019c) has provided methods for IPV screening and recommends their use at the first prenatal visit, again at least once per trimester, and again at the postpartum visit. Such screening should be done privately and away from family members and friends. Patient self-administered or computerized screenings appear to be as effective for disclosure as clinician-directed interviews (Ahmad, 2009; Chen, 2007). Physicians should be familiar with state laws that may require reporting of IPV. Coordination with social services can be invaluable in these cases. The National Domestic Violence Hotline (1–800–799-SAFE [7233]) is a nonprofit telephone referral service that provides individualized information regarding city-specific shelter locations, counseling resources, and legal advocacy.

Clinical Evaluation

Thorough, general physical and pelvic examinations should be completed at the initial prenatal encounter. The cervix is visualized using a speculum lubricated with warm water or water-based lubricant gel. Bluish-red passive hyperemia of the cervix is characteristic, but not diagnostic, of pregnancy. Dilated, occluded cervical glands bulging beneath the ectocervical mucosa—*nabothian cysts*—may be prominent. The cervix is not normally dilated except at the external os. To identify cytological abnormalities, a Pap test is performed according to current guidelines noted in Chapter 66 (p. 1164). Specimens for identification of *Chlamydia trachomatis* and *Neisseria gonorrhoeae* are obtained when indicated (p. 181).

Bimanual examination is completed by palpation. Special attention is given to the consistency, length, and dilation of the

cervix; to uterine and adnexal size; to the bony pelvic architecture; and to any vaginal or perineal anomalies. Often, later in pregnancy, fetal presentation also can be determined. Lesions of the cervix, vagina, or vulva are further evaluated as needed by colposcopy, biopsy, or culture. The perianal region is inspected, and digital rectal examination is performed as required for complaints of rectal pain, bleeding, or mass.

Gestational Age Assessment

Precise knowledge of gestational age is essential for prenatal care, because several pregnancy complications may develop and optimal treatment will depend on fetal age. Menstrual history is best confirmed by first-trimester sonography (Chap. 14, p. 248). That said, gestational age can also be estimated with considerable precision by a carefully performed clinical uterine size examination that is coupled with last menstrual period dating. Uterine size similar to a small orange roughly correlates with a 6-week gestation; a large orange, with an 8-week pregnancy; and a grapefruit, with one at 12 weeks (Margulies, 2001).

Laboratory Tests

Recommended routine tests at the first prenatal encounter are listed in Table 10-1. Initial blood tests include a complete blood count, a determination of blood type and Rh status, and an antibody screen. The Institute of Medicine recommends universal human immunodeficiency virus (HIV) testing as a routine part of prenatal care. This testing is explained to the patient, who may decline. The American College of Obstetricians and Gynecologists (2018j) continues to support this practice. If a woman declines, this is recorded in the prenatal record. All pregnant women are screened also for hepatitis B virus infection, syphilis, and immunity to rubella at the initial visit.

Based on their prospective investigation of 1000 women, Murray and coworkers (2002) concluded that in the absence of hypertension, routine urinalysis beyond the first prenatal visit was unnecessary. A urine culture is recommended by most, because treating bacteriuria significantly reduces the likelihood of developing symptomatic urinary tract infections in pregnancy (Chap. 56, p. 996).

Cervical Infections

C trachomatis is isolated from the cervix in 2 to 13 percent of pregnant women. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) recommend that all women be screened for chlamydia during the first prenatal visit, with additional third-trimester testing for those at increased risk. Risk factors include unmarried status, recent change in sexual partner or multiple concurrent partners, age younger than 25 years, inner-city residence, history or presence of other sexually transmitted diseases, and little or no prenatal care. For those testing positive, treatment described in Chapter 68 (p. 1212) is followed by a second testing—a *test of cure*—3 to 4 weeks after treatment completion.

N gonorrhoeae typically causes cervicitis or urethritis in pregnancy. Infrequently, it may also cause septic arthritis (Bleich, 2012). Risk factors for gonorrhea are similar to those for chlamydial infection. The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) recommend that pregnant women with risk factors or those living in an area of high *N gonorrhoeae* prevalence be screened at the initial prenatal visit and again in the third trimester. Treatment is given for gonorrhea and simultaneously for possible coexisting chlamydial infection (Chap. 68, p. 1211). Test of cure is recommended following treatment.

Pregnancy Risk Assessment

Many factors can adversely affect maternal and fetal well-being. Some are evident at conception, but many become apparent during the course of pregnancy. The designation of "high-risk pregnancy" is overly vague for an individual woman and is best avoided if a more specific diagnosis can be assigned. Some common risk factors for which consultation is recommended by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) are shown in Table 10-3. Some conditions may require the involvement of a maternal-fetal medicine specialist, geneticist, neonatologist, anesthesiologist, cardiologist, or other specialist.

SUBSEQUENT PRENATAL VISITS

These are traditionally scheduled at 4-week intervals until 28 weeks, then every 2 weeks until 36 weeks, and weekly thereafter. Women with complicated pregnancies—for example, with twins or diabetes—often require return visits at 1- to 2-week intervals (Power, 2013). In 1986, the Department of Health and Human Services convened an expert panel to review the content of prenatal care. This report was subsequently reevaluated and revised in 2005 (Gregory, 2006). The panel recommended, among other things, early and continuing risk assessment that is patient specific. It also endorsed flexibility in clinical visit spacing; health promotion and education, including preconceptional care; medical and psychosocial interventions; standardized documentation; and expanded prenatal care objectives that include family health up to 1 year after birth.

The World Health Organization conducted a multicenter randomized trial with almost 25,000 women that compared routine prenatal care with an experimental model designed to minimize visits (Villar, 2001). In the new model, women were seen once in the first trimester and screened for certain risks. Those without anticipated complications—80 percent of those screened—were seen again at 26, 32, and 38 weeks. Compared with routine prenatal care, which required a median of eight visits, the new model required a median of only five. No disadvantages were attributed to the regimen with fewer visits, and these findings are consistent with other randomized trials.

Prenatal Surveillance

At each return visit, the well-being of mother and fetus are assessed (see Table 10-1). Fetal heart rate, growth, and activity are evaluated. Maternal blood pressure and weight and their extent of change are assessed. Symptoms such as abdominal pain, nausea and vomiting, bleeding, vaginal fluid leakage, headache, altered vision, and dysuria are sought. After 20 weeks' gestation, uterine examination measures size from the symphysis to the fundus with

TABLE 10-3. Conditions for Which Maternal-Fetal Medicine Consultation May Be Beneficial

Medical History and Conditions
Cardiac disease—moderate to severe disorders
Diabetes mellitus with evidence of end-organ damage or uncontrolled hyperglycemia
Family or personal history of genetic abnormalities
Hemoglobinopathy
Chronic hypertension if uncontrolled or associated with renal or cardiac disease
Renal insufficiency if associated with significant proteinuria (≥500 mg/24 hour), serum creatinine ≥1.5 mg/dL, or hypertension
Pulmonary disease if severe restrictive or obstructive, including severe asthma
Human immunodeficiency virus infection
Prior pulmonary embolus or deep-vein thrombosis
Severe systemic disease, including autoimmune conditions
Bariatric surgery
Epilepsy if poorly controlled or requires more than one anticonvulsant
Cancer, especially if treatment is indicated in pregnancy
Obstetrical History and Conditions
CDE (Rh) or other blood group alloimmunization (excluding ABO, Lewis)
Prior or current fetal structural or chromosomal abnormality
Desire or need for prenatal diagnosis or fetal therapy
Periconceptional exposure to known teratogens
Infection with or exposure to organisms that cause congenital infection
Higher-order multifetal gestation
Severe disorders of amnionic fluid volume

a traditional tape measure. In late pregnancy, vaginal examination often provides valuable information. This may include confirmation of the presenting part and its station, clinical estimation of pelvic capacity and configuration, fetal ballottement as a reflection of sufficient amnionic fluid volume, and cervical consistency, effacement, and dilation (Chap. 22, p. 426).

Fundal Height

Between 20 and 34 weeks' gestation, the height of the uterine fundus measured in centimeters correlates closely with gestational age in weeks. This measurement is used to monitor fetal growth and amnionic fluid volume. It is measured along the abdominal wall from the top of the symphysis pubis to the top of the fundus. Importantly, the bladder must be emptied before fundal measurement. Obesity or the presence of uterine masses such as leiomyomas also may limit fundal height measurement accuracy. Moreover, using fundal height alone, fetal-growth restriction may be undiagnosed in up to a third of cases (American College of Obstetricians and Gynecologists, 2021b; Haragan, 2015).

Fetal Heart Sounds

Instruments incorporating Doppler ultrasound are usually used to easily detect fetal heart action, and in the absence of maternal obesity, heart sounds are almost always detectable by 10 weeks with such instruments (Chap. 24, p. 447). The fetal heart rate ranges from 110 to 160 beats per minute and is typically heard as a double sound. Using a standard nonamplified stethoscope, the fetal heart is audible by 20 weeks in 80 percent of women, and by 22 weeks, heart sounds are expected to be heard in all (Herbert, 1987). Because the fetus moves freely in amnionic fluid, the site on the maternal abdomen where fetal heart sounds can be heard best will vary.

Additionally, with ultrasonic auscultation, one may hear the *funic souffle*, which is a sharp, whistling sound that is synchronous with the fetal pulse. It is caused by the rush of blood through the umbilical arteries and may not be heard consistently. In contrast, the *uterine souffle* is a soft, blowing sound that is synchronous with the maternal pulse. It is produced by the passage of blood through the dilated uterine vessels and is heard most distinctly near the lower portion of the uterus.

Sonography

Ultrasound imaging provides invaluable information regarding fetal anatomy, growth, and well-being. As such, it is recommended that all pregnant women be offered at least one prenatal sonographic examination (American College of Obstetricians and Gynecologists, 2018l). Continuing trends suggest that the number of these examinations performed per pregnancy is increasing. Data from commercial insurance plans indicate that even low-risk pregnancies receive an average of 4 to 5 ultrasound examinations (O'Keeffe, 2013). Sonography should be performed only for valid medical indications. Additionally, needed information is obtained using the lowest possible ultrasound exposure settings, which is the as low as reasonably achievable (ALARA) principle (American Institute of Ultrasound in Medicine, 2016).

■ Subsequent Laboratory Tests

If initial results were normal, most tests need not be repeated. Hematocrit or hemoglobin determination, along with serology

for syphilis if it is prevalent in the population, is repeated at 28 to 32 weeks (Hollier, 2003; Kiss, 2004). For women at increased risk for HIV acquisition during pregnancy, repeat testing is recommended in the third trimester, preferably before 36 weeks (American College of Obstetricians and Gynecologists, 2018j). Similarly, women who engage in behaviors that place them at high risk for hepatitis B virus infection are retested at the time of delivery. Women who are D (Rh) negative and are unsensitized should have an antibody screening test repeated at 28 to 29 weeks. Anti-D immunoglobulin is given if they remain unsensitized (Chap. 18, p. 354).

Group B Streptococcal Infection

The CDC (2010b) recommends that vaginal and rectal group B streptococcal (GBS) cultures be obtained in all women between 35 and 37 weeks' gestation, and the American College of Obstetricians and Gynecologists (2020f) endorses this recommendation. Intrapartum antimicrobial prophylaxis is provided to those whose culture results are positive. Women with GBS bacteriuria, preterm labor, or a previous infant with invasive disease are given empirical intrapartum prophylaxis. Trials are in progress to test an investigational vaccine (Madhi, 2016). These infections are described further in Chapter 67 (p. 1194).

Gestational Diabetes

All pregnant women are screened for gestational diabetes mellitus, whether by history, clinical factors, or routine laboratory testing. Although laboratory testing between 24 and 28 weeks' gestation is the most sensitive approach, there may be women at low risk who are less likely to benefit from testing (American College of Obstetricians and Gynecologists, 2019d). Gestational diabetes is discussed in Chapter 60 (p. 1079).

Genetic Screening

Serum screening for fetal aneuploidy is routinely offered to all pregnant women—in the first trimester at 10 to 14 weeks, in the second trimester at 15 to 20 weeks, or as cell-free DNA screening at any point after 10 weeks (American College of Obstetricians and Gynecologists, 2020d). Additionally, the College recommends that both cystic fibrosis carrier screening and screening for spinal muscular atrophy should be offered to all women considering pregnancy or who are currently pregnant, provided that carrier or disease status is not already known (American College of Obstetricians and Gynecologist, 2017b).

Historically, carrier screening for selected genetic abnormalities was offered only to women at increased risk based on ethnic or racial background. One example is screening for Tay-Sachs disease in those of Ashkenazi Jewish descent. However, given our increasingly diverse, multiethnic society, previous assumptions about carrier risk may no longer apply. Although ethnicity-specific carrier screening remains an option, providers should also consider panethnic and expanded carrier screening strategies (American College of Obstetricians and Gynecologists, 2017c). These are discussed further in Chapter 17 (p. 342). All genetic screening is optional, and ideally, genetic carrier screening and counseling should be performed before pregnancy.

Neural-Tube Defects

Traditionally, screening for neural-tube defects has been performed as part of second-trimester aneuploidy screening. An elevation of maternal serum alpha-fetoprotein (MSAFP) levels then prompted additional evaluation with ultrasound and/or amniocentesis. With the advent of other screening modalities for aneuploidy, second-trimester MSAFP testing is less frequently obtained. For example, the expansion of second-trimester fetal anatomical surveillance has been used to screen and identify neural-tube defects (American College of Obstetricians and Gynecologists, 2017f).

NUTRITIONAL COUNSELING

Weight Gain Recommendations

In 2009, the Institute of Medicine and National Research Council revised guidelines for weight gain in pregnancy and continued to stratify suggested weight gain ranges based on prepregnancy body mass index (BMI) (Table 10-4). The same recommendations apply to women in all age, race, and ethnic groups. The American College of Obstetricians and Gynecologists (2018n) endorses these measures.

When the initial Institute of Medicine guidelines were formulated, concern focused on low-birthweight newborns. However, current emphasis is directed to the obesity epidemic. The specific and relatively narrow range of recommended weight gains for obese women emphasizes the renewed interest in *lower* weight gains during pregnancy. Obesity is associated with significantly greater risks for gestational hypertension, preeclampsia, gestational diabetes, macrosomia, cesarean delivery, and other complications (Chap. 51, p. 905). The risk appears proportionate to prenatal weight gain. In a Maternal-Fetal Medicine Units Network cohort of more than 29,000 pregnant women, 51 percent had weight gain above and 21 percent below the guidelines

TABLE 10-4. Recommendations for Total and Rate of Weight Gain During Pregnancy

Category (BMI)	Total Weight Gain Range (lb)[a]	Weight Gain in 2nd and 3rd Trimesters Mean in lb/wk (range)
Underweight (<18.5)	28–40	1 (1–1.3)
Normal weight (18.5–24.9)	25–35	1 (0.8–1)
Overweight (25.0–29.9)	15–25	0.6 (0.5–0.7)
Obese (≥30.0)	11–20	0.5 (0.4–0.6)

[a]Empirical recommendations for weight gain in twin pregnancies include: normal BMI, 37–54 lb; overweight women, 31–50 lb; and obese women, 25–42 lb.
BMI = body mass index.
Modified from the Centers for Disease Control and Prevention, 2019b; Institute of Medicine and National Research Council, 2009.

(Kominiarek, 2018). Those with excessive weight gain had higher rates of hypertension and cesarean delivery. This risk is even greater in chronically hypertensive women (Ornaghi, 2018).

Conversely, among 100,000 women with normal prepregnancy BMI, DeVader and colleagues (2007) found that those who gained <25 lb during pregnancy had a lower risk for preeclampsia, failed induction, cephalopelvic disproportion, cesarean delivery, and large-for-gestational age neonates. This cohort, however, had an increased risk for small-for-gestational age newborns.

Severe Undernutrition

Meaningful studies of nutrition in human pregnancy are exceedingly difficult to design because experimental dietary deficiency is not ethical. In those instances in which severe nutritional deficiencies have been induced as a consequence of social, economic, or political disaster, coincidental events have often created many variables, the effects of which are not amenable to quantification. Some past experiences suggest, however, that in otherwise healthy women, a state of near starvation is required to establish clear differences in pregnancy outcome. These are discussed in Chapter 47 (p. 827).

Weight Retention After Pregnancy

Not all the weight gained during pregnancy is lost during and immediately after delivery. Schauberger and coworkers (1992) studied prenatal and postpartum weights in 795 women. Their average weight gain was 28.6 lb or 12.9 kg. As shown in Figure 10-3, most maternal weight loss was at delivery—approximately 12 lb or 5.4 kg—and in the ensuing 2 weeks—approximately 9 lb or 4 kg. An additional 5.5 lb or 2.5 kg was lost between 2 weeks and 6 months postpartum. Thus, average retained pregnancy weight was 2.1 lb or 1 kg. Excessive weight gain is manifest by accrual of fat and may be partially retained as long-term fat (Berggren, 2016; Widen, 2015). Overall, the more weight that was gained during pregnancy, the more that was lost postpartum. And breastfeeding duration is inversely related to weight retention (Jiang, 2018).

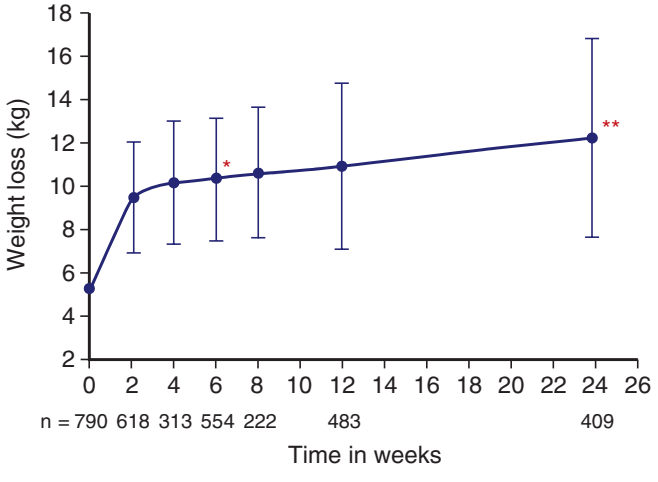

FIGURE 10-3 Cumulative weight loss from last antepartum visit to 6 months postpartum. On average, 1 kg will be retained after pregnancy. *Significantly different from 2-week weight loss; **Significantly different from 6-week weight loss. (Redrawn with permission from Schauberger CW, Rooney BL, Brimer LM: Factors that influence weight loss in the puerperium. Obstet Gynecol 79:424, 1992.)

Dietary Reference Intakes—Recommended Allowances

Periodically, the Institute of Medicine (2006, 2011) publishes recommended dietary allowances, including those for pregnant or lactating women. Some of its latest recommendations are summarized in Table 10-5. Certain prenatal vitamin–mineral supplements may lead to intakes well in excess of the recommended allowances. Moreover, the use of excessive supplements, which often are self-prescribed, has led to concern regarding nutrient toxicities during pregnancy. *Those with potentially toxic effects include iron, zinc, selenium, and vitamins A, B_6, C, and D.*

Calories

As shown in Figure 10-4, pregnancy requires an additional 80,000 kcal, mostly during the last 20 weeks. To meet this demand, a caloric increase of 100 to 300 kcal/d is recommended

TABLE 10-5. Recommended Daily Dietary Allowances for Pregnant and Lactating Women

	Pregnant	Lactating
Fat-Soluble Vitamins		
Vitamin A	770 µg	1300 µg
Vitamin D[a]	15 µg	15 µg
Vitamin E	15 mg	19 mg
Vitamin K[a]	90 µg	90 µg
Water-Soluble Vitamins		
Vitamin C	85 mg	120 mg
Thiamin	1.4 mg	1.4 mg
Riboflavin	1.4 mg	1.6 mg
Niacin	18 mg	17 mg
Vitamin B_6	1.9 mg	2 mg
Folate	600 µg	500 µg
Vitamin B_{12}	2.6 µg	2.8 µg
Minerals		
Calcium[a]	1000 mg	1000 mg
Sodium[a]	1.5 g	1.5 g
Potassium[a]	4.7 g	5.1 g
Iron	27 mg	9 mg
Zinc	11 mg	12 mg
Iodine	220 µg	290 µg
Selenium	60 µg	70 µg
Other		
Protein	71 g	71 g
Carbohydrate	175 g	210 g
Fiber[a]	28 g	29 g

[a]Recommendations measured as adequate intake.
Modified from the American Academy of Pediatrics, 2017; Institute of Medicine, 2006, 2011.

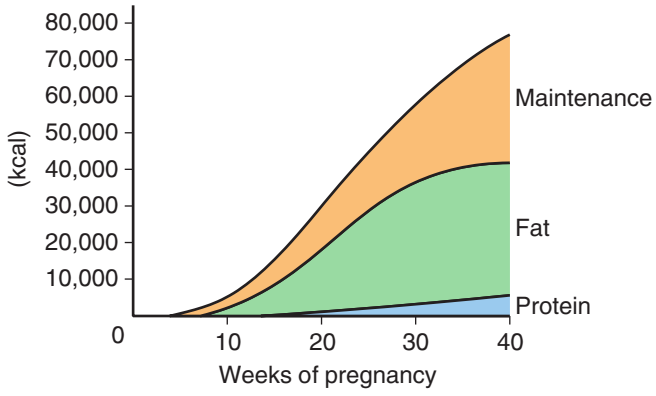

FIGURE 10-4 Cumulative kilocalories required for pregnancy. (Redrawn with permission from Chamberlain G, Broughton-Pipkin F [eds]: Clinical Physiology in Obstetrics, 3rd ed. Oxford, Blackwell Science, 1998.)

during pregnancy (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2017). This greater intake, however, should not be divided equally during the course of pregnancy. The Institute of Medicine (2006) recommends adding 0, 340, and 452 kcal/d to the estimated nonpregnant energy requirements in the first, second, and third trimesters, respectively. The addition of 1000 kcal/d or more results in fat accrual (Jebeile, 2015).

Whenever caloric intake is inadequate, protein is metabolized rather than being spared for its vital role in fetal growth and development. Total physiological requirements during pregnancy are not necessarily the sum of ordinary nonpregnant requirements plus those specific to pregnancy. For example, the additional energy required during pregnancy may be compensated in whole or in part by reduced physical activity (Hytten, 1991).

Protein

Protein requirements rise to meet the demands for growth and remodeling of the fetus, placenta, uterus, and breasts, and for the expanded maternal blood volume (Chap. 4, p. 51). During the second half of pregnancy, approximately 1000 g of protein are deposited, amounting to 5 to 6 g/d (Hytten, 1971). To accomplish this, protein intake that approximates 1 g/kg/d is recommended (see Table 10-5). Data suggest this should be doubled in late gestation (Stephens, 2015). Most amino-acid levels in maternal plasma fall markedly, including ornithine, glycine, taurine, and proline (Hytten, 1991). Exceptions during pregnancy are glutamic acid and alanine, the concentrations of which rise.

Preferably, most protein is supplied from animal sources, such as meat, milk, eggs, cheese, poultry, and fish. These furnish amino acids in optimal combinations. Milk and dairy products are considered nearly ideal sources of nutrients, especially protein and calcium, for pregnant or lactating women. Ingestion of specific fish and potential methylmercury toxicity are discussed later (p. 188).

Minerals

The intakes recommended by the Institute of Medicine (2006) for various minerals are listed in Table 10-5. With the exception of iron and iodine, practically all diets that supply sufficient calories for appropriate weight gain will contain enough minerals to prevent deficiency.

Iron requirements substantively rise during pregnancy, and reasons for this are discussed in Chapter 4 (p. 60). Of the approximately 300 mg of iron transferred to the fetus and placenta and the 500 mg incorporated into the expanding maternal hemoglobin mass, nearly all is used after midpregnancy. During that time, iron requirements imposed by pregnancy and maternal excretion total approximately 7 mg/d (Pritchard, 1970). Few women have sufficient iron stores or dietary intake to supply this amount. Thus, the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017) endorse the recommendation by the National Academy of Sciences that at least 27 mg of elemental iron be supplemented daily to pregnant women. This amount is contained in most prenatal vitamins.

As little as 30 mg of elemental iron, supplied as ferrous gluconate, sulfate, or fumarate, and taken daily throughout the latter half of pregnancy, provides sufficient iron to meet pregnancy requirements and protect preexisting iron stores (Scott, 1970). This amount will also provide for iron requirements of lactation. Notably, in iron preparations, the number of milligrams of compound is followed by the milligrams of elemental iron, which is enclosed by parentheses. The pregnant woman may benefit from 60 to 100 mg of elemental iron per day if she is obese, has a multifetal gestation, begins supplementation late in pregnancy, takes iron irregularly, or has a depressed hemoglobin level. The woman who is overtly anemic from iron deficiency responds well to oral supplementation with iron salts. In response, serum ferritin levels rise more than the hemoglobin concentration (Daru, 2016).

Iodine also is needed, and the recommended iodine allowance is 220 µg/d (see Table 10-5). The use of iodized salt and bread products is recommended during pregnancy to offset the increased fetal requirements and maternal renal losses of iodine. Despite this, iodine intake has declined substantially in the past 15 years, and in some areas it is probably inadequate (Caldwell, 2013; Chittimoju, 2019). Severe maternal iodine deficiency predisposes offspring to endemic cretinism, which is characterized by multiple severe neurological defects. In parts of China and Africa, where this condition is common, iodide supplementation very early in pregnancy prevents some cretinism cases (Cao, 1994). To obviate this, most prenatal supplements now contain various quantities of iodine (Patel, 2019).

Calcium is retained by the pregnant woman during gestation and approximates 30 g. Most of this is deposited in the fetus late in pregnancy (Pitkin, 1985). This amount of calcium represents only approximately 2.5 percent of total maternal calcium, most of which is in bone and can readily be mobilized for fetal growth. As another potential use, routine calcium supplementation to prevent preeclampsia is ineffective (Chap. 40, p. 704).

Zinc deficiency if severe may lead to poor appetite, suboptimal growth, and impaired wound healing. During pregnancy, the recommended daily intake approximates 12 mg. But, the safe level of zinc supplementation for pregnant women is not clearly established. Vegetarians have lower zinc intakes (Foster, 2015). The bulk of studies support zinc supplementation only

in zinc-deficient women in poor-resource countries (Nossier, 2015; Ota, 2015).

Magnesium deficiency as a consequence of pregnancy has not been recognized. Undoubtedly, during prolonged illness with no magnesium intake, the plasma level might become critically low, as it would in the absence of pregnancy. We have observed this deficiency during pregnancies in some with previous intestinal bypass surgery. Instead, as a preventive agent, Sibai and colleagues (1989) randomly assigned 400 normotensive primigravidas to receive 365-mg elemental magnesium supplementation or placebo tablets from 13 to 24 weeks' gestation. Supplementation did not improve any measures of pregnancy outcome.

Trace metals include copper, selenium, chromium, and manganese, which all have important roles in certain enzyme functions. In general, most are provided by an average diet. Selenium deficiency is manifested by a frequently fatal cardiomyopathy in young children and reproductive-aged women. Conversely, selenium toxicity resulting from oversupplementation also has been observed. Selenium supplementation is not needed in American women.

Potassium concentrations in maternal plasma decline by approximately 0.5 mEq/L by midpregnancy (Brown, 1986). Potassium deficiency develops in the same circumstances as in nonpregnant individuals. One common example in pregnant women is hyperemesis gravidarum.

Fluoride metabolism is not altered appreciably during pregnancy (Maheshwari, 1983). Horowitz and Heifetz (1967) concluded that no additional offspring benefits accrued from maternal ingestion of fluoridated water if the newborn ingested such water from birth. Sa Roriz Fonteles and associates (2005) studied microdrill biopsies of deciduous teeth and concluded that antenatal fluoride provided no additional fluoride uptake compared with postnatal fluoride alone. Finally, supplemental fluoride ingested by lactating women does not raise the fluoride concentration in breast milk (Ekstrand, 1981).

Vitamins

The increased requirements for most vitamins during pregnancy shown in Table 10-5 usually are supplied by any general diet that provides adequate calories and protein. The exception is folic acid during times of unusual requirements, such as pregnancy complicated by protracted vomiting, hemolytic anemia, or multiple fetuses. That said, in impoverished countries, routine multivitamin supplementation reduced the incidence of low-birthweight and growth-restricted fetuses but did not alter preterm delivery or perinatal mortality rates (Fawzi, 2007).

Folic acid supplementation in early pregnancy can lower neural-tube defect risks (Chap. 15, p. 276). For example, the CDC (2004) estimated that the number of affected pregnancies had decreased from 4000 per year to approximately 3000 per year after mandatory fortification of cereal products with folic acid in 1998. Perhaps more than half of all neural-tube defects can be prevented with daily intake of 400 µg of folic acid throughout the periconceptional period (Centers for Disease Control and Prevention, 2019a). Evidence also suggests that folate insufficiency has a global effect on brain development (Ars, 2016). Putting 140 µg of folic acid into each 100 g of grain products may increase the folic acid intake of the average American woman of childbearing age by 100 µg/d. Because nutritional sources alone are insufficient, however, folic acid supplementation is still recommended.

A woman with a prior child with a neural-tube defect can reduce the 2- to 5-percent recurrence risk by more than 70 percent with a daily 4-mg folic acid supplement taken during the month before conception and during the first trimester. As emphasized by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2017), this dose should be consumed as a separate supplement and not as multivitamin tablets. This practice avoids excessive intake of fat-soluble vitamins.

Vitamin A, although essential, has been associated with congenital malformations when taken during pregnancy in high doses (>10,000 IU/d). These malformations are similar to those produced by the vitamin A derivative isotretinoin (Accutane), which is a potent teratogen (Chap. 8, p. 155). Beta-carotene, the precursor of vitamin A found in fruits and vegetables, does not produce vitamin A toxicity. Most prenatal vitamins contain vitamin A in doses considerably below the teratogenic threshold. Dietary intake of vitamin A in the United States appears to be adequate, and additional supplementation is not routinely recommended. In contrast, vitamin A deficiency is an endemic nutritional problem in the developing world (McCauley, 2015). Vitamin A deficiency, whether overt or subclinical, is associated with night blindness and with an increased risk of maternal anemia and spontaneous preterm birth (West, 2003).

Vitamin B_{12} plasma levels drop in normal pregnancy, mostly as a result of reduced plasma levels of their carrier proteins—*transcobalamins*. Vitamin B_{12} occurs naturally only in foods of animal origin, and strict vegetarians may give birth to neonates whose B_{12} stores are low. Likewise, because breast milk of a vegetarian mother contains little vitamin B_{12}, the deficiency may become profound in the breastfed infant (Higginbottom, 1978). Excessive ingestion of vitamin C also can lead to a functional deficiency of vitamin B_{12}. Although its role is still controversial, vitamin B_{12} deficiency may be an independent factor associated with neural-tube defects (Molloy, 2018).

Vitamin B_6, which is pyridoxine, does not require supplementation in most gravidas (Salam, 2015). For women at high risk for inadequate nutrition, a daily 2-mg supplement is recommended. As discussed on page 191, vitamin B_6, when combined with the antihistamine *doxylamine*, is helpful in many cases of nausea and vomiting of pregnancy.

Vitamin C allowances during pregnancy are 80 to 85 mg/d—approximately 20 percent more than when nonpregnant (see Table 10-5). A reasonable diet should readily provide this amount, and supplementation is unnecessary (Rumbold, 2015). Maternal plasma levels decline during pregnancy, whereas cord blood levels are higher. This is a phenomenon observed with most water-soluble vitamins.

Vitamin D is a fat-soluble vitamin. After being metabolized to its active form, it boosts the efficiency of intestinal calcium absorption and promotes bone mineralization and growth. Unlike most vitamins that are obtained exclusively from dietary intake, vitamin D is also synthesized endogenously with exposure to sunlight. Vitamin D deficiency is common during pregnancy. This is especially

true in high-risk groups such as women with limited sun exposure, vegetarians, and ethnic minorities—particularly those with darker skin (Bodnar, 2007). Maternal deficiency can cause disordered skeletal homeostasis, congenital rickets, and fractures in the newborn (American College of Obstetricians and Gynecologists, 2017j). However, vitamin D supplementation in women with asthma *may* decrease the likelihood of childhood asthma in their offspring (Litonjua, 2016). The Food and Nutrition Board of the Institute of Medicine (2011) established that an adequate intake of vitamin D during pregnancy and lactation was 15 µg/d (600 IU/d). In women suspected of having vitamin D deficiency, serum levels of 25-hydroxyvitamin D can be obtained. Even then, the optimal levels in pregnancy have not been established (De-Regil, 2016).

Pragmatic Nutritional Surveillance

Although researchers continue to study the ideal nutritional regimen for the pregnant woman and her fetus, basic tenets for the clinician include:

1. Advise the pregnant woman to eat food types she wants in reasonable amounts and salted to taste.
2. Ensure that food is amply available for socioeconomically deprived women.
3. Monitor weight gain and align goals with the Institute of Medicine recommendations.
4. Explore food intake by dietary recall periodically to discover the occasional nutritionally errant diet.
5. Give tablets of simple iron salts that provide at least 30 mg of elemental iron daily. Give folate supplementation before and in the early weeks of pregnancy. Provide iodine supplementation in areas of known dietary insufficiency.
6. Recheck the hematocrit or hemoglobin concentration at 28 to 32 weeks' gestation to detect significant anemia.

COMMON CONCERNS

Employment

More than half of the children in the United States are born to working mothers. Several federal laws have been passed to protect pregnant workers. These prohibit employers from excluding women from job categories on the basis that they are or might become pregnant. The Family and Medical Leave Act of 1993 requires that covered employers must grant up to 12 work weeks of unpaid leave to an employee for the birth and care of a newborn child.

In the absence of complications, most women can continue to work until labor onset (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2017). Some types of work, however, may increase pregnancy complication risks. According to the American College of Obstetricians and Gynecologists (2018b), risks of preterm birth are slightly to modestly increased with standing or walking at work >3 hours daily, lifting and carrying >5 kg, or physically exerting oneself at work. In a prospective study of more than 900 healthy nulliparas, women who worked had a fivefold higher risk of preeclampsia (Higgins, 2002). Thus, any occupation that subjects the gravida to severe physical strain should be avoided. Ideally, no work or play is continued to the extent that undue fatigue develops. Adequate periods of rest should be provided.

Exercise

In general, pregnant women do not need to limit exercise, provided they do not become excessively fatigued or risk injury (Davenport, 2016). Clapp and associates (2000) reported that both placental size and birthweight were significantly greater in women who exercised. Duncombe and coworkers (2006) reported similar findings in 148 women. In contrast, Magann and colleagues (2002) prospectively analyzed exercise behavior in 750 healthy women and found that working women who exercised had smaller neonates and more dysfunctional labors.

The American College of Obstetricians and Gynecologists (2020a) advises a thorough clinical evaluation before recommending an exercise program. In the absence of contraindications listed in Table 10-6, pregnant women are encouraged to engage in regular, moderate-intensity physical activity for at least 150 minutes each week. Such activity has been shown to not adversely alter uterine artery Doppler studies (Szymanski, 2018). Each activity should be reviewed individually for its potential risk. Examples of safe activities are walking, running, swimming, stationary cycling, and low-impact aerobics. However, they should refrain from activities with a high risk of falling or abdominal trauma. Similarly, scuba diving is avoided because the fetus is at increased risk for decompression sickness (Reid, 2018).

In the setting of certain pregnancy complications, it is wise to abstain from exercise and even limit physical activity. Some women with pregnancy-associated hypertensive disorders, preterm labor, placenta previa, or severe cardiac or pulmonary disease may accrue advantages from being sedentary. Also, those with multiple or suspected growth-restricted fetuses may be served by greater rest.

TABLE 10-6. Some Contraindications to Exercise During Pregnancy

Significant cardiovascular or pulmonary disease: chest pain, calf pain or swelling
Significant risk for preterm labor: cerclage, multifetal gestation, significant bleeding, threatened preterm labor, ruptured membranes
Obstetrical complications: preeclampsia, placenta previa, anemia, poorly controlled diabetes or epilepsy, morbid obesity, fetal-growth restriction

Summarized from American College of Obstetricians and Gynecologists, 2017g; The American Academy of Pediatrics, 2017.

Seafood Consumption

Fish are an excellent source of protein, are low in saturated fats, and contain omega-3 fatty acids. It is recommended that pregnant women ingest 8 to 12 ounces of fish weekly, but no more than 6 ounces of albacore or "white" tuna (U.S. Environmental Protection Agency, 2019). Because nearly all fish and shellfish contain trace amounts of mercury, pregnant and lactating women are advised to avoid specific types of fish with potentially high methylmercury levels. These include shark, swordfish, king mackerel, and tile fish. If the mercury content of locally caught fish is unknown, overall fish consumption should be limited to 6 ounces per week. Finally, to help avert listeriosis, eating raw or undercooked fish is avoided (American College of Obstetricians and Gynecologists, 2017j).

Lead Screening

Maternal lead exposure is associated with several adverse maternal and fetal outcomes across a range of maternal blood lead levels (Taylor, 2015). These include gestational hypertension, miscarriage, low birthweight, and neurodevelopmental impairments in exposed pregnancies. The levels at which these risks rise remains unclear. However, recognizing that such exposure remains a significant health issue for reproductive-aged women, the CDC (2010a) provides guidance for screening and managing exposed pregnant and lactating women. These guidelines, which have been endorsed by the American College of Obstetricians and Gynecologists (2018f), recommend blood lead testing only if a risk factor is identified. If the levels are >5 μg/dL, the lead source is sought and removed. Subsequent blood levels are obtained. Blood lead levels >45 μg/dL are consistent with lead poisoning, and women in this group may be candidates for chelation therapy. Affected pregnancies are best managed in consultation with lead poisoning treatment experts. National and state resources are available at the CDC website: www.cdc.gov/nceh/lead/.

Automobile and Air Travel

Pregnant women are encouraged to wear properly positioned three-point restraints as protection against automobile accident injury (Chap. 50, p. 892). The lap portion of the restraining belt is placed under the abdomen and across her upper thighs. The belt should be comfortably snug. The shoulder belt also is firmly positioned between the breasts. Airbags should not be disabled for the pregnant woman.

In general, air travel in a properly pressurized aircraft has no harmful effect on pregnancy. Thus, in the absence of obstetrical or medical complications, the American College of Obstetricians and Gynecologists (2018a) has concluded that pregnant women can safely fly up to 36 weeks' gestation. It is recommended that they observe the same precautions for air travel as the general population. Seatbelts are used while seated. Support stockings, periodic lower extremity movement, and at least hourly ambulation help lower the venous thromboembolism threat. Significant risks with travel, especially international travel, are infectious disease acquisition and development of complications remote from adequate health-care resources.

Coitus

In healthy pregnant women, sexual intercourse usually is not harmful. Whenever miscarriage, placenta previa, or preterm labor threatens, however, coitus is avoided. Nearly 10,000 women enrolled in a prospective investigation by the Vaginal Infection and Prematurity Study Group were interviewed regarding sexual activity (Read, 1993). They reported a decreased frequency of coitus with advancing gestation. By 36 weeks, 72 percent had intercourse less than once weekly. The decline is attributed to lower desire and fear of harming the pregnancy (Staruch, 2016).

Intercourse specifically late in pregnancy is not harmful. Sayle and colleagues (2001) reported no increased—and actually a decreased—risk of delivery within 2 weeks of intercourse. Tan and associates (2007) studied women scheduled for nonurgent labor induction and found that spontaneous labor ensued at equal rates in groups either participating in or abstaining from intercourse.

Oral-vaginal intercourse is occasionally hazardous. Aronson and Nelson (1967) described a fatal air embolism late in pregnancy as a result of air blown into the vagina during cunnilingus. Other near-fatal cases have been described (Bernhardt, 1988).

Dental Care

Examination of the teeth is included in the prenatal examination, and good dental hygiene is encouraged. Indeed, periodontal disease is linked to preterm labor. Unfortunately, although its treatment improves dental health, it does not prevent preterm birth (Daalderop, 2018). Dental caries are not aggravated by pregnancy. Importantly, pregnancy is not a contraindication to dental treatment including dental radiographs (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2017).

Immunization

Current recommendations for immunization during pregnancy are summarized in Table 10-7. Well-publicized concerns regarding a causal link between childhood exposure to the thimerosal preservative in some vaccines and neuropsychological disorders have led some parents to vaccine prohibition. Although controversy continues, these associations have been proven groundless. Thus, many vaccines may be used in pregnancy (Munoz, 2019). The American College of Obstetricians and Gynecologists (2020c) stresses the importance of integrating an effective vaccine strategy into the care of both obstetrical and gynecological patients. The College further emphasizes that information on the safety of vaccines given during pregnancy is subject to change, and recommendations can be found on the CDC website at www.cdc.gov/vaccines.

Influenza and tetanus–diphtheria–acellular pertussis (Tdap) vaccinations are recommended routinely for all pregnant women (Munoz, 2019; Sperling, 2018b). Others are recommended for specific indications (see Table 10-7). Women who are susceptible to rubella should receive measles, mumps, and rubella (MMR) vaccination postpartum. This vaccine is contraindicated during pregnancy.

TABLE 10-7. Recommendations for Immunization During Pregnancy and Postpartum

Immunobiological Agent	Indications for Immunization During Pregnancy	Dose Schedule	Comments
Live Attenuated Virus Vaccines			
Measles	Contraindicated—see immune globulins	Single dose SC, preferably as MMR[a]	Vaccinate susceptible women postpartum; breastfeeding is not a contraindication
Mumps	Contraindicated	Single dose SC, preferably as MMR	Vaccinate susceptible women postpartum
Rubella	Contraindicated, but congenital rubella syndrome has never been described after vaccine	Single dose SC, preferably as MMR	Teratogenicity of vaccine is theoretical and not confirmed to date; vaccinate susceptible women postpartum
Poliomyelitis oral = live attenuated; injection = enhanced-potency inactivated virus	Not routinely recommended for women in the United States, except women at increased risk of exposure[b]	Primary: Two doses of enhanced-potency inactivated virus SC at 4- to 8-week intervals and a 3rd dose 6–12 months after 2nd dose Immediate protection: One dose oral polio vaccine (in outbreak setting)	Vaccine indicated for susceptible women traveling in endemic areas or in other high-risk situations
Yellow fever	Travel to high-risk areas	Single dose SC	Limited theoretical risk outweighed by risk of yellow fever
Varicella	Contraindicated, but no adverse outcomes reported in pregnancy	Two doses needed: 2nd dose given 4–8 weeks after 1st dose	Teratogenicity of vaccine is theoretical; vaccination of susceptible women should be considered postpartum
Zoster	Contraindicated	Single dose	Teratogenicity is theoretical
Smallpox (vaccinia)	Contraindicated in pregnant women and in their household contacts	One dose SC, multiple pricks with lancet	Only vaccine known to cause fetal harm
Other			
Influenza	All pregnant women, regardless of trimester during flu season (October–May)	One dose IM every year	Inactivated or recombinant virus vaccine
Rabies	Indications for prophylaxis not altered by pregnancy; each case considered individually	Public health authorities to be consulted for indications, dosage, and route of administration	Killed-virus vaccine
Human papillomavirus	Not recommended	Three-dose series IM at 0, 1, and 6 months	Nonavalent vaccine is inactivated virus; no teratogenic effects have been observed
Hepatitis B	Preexposure and postexposure for women at risk of infection, e.g., chronic liver or kidney disease	Three-dose series IM at 0, 1, and 6 months	Used with hepatitis B immune globulin for some exposures; exposed newborn needs birth-dose vaccination and immune globulin as soon as possible; all infants should receive birth dose of vaccine
Hepatitis A	Preexposure and postexposure if at risk (international travel); chronic liver disease	Two-dose schedule IM, 6 months apart	Inactivated virus

(*continued*)

TABLE 10-7. Continued

Immunobiological Agent	Indications for Immunization During Pregnancy	Dose Schedule	Comments
Inactivated Bacterial Vaccines			
Pneumococcus	(1) For chronic metabolic, liver, cardiac, or lung ds. (2) For immunosuppression, general malignancy, chronic renal disease, or asplenia	One lifetime dose: (1) One dose PPSV23 (2) One dose PCV13 with PPSV23 given 8 weeks later	Indications not altered by pregnancy Polyvalent polysaccharide vaccine; safety in the first trimester has not been evaluated
Meningococcus	Indications not altered by pregnancy; vaccination recommended in unusual outbreaks	One dose MenACWY or MPSV4; tetravalent vaccine; two doses for asplenia	Antimicrobial prophylaxis if significant exposure
Typhoid	Not recommended routinely except for close, continued exposure or travel to endemic areas	Killed Primary: 2 injections IM 4 weeks apart Booster: One dose; schedule not yet determined	Killed, injectable vaccine or live attenuated oral vaccine; oral vaccine preferred
Anthrax	See text	Six-dose primary vaccination, then annual booster vaccination	Preparation from cell-free filtrate of *B anthracis*; no dead or live bacteria; teratogenicity of vaccine theoretical
Toxoids			
Tetanus-diphtheria-acellular pertussis (Tdap)	Recommended in every pregnancy, preferably between 27 and 36 weeks to maximize passive antibody transfer	Primary: Two doses IM at 1–2 month interval with 3rd dose 6–12 months after the 2nd Booster: Single dose IM every 10 years, as a part of wound care if ≥5 years since last dose, or once per pregnancy	Combined tetanus-diphtheria toxoids with acellular pertussis (Tdap) preferred; updating immune status should be part of antepartum care
Specific Immune Globulins			
Hepatitis B	Postexposure prophylaxis	Depends on exposure	Usually given with hepatitis B virus vaccine; exposed newborn needs immediate prophylaxis
Rabies	Postexposure prophylaxis	Half dose at injury site, half dose in deltoid	Used in conjunction with rabies killed-virus vaccine
Tetanus	Postexposure prophylaxis	One dose IM	Used in conjunction with tetanus toxoid
Varicella	Should be considered for exposed pregnant women to protect against maternal, not congenital, infection	One dose IM within 96 hours of exposure	Indicated also for newborns or women who developed varicella within 4 days before delivery or 2 days following delivery
Standard Immune Globulins			
Hepatitis A: Hepatitis A virus vaccine should be used with hepatitis A immune globulin	Postexposure prophylaxis and those at high risk	0.02 mL/kg IM in one dose	Immune globulin should be given as soon as possible and within 2 weeks of exposure; infants born to women who are incubating the virus or are acutely ill at delivery should receive one dose of 0.5 mL as soon as possible after birth

[a]Two doses necessary for students entering institutions of higher education, newly hired medical personnel, and travel abroad.
[b]Inactivated polio vaccine recommended for nonimmunized adults at increased risk.
Ds. = disease; ID = intradermally; IM = intramuscularly; MMR = measles, mumps, rubella; PO = orally; SC = subcutaneously.
From the American College of Obstetricians and Gynecologists, 2018o; Centers for Disease Control and Prevention, 2011; Kim, 2016; Munoz, 2019.

Caffeine

Whether adverse pregnancy outcomes are related to caffeine consumption is somewhat controversial. As summarized from Chapter 11 (p. 200), heavy intake of coffee each day—approximately five cups or 500 mg of caffeine—slightly raises the miscarriage risk. Studies of "moderate" intake—less than 200 mg daily—did not find a higher risk.

It is unclear if caffeine consumption is associated with preterm birth or impaired fetal growth. Clausson and coworkers (2002) found no association between caffeine consumption <500 mg/d and low birthweight, fetal-growth restriction, or preterm delivery. Bech and associates (2007) randomly assigned more than 1200 pregnant women who drank at least three cups of coffee per day to caffeinated versus decaffeinated coffee. They found no difference in birthweight or gestational age at delivery between groups. The CARE Study Group (2008), however, evaluated 2635 low-risk pregnancies and reported a 1.4-fold risk for fetal-growth restriction among those whose daily caffeine consumption was >200 mg/d compared with those who consumed <100 mg/d. The American College of Obstetricians and Gynecologists (2018g) concludes that moderate consumption of caffeine—less than 200 mg/d—does not appear to be associated with miscarriage or preterm birth, but that the relationship between caffeine consumption and fetal-growth restriction remains unsettled.

Nausea and Heartburn

Nausea and vomiting are common complaints during the first half of pregnancy. These vary in severity and usually commence between the first and second missed menstrual period and continue until 14 to 16 weeks' gestation. Although nausea and vomiting tend to be worse in the morning—thus termed *morning sickness*—both symptoms frequently continue throughout the day. Lacroix and associates (2000) found that nausea and vomiting were reported by three fourths of pregnant women and lasted an average of 35 days. Half had relief by 14 weeks' gestation, and 90 percent by 22 weeks' gestation. In 80 percent of these women, nausea lasted all day.

Treatment of pregnancy-associated nausea and vomiting seldom provides complete relief, but symptoms can be minimized. Eating small meals at frequent intervals is valuable. One systematic literature search reported that the herbal remedy ginger was likely effective (Borrelli, 2005). Mild symptoms usually respond to vitamin B_6 given with doxylamine, but some women require phenothiazine or H_1-receptor blocking antiemetics (American College of Obstetricians and Gynecologists, 2018h). In some with *hyperemesis gravidarum*, vomiting is so severe that dehydration, electrolyte and acid-base disturbances, and starvation ketosis become serious problems (Chap. 57, p. 1014).

Heartburn is another common complaint of gravidas and is caused by gastric content reflux into the lower esophagus. The greater frequency of regurgitation during pregnancy most likely results from upward displacement and compression of the stomach by the uterus, combined with relaxation of the lower esophageal sphincter. Avoiding bending over or lying flat can be preventive. In most pregnant women, symptoms are mild and relieved by a regimen of more frequent but smaller meals. Antacids may provide considerable relief (Phupong, 2015). Specifically, aluminum hydroxide, magnesium trisilicate, or magnesium hydroxide are given alone or in combination. Management of heartburn or nausea that does not respond to simple measures is discussed in Chapter 57 (p. 1017).

Pica and Ptyalism

The craving for strange foods is termed pica. Worldwide, its prevalence among pregnant women is estimated to be 30 percent (Fawcett, 2016). At times, nonfoods such as ice (pagophagia), starch (amylophagia), or clay (geophagia) may predominate. This desire is considered by some to be triggered by severe iron deficiency (Epler, 2017). Although such cravings usually abate after deficiency correction, not all pregnant women with pica are iron deficient. Indeed, if strange "foods" dominate the diet, iron deficiency will be aggravated or will develop eventually. Patel and colleagues (2004) prospectively completed a dietary inventory on more than 3000 women during the second trimester. The prevalence of pica was 4 percent. The most common nonfood items ingested were starch in 64 percent, dirt in 14 percent, sourdough in 9 percent, and ice in 5 percent.

Women during pregnancy are occasionally distressed by profuse salivation—*ptyalism*. Although usually unexplained, ptyalism sometimes appears to follow salivary gland stimulation by the ingestion of starch. It commonly occurs with hyperemesis gravidarum (Bronshtein, 2018).

Headache or Backache

Headaches are common in pregnancy. At least 5 percent of pregnancies are estimated to be complicated by new-onset or new-type headache (Spierings, 2016). Acetaminophen is suitable for treatment of most, and an in-depth discussion is found in Chapter 63 (p. 1127).

Low back pain to some extent is reported by nearly 70 percent of gravidas (Liddle, 2015). Minor degrees follow excessive strain or significant bending, lifting, or walking. It can be reduced by squatting rather than bending when reaching down, by using a back-support pillow when sitting, and by avoiding high-heeled shoes. Back pain complaints increase with progressing gestation and are more prevalent in obese women and those with a history of low back pain. In some cases, troublesome pain may persist for years after the pregnancy (Norén, 2002).

Severe back pain should not be attributed simply to pregnancy until a thorough orthopedic examination has been conducted. Severe pain has other uncommon causes that include pregnancy-associated osteoporosis, disc disease, vertebral osteoarthritis, or septic arthritis (Smith, 2008). More commonly, muscular spasm and tenderness are classified clinically as acute strain or fibrositis. Although evidence-based clinical research directing care in pregnancy is limited, low back pain usually responds well to analgesics, heat, and rest. Acetaminophen may be used as needed. Nonsteroidal antiinflammatory drugs also may be beneficial but are used only in short courses to avoid fetal effects (Chap. 8, p. 151). Muscle relaxants that include cyclobenzaprine or baclofen may be added when needed. Once acute pain is improved, stabilizing and strengthening exercises provided by physical therapy help improve spine and hip stability, which is essential for the increased load of

pregnancy. For some, a support belt that stabilizes the sacroiliac joint may be helpful (Gutke, 2015).

Varicosities and Hemorrhoids

Venous leg varicosities have a congenital predisposition and accrue with advancing age. They can be aggravated by factors that raise lower-extremity venous pressures, such as an enlarging uterus. Femoral venous pressures in the supine gravida rise from 8 mm Hg in early pregnancy to 24 mm Hg at term. Thus, leg varicosities typically worsen as pregnancy advances, especially with prolonged standing. Symptoms vary from cosmetic blemishes and mild discomfort at the end of the day to severe discomfort that requires prolonged rest with feet elevation. Treatment is generally limited to periodic rest with leg elevation, elastic stockings, or both. Surgical correction during pregnancy generally is not advised, although rarely the symptoms may be so severe that injection, ligation, or even stripping of the veins is necessary. Superficial varicosities are a risk factor for deep-vein thrombosis and pulmonary embolism (Chap. 55, p. 980).

Vulvar varicosities frequently coexist with leg varicosities, but they may appear without other venous pathology. Uncommonly, they become massive and almost incapacitating (Pratilas, 2018). If these large varicosities rupture, either spontaneously or at the time of delivery, blood loss can be severe. Treatment is with specially fitted pantyhose that will also minimize lower extremity varicosities. With particularly bothersome vulvar varicosities, a foam rubber pad suspended across the vulva by a belt can be used to exert pressure on the dilated veins.

Hemorrhoids are rectal vein varicosities and may first appear during pregnancy as pelvic venous pressures rise. Commonly, they are recurrences of previously encountered hemorrhoids. Up to 40 percent of pregnant women develop these (Poskus, 2014). Pain and swelling usually are relieved by topically applied anesthetics, warm soaks, and stool-softening agents. With thrombosis of an external hemorrhoid, pain can be considerable. This may be relieved by incision and removal of the clot following injection of a local anesthetic.

Sleeping and Fatigue

Beginning early in pregnancy, many women experience fatigue and need greater amounts of sleep. The soporific effect of progesterone contributes but may be compounded in the first trimester by nausea and vomiting. In the latter stages, general discomforts, urinary frequency, and dyspnea can be additive. Sleep-disordered breathing may be associated with significant morbidities such as hypertensive disorders of pregnancy, stillbirth, and preterm delivery (Brown, 2018; Dominguez, 2018). Moreover, sleep efficiency appears to progressively diminish as pregnancy advances. Wilson and associates (2011) performed overnight polysomnography and observed that women in the third trimester had poorer sleep efficiency, more awakenings, and less of both stage 4 (deep) and rapid-eye-movement sleep. Women in the first trimester also were affected, but to a lesser extent. Daytime naps and mild sedatives at bedtime such as diphenhydramine (Benadryl) can be helpful.

Cord Blood Banking

Cord blood contains hemopoietic stem cells that can be used to treat more than 70 types of diseases. These include immunological and genetic diseases and some forms of cancer. Of the two cord blood bank types, public banks promote allogeneic donation, for use by a related or unrelated recipient, similar to blood product donation. Private banks store stem cells for future autologous use and charge fees for initial processing and annual storage.

The American College of Obstetricians and Gynecologists (2020e) has concluded that if a woman requests data on umbilical cord banking, information regarding advantages and disadvantages of public versus private banking should be explained. Some states have passed laws that require physicians to inform patients about cord blood banking options. Importantly, few transplants have been performed by using cord blood stored in the absence of a known indication in the recipient (Screnci, 2016). The likelihood that cord blood would be used for the child or family member of the donor couple is considered remote. Instead, it is recommended that directed donation be considered when an immediate family member carries the diagnosis of a specific condition known to be treatable by hemopoietic transplantation.

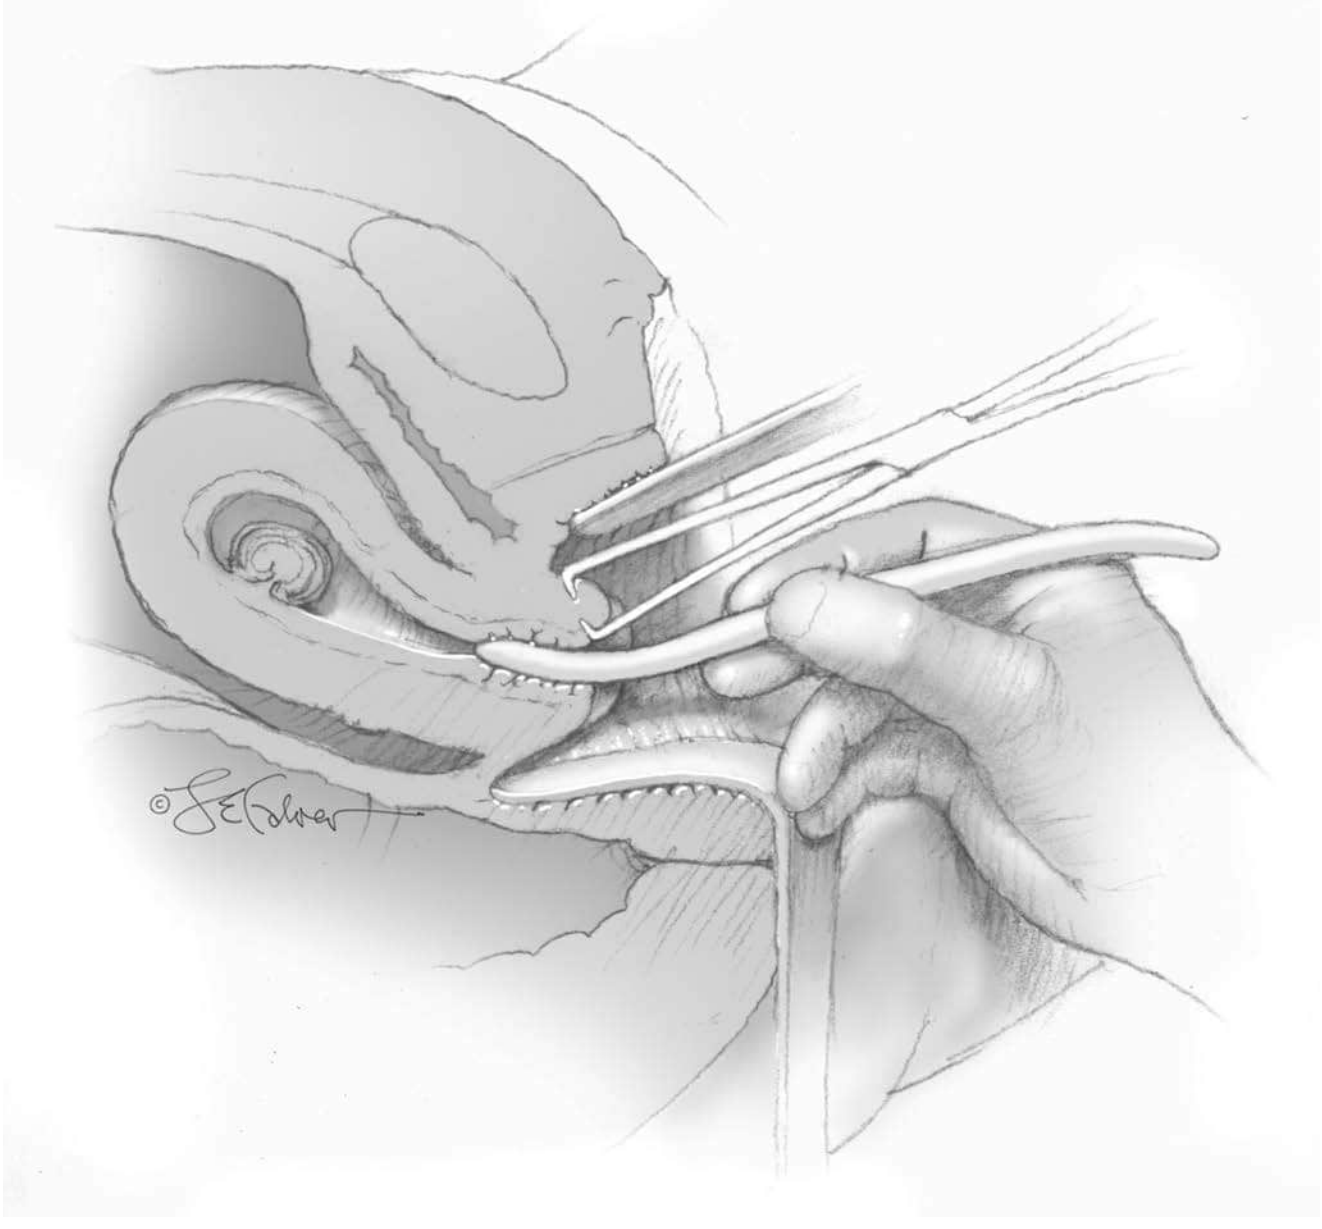
SECTION 5

FIRST- AND SECOND-TRIMESTER PREGNANCY LOSS



CHAPTER 11

First- and Second-Trimester Pregnancy Loss

Miscarriage is a common event in pregnancy. Most early losses stem from genetic abnormalities, and thus the opportunity for prevention is small. Women with later miscarriage or with recurrent miscarriage more likely have a chronic etiology that may be modified. In contrast to these spontaneous losses, pregnancy termination may be elected. For both induced abortion and miscarriage, management options include surgery or medication, and providers should have an understanding of these methods and their potential complications.

NOMENCLATURE

Abortion is defined as the spontaneous or induced termination of pregnancy before fetal viability. Many prefer *miscarriage* for spontaneous loss. *Induced abortion* describes termination with surgery or medication of a live fetus that has not reached viability.

Definitions of an abortus vary among organizations. The National Center for Health Statistics and the World Health Organization define *abortion* as loss or termination of a pregnancy with a fetus aged younger than 20 weeks' gestation or weighing <500 g. These criteria, however, are somewhat contradictory because the mean birthweight of a 20-week fetus approximates 330 g, whereas 500 g is the mean for 22 weeks (Hadlock, 1991). Further confusion may derive from criteria that are set by state laws and define abortion even more widely.

Incongruity also exists for the term *early pregnancy loss* itself. The American College of Obstetricians and Gynecologists (2019b) defines this as a nonviable, intrauterine pregnancy (IUP) within the first $12^{6/7}$ weeks of gestation that consists of either an empty gestational sac or one containing an embryo or fetus without fetal heart activity. *Recurrent pregnancy loss* is variably defined but is meant to identify women with repetitive miscarriage (p. 203).

Other definitions help distinguish intrauterine from ectopic gestations. The term *pregnancy of unknown location (PUL)* describes a pregnancy identified by human chorionic gonadotropin (hCG) level testing but without a confirmed sonographic location. In this context, five categories are proposed for early pregnancies: definite ectopic pregnancy, probable ectopic pregnancy, PUL, probable IUP, and definite IUP (Barnhart, 2011). Diagnostic and management options for ectopic gestation are described in Chapter 12.

Last, spontaneous abortion includes subcategories of threatened, incomplete, complete, missed, and inevitable abortions. These are discussed in the next sections. Septic abortion is used to further classify any of these that are complicated by infection.

FIRST-TRIMESTER SPONTANEOUS ABORTION

Pathogenesis

More than 80 percent of spontaneous abortions occur within the first 12 weeks of gestation. With first-trimester losses, demise

of the embryo or fetus nearly always precedes spontaneous expulsion. Death is usually accompanied by hemorrhage into the decidua basalis. This is followed by adjacent tissue necrosis that stimulates uterine contractions and expulsion. An intact gestational sac is usually filled with fluid. *Anembryonic miscarriage* or *preembryonic loss* describes the group with no identifiable embryo. The term *blighted ovum* is less preferred. An *embryonic miscarriage or embryonic loss* displays an embryo without cardiac activity during ultrasound evaluation (Kolte, 2015; Pinar, 2018).

In second-trimester losses, the fetus usually does not die before expulsion. Thus, other sources for abortion are sought and described on page 213.

Incidence

Rates for miscarriage vary according to the study population. In pregnancies aged 5 to 20 weeks' gestation, the incidence ranges from 10 to 20 percent and is higher in earlier weeks (Ammon Avalos, 2012). To evaluate rates starting at conception, researchers have tested daily urinary samples for β-hCG in women trying to conceive and found that approximately 20 percent of pregnancies failed very early (Wang, 2003). These *biochemical pregnancy losses* are clinically silent and are identified only by dropping β-hCG levels (Kolte, 2015).

Certain factors influence the clinically apparent miscarriage rate and are described next. It is unknown if these same factors also affect biochemical pregnancy loss.

Fetal Factors

Of all miscarriages, approximately half are *euploid abortions,* that is, carrying a normal chromosomal complement. The other half of all miscarriages has a chromosomal abnormality. This percentage appears to persist even from evaluations with newer cytogenetic techniques (Sahoo, 2017). However, outside of research, routine use of chromosomal microarray testing of first-trimester fetal tissues is not endorsed by the American College of Obstetricians and Gynecologists (2020d). The American Society for Reproductive Medicine (2012) recognize its value only if cytogenetic analysis alters future care of a patient.

Both abortion and chromosomal anomaly rates decline with advancing gestational age (Eiben, 1990). Of chromosomally abnormal embryos, 75 percent aborts by 8 weeks' gestation. The rate of abortion with euploid fetuses peaks at approximately 13 weeks (Kajii, 1980).

Of chromosomal abnormalities, 95 percent are caused by maternal gametogenesis errors, and 5 percent by paternal errors (Jacobs, 1980). Thus, the aneuploid abortion incidence rises dramatically after maternal age exceeds 35 years (Eiben, 1990). Indeed, maternal age is a primary factor underlying the spontaneous loss of aneuploid fetuses (Nybo Andersen, 2000). To a lesser degree, increasing paternal age is also associated with a greater abortion risk (Nguyen, 2019). Not yet well studied, chromosomal abnormalities in spermatozoa likely play a role (Pohl, 2021).

Most common abnormalities are trisomy, found in 50 to 60 percent; monosomy X, in 9 to 13 percent; and triploidy, in 11 to 12 percent (Jenderny, 2014; Sahoo, 2017). *Trisomies* typically result from isolated nondisjunction, and rates rise with maternal age (Boué, 1975). Trisomies of chromosomes 13, 16, 18, 21, and 22 are most common. Less often, a trisomy forms from a balanced structural chromosomal rearrangements. These may originate from either parent and are found in 2 to 4 percent of couples with recurrent pregnancy loss (p. 204).

Monosomy X (45,X) is the single most frequent specific chromosomal abnormality. This is *Turner syndrome*, which usually results in miscarriage, but liveborn females are described in Chapter 3 (p. 36). Conversely, *autosomal monosomy* is rare and incompatible with life.

Triploidy is an additional haploid set of chromosomes, and cells thus contain a total of 69 chromosomes. The extra haploid set can be either maternally or paternally derived. Maternally derived *digynic triploidy* typically results from a meiosis error and fertilization of a diploid ovum by a normal haploid sperm. Paternally derived *diandric triploidy* usually forms from the fertilization of a normal haploid ovum by two haploid spermatozoa and leads to partial molar pregnancy (Chap. 13, p. 237). Triploid fetuses frequently spontaneously abort early, and the few carried longer are all grossly deformed.

Maternal Factors

Medical Disorders

In chromosomally normal pregnancy losses, maternal contributions can play a role. For example, a prominent miscarriage risk is associated with poorly controlled diabetes mellitus, obesity, thyroid disease, and systemic lupus erythematosus. In these, inflammatory mediators may be an underlying theme to pregnancy loss (Kalagiri, 2016; Sjaarda, 2017). In chapters on these disorders, the miscarriage rate and attempts to lower it are discussed. In contrast, thrombophilias are no longer linked to miscarriage (American College of Obstetricians and Gynecologists (2020b).

For women undergoing cancer treatment, direct therapeutic radiation can cause miscarriage. Suggested safe parameters are found in Chapter 49 (p. 872). Similarly, the effects of chemotherapy on miscarriage rates are not well defined. Particularly worrisome are women with an ongoing pregnancy after early exposure to the teratogen methotrexate, described in Chapter 8 (p. 152). Cancer survivors previously treated with abdominopelvic radiotherapy and now subsequently pregnant may carry a greater risk for miscarriage (Chap. 66, p. 1164).

Surgical Procedures

The miscarriage risk associated with surgery is not well studied. But, as discussed in Chapter 49 (p. 867), *uncomplicated* surgical procedures performed during early pregnancy are unlikely to raise this risk (Mazze, 1989).

If indicated, ovarian tumors can generally be resected without inciting miscarriage. An exception involves early removal of the corpus luteum or the entire ovary in which it resides. If performed before 10 weeks' gestation, supplemental progesterone should be given and is described in Chapter 66 (p. 1170).

Trauma seldom causes first-trimester miscarriage, and although Parkland Hospital is a busy trauma center, this is an infrequent association. Major trauma—especially abdominal—can cause fetal loss but is more likely as pregnancy advances (Chap. 50, p. 891).

Nutrition

Sole deficiency of one nutrient or moderate deficiency of all does not appear to raise miscarriage risks. Even in extreme cases—for example, hyperemesis gravidarum—abortion is rare. Dietary quality may play a small role, and some data suggest miscarriage risk may decline in women who eat a diet rich in fruits, vegetables, whole grains, and fish (Gaskins, 2015). Unlike obesity, underweight is not associated with a greater miscarriage risk (Balsells, 2016).

With caffeine, reports link heavy intake of approximately five cups of coffee per day—about 500 mg of caffeine—with a slightly greater abortion risk (Cnattingius, 2000; Klebanoff, 1999). Values vary depending on brewing style, but an 8-ounce cup of coffee contains 80 to 100 mg of caffeine. Black or green tea has half this dose (Food and Drug Administration, 2018). Currently, the American College of Obstetricians and Gynecologists (2020e) concludes consumption of <200 mg/d likely is not a major miscarriage risk and that any associated risk with higher intake is unsettled. Metaanalyses support an increasing dose-related risk (Chen, 2016; Li, 2015).

Behavioral Factors

Approximately 7 percent of pregnant women acknowledge cigarette smoking (Kondracki, 2019). One metaanalysis found a slight dose-related relationship between current smoking and early pregnancy loss (Pineles, 2014). The serious later risks of persistent smoking on pregnancy outcomes are discussed in Chapter 8 (p. 156).

Alcohol consumption carries miscarriage risk mainly in those with chronic or heavy use (Feodor Nilsson, 2014). The potent teratogenic effects in these instances are also discussed in Chapter 8 (p. 149).

Environmental Factors

Despite the many infections acquired in pregnancy, these uncommonly cause early miscarriage. The important maternofetal consequences of specific infections in later pregnancy are discussed in Chapters 67 and 68.

Environmental toxins suggested to have a possible link to miscarriage include bisphenol A, phthalates, polychlorinated biphenyls, and dichlorodiphenyltrichloroethane (DDT) (Krieg, 2016). Even fewer studies implicate occupational exposures. Data suggest a slight increased miscarriage risk in health-care workers exposed to radiation or antineoplastic drugs (Anderson, 2020). The National Institute for Occupational Safety and Health publishes guidelines on potentially hazardous drugs (Connor, 2016). Evidence implicating occupational anesthetic gases in miscarriage is not robust (Oliveira, 2021). Still, gas scavenging systems and workplace exposure limits are recommended (McGlothin, 2014).

■ Spontaneous Abortion Clinical Classification

Threatened Abortion

This is defined as bleeding through a closed cervical os in the first 20 weeks of pregnancy and with a live embryo or fetus. It may portend abortion, or it may be associated with conceptus implantation. Other bleeding sources to exclude are ectopic pregnancy, cervical infection, and dysplastic or neoplastic cervical lesions.

Almost one fourth of women develop bleeding during early gestation that is attributed to threatened abortion (Everett, 1997). Bleeding or spotting may persist for days or weeks. It may be accompanied by suprapubic discomfort, mild cramps, pelvic pressure, or persistent low backache. Of symptoms, bleeding is by far the most predictive factor for subsequent pregnancy loss.

Vaginal bleeding or abdominal pain in early pregnancy should prompt hematocrit and blood type assessment. One primary goal is to exclude ectopic pregnancy, and strategic use of β-hCG levels and transvaginal sonography (TVS) is outlined in Chapter 12 (p. 222). A second goal is to determine IUP viability. With an IUP, the gestational sac—an anechoic fluid collection that represents the exocoelomic cavity—may be seen by 4.5 weeks (Fig. 10-2, p. 177). At this time, β-hCG levels generally measure 1500 to 2000 mIU/mL (Barnhart, 1994; Timor-Tritsch, 1988). Connolly and colleagues (2013), however, noted that a threshold as high as 3500 mIU/mL may be needed to identify the gestational sac in some cases that ultimately yield a viable singleton IUP.

One caveat during TVS is that a gestational sac may appear similar to a *pseudogestational sac*, which is an anechoic intrauterine fluid collection (Fig. 12-3, p. 223). This pseudosac may be blood derived from a bleeding ectopic pregnancy and is easier to exclude once a yolk sac is seen. Typically, the yolk sac is visible by 5.5 weeks and with a mean gestational-sac diameter of 10 mm. Thus, the diagnosis of an IUP should be made cautiously if the yolk sac is not yet seen (American College of Obstetricians and Gynecologists, 2020h). Fetal cardiac activity can typically be detected at 6 to 6.5 weeks.

A subchorionic hematoma may also be seen sonographically with threatened miscarriage (Fig. 11-1). In general, this collection does not portend a greater miscarriage risk (Naert, 2019).

Once threatened abortion is diagnosed, observation is the norm. Acetaminophen-based analgesia will help relieve

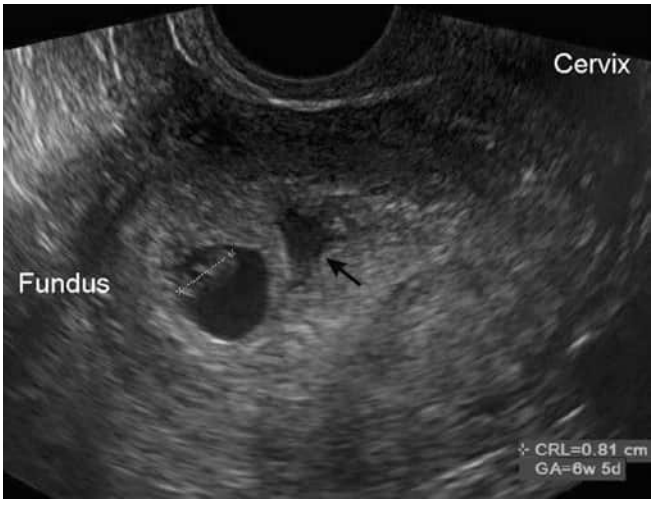


FIGURE 11-1 In this transvaginal sonogram sagittal view of the uterus, a subchorionic hematoma is seen as a very hypoechoic collection (*arrow*). It lies adjacent to the round anechoic gestational sac that contains a nearly 7-week embryo (*calipers*). (Reproduced with permission from Jason McWhirt, ARDMS.)

cramping discomfort. The randomized Progesterone in Spontaneous Miscarriage (PRISM) trial found no advantage to progesterone supplementation to lower miscarriage rates in women with first-trimester bleeding (Coomarasamy, 2019). Bed rest does not improve outcomes and may cause harms such a deep-vein thrombosis (McCall, 2013). We do counsel against intercourse until bleeding subsides. In unusual cases, bleeding with threatened abortion can lead acute severe anemia or hypovolemia. Pregnancy evacuation is generally indicated. Less often, transfusion and further observation is elected.

Even if miscarriage does not follow threatened abortion, later rates of preterm birth and placental abruption are slightly increased (Saraswat, 2010). Weiss and coworkers (2004) noted greater risks for later adverse outcomes if early bleeding was heavy rather than light. Despite these associations, we typically do not add sonography or other surveillance later in pregnancy solely for a first-trimester diagnosis of threatened abortion.

Incomplete Abortion

During miscarriage, the cervix opens and placental separation causes bleeding. Before 10 weeks' gestation, the fetus and the placenta are frequently expelled together, but later, they often deliver separately. Thus, tissue may remain entirely within the uterus or partially extrude through the cervix. Products lying loosely within the cervical canal can be easily extracted or teased out with ring forceps. For uterine infection or for hemodynamically unstable women with heavy bleeding, prompt surgical evacuation is performed.

For less urgent cases, three management options are curettage, expectant management, or misoprostol (Cytotec), which is prostaglandin E_1 (PGE_1) (Kim, 2017). With all three, treatment complications such as infection and need for transfusion are infrequent. However, misoprostol and expectant care can be associated with unpredictable bleeding. Thus, some women will still require unscheduled curettage, which studies have used as a failure endpoint. Expectant management of spontaneous incomplete abortion has failure rates that approximate 25 percent in randomized trials (Nielsen, 1999; Trinder, 2006). Medication therapy carries failure rates of 5 to 30 percent (Shochet, 2012; Trinder, 2006). Many of the studies assessing treatment have used an 800-µg vaginal, a 400-µg sublingual, or a 600-µg oral misoprostol dose. Last, curettage usually results in a quick resolution that is 95- to 100-percent successful. However, it is invasive, carries surgical risks, and is not necessary for all women (p. 211).

Complete Abortion

At times, the entire pregnancy is expelled. With completion, bleeding ebbs, and the internal cervical os subsequently closes over the next hour or so. Patients are encouraged to bring in passed tissue, and a gestation should be documented within blood clots or within a decidual cast (Fig. 11-2). The latter is the thickened endometrium, in the shape of the uterine cavity, that may slough with miscarriage.

If a gestational sac is not identified within the expelled tissue, TVS helps differentiate a complete abortion from a threatened abortion or ectopic pregnancy. Findings of complete abortion include a thin endometrium without a gestational sac. However, this does not guarantee a recent IUP. One study evaluated

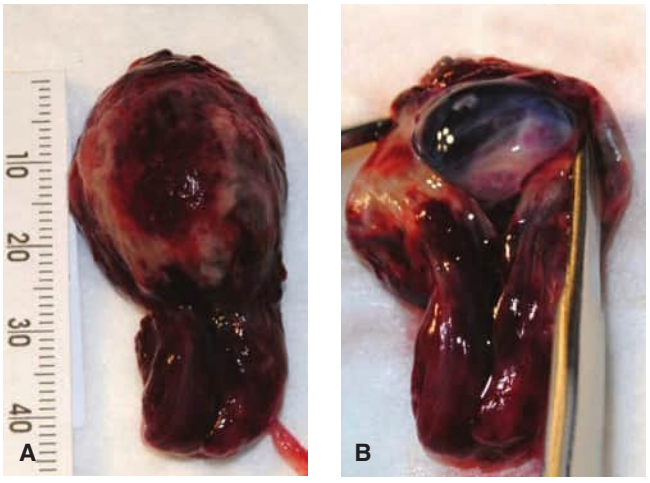

FIGURE 11-2 A. Decidual cast from a complete abortion. **B.** Opening the cast reveals a clear translucent gestational sac, which confirms the diagnosis.

152 women with heavy bleeding and an empty uterus with endometrial thickness <15 mm. Six percent were subsequently found to have an ectopic pregnancy (Condous, 2005). Thus, a complete abortion cannot be surely diagnosed unless: (1) true products of conception are seen grossly or (2) sonography documents first an IUP and then later an empty cavity. In unclear settings, serial serum β-hCG levels aid clarification. With complete abortion, these levels drop quickly (Table 11-1).

Missed Abortion

This describes dead products of conception that have been retained for days or weeks within a uterus with a closed cervical

TABLE 11-1. Percentage Decline of Initial Serum β-hCG Levels Following Complete Spontaneous Abortion

Initial hCG (mIU/mL)	Percentage Decline[a] by day 2 Expected % (Minimum %)	by day 4 Expected % (Minimum %)	by day 7 Expected % (Minimum %)
50	68 (12)	78 (26)	88 (34)
100	68 (16)	80 (35)	90 (47)
300	70 (22)	83 (45)	93 (62)
500	71 (24)	84 (50)	94 (68)
1000	72 (28)	86 (55)	95 (74)
2000	74 (31)	88 (60)	96 (79)
3000	74 (33)	88 (63)	96 (81)
4000	75 (34)	89 (64)	97 (83)
5000	75 (35)	89 (66)	97 (84)

[a]The percentage decline is given as the expected decline. The minimum expected decline in parentheses is the 95th percentile value. Declines less than this minimum may reflect retained either intrauterine or extrauterine trophoblast.
hCG = human chorionic gonadotropin.
Data from Barnhart, 2004; Chung, 2006.

TABLE 11-2. Guidelines for Early Pregnancy Loss Diagnosis

Sonographic Findings
CRL ≥7 mm and no heartbeat
MSD ≥25 mm and no embryo
An initial US scan shows a gestational sac with yolk sac, and after ≥11 days no embryo with a heartbeat is seen
An initial US scan shows a gestational sac without a yolk sac, and after ≥2 weeks no embryo with a heartbeat is seen
Modalities
Transvaginal preferable to transabdominal US
M-mode imaging used to document and measure heartbeat
Pulsed Doppler US methods generally not used to evaluate a normal early embryo

CRL = crown-rump length; MSD = mean sac diameter; US = ultrasound.
From American College of Obstetricians and Gynecologists, 2019b; Brown, 2018; Doubilet, 2013.

os. Diagnosis is imperative prior to intervention and avoids interruption of a potentially live IUP. Again, TVS and β-hCG levels are primary tools. With the latter, levels that plateau or drop are typical.

With TVS, a 1- to 2-mm embryo adjacent to the yolk sac can be seen at 5 to 6 weeks' gestation. As listed in Table 11-2, absence of an embryo in a sac with a mean sac diameter (MSD) ≥25 mm signifies pregnancy loss. The MSD is calculated by summing the length, width, and height of a gestational sac and dividing the sum by three. Fetal cardiac activity can typically be detected at 6 to 6.5 weeks, with a crown-rump length (CRL) of 1 to 5 mm, and an MSD of 13 to 18 mm (Goldstein, 1992; Levi, 1990). A CRL threshold ≥7 mm plus absent cardiac activity also is used to diagnose nonviability (Doubilet, 2013). For cases in which a gestational sac has no embryo or yolk sac, additional time and repeat TVS are recommended. M-mode should be used to document cardiac activity and measure the rate (Brown, 2018). Pulsed Doppler is not used routinely and is reserved for specific diagnostic purposes because of theoretical temperature elevation in exposed fetal tissues (Chap. 14, p. 247).

Less robust sonographic markers may portend pregnancy failure. A yolk sac diameter >7 mm in pregnancies <10 weeks' gestation is one (Rodgers, 2015). The fetal heart rate in the first trimester rises from 110 to 130 beats per minute (bpm) at 6 weeks' gestation to 160 to 170 bpm at 8 weeks (Achiron, 1991; Rauch, 2009). A slower heart rate is unfavorable, especially one <85 bpm (DeVilbiss, 2020). Even with cardiac activity, fetuses with a small MSD may presage embryonic loss. A difference <5 mm between the MSD and CRL values raises concern (Bromley, 1991). Last, an irregular gestational sac contour may portend loss (Nyberg, 1986).

With embryonic or fetal death confirmed, expectant observation, surgery, or medication is an option. Nonsurgical options balance less invasiveness against heavier associated bleeding, longer completion times, and lower success rates. Of options, expectant care underperforms medication or surgery, and failure rates range from 15 to 50 percent (Luise, 2002; Trinder, 2006; Zhang, 2005). Also, weeks may pass between pregnancy failure diagnosis and actual spontaneous miscarriage.

As a medication option, misoprostol can be given, and a single 800-μg dose vaginally is a common standard. It may be repeated once in 1 to 2 days, and one large trial reported that 22 percent of women required a second dose (Zhang, 2005). Overall, failure rates range from 15 to 40 percent (Petersen, 2013; Trinder, 2006). Success rates are improved by a 200-mg oral dose of mifepristone (Mifeprex) given 24 hours prior to misoprostol (Schreiber, 2018). In the United States, access to this antiprogestin is limited by the Food and Drug Administration (FDA) to providers participating in the manufacturer's Risk Evaluation and Mitigation Strategy (REMS) (Danco Laboratories, 2021). Contraindications mirror those listed in the section describing induced abortion (p. 212).

Inevitable Abortion of a Previable Fetus

Either rupture of placental membranes or marked ballooning of membranes into the vagina may lead to inevitable abortion. The latter is discussed in the cervical insufficiency section (p. 205).

Preterm prelabor rupture of membranes (PPROM) at a *previable* gestational age complicates 0.5 percent of pregnancies (Hunter, 2012). Instead, *periviable birth* is defined as delivery between $20^{0/7}$ and $25^{6/7}$ weeks and is discussed in Chapter 45 (p. 785). Clinically with PPROM, abundant vaginal fluid that pools during sterile speculum examination confirms the diagnosis. Patient coughing or Valsalva maneuver may accentuate this. Other diagnostic steps can include pH testing, microscopic examination, and sonographic assessment of amnionic fluid volume, and these are outlined in Chapter 22 (p. 426).

Rupture may be spontaneous, and risks are prior PPROM, prior second-trimester delivery, and tobacco use (Kilpatrick, 2006). Iatrogenic fluid leakage can follow amniocentesis or fetal surgery. In some second-trimester cases, fluid may have collected previously between the amnion and chorion and reflects only chorion leakage.

Spontaneous rupture in the first trimester is nearly always followed by either uterine contractions or infection, and termination is typical. With second-trimester spontaneous PPROM at a previable age, 40 to 50 percent of women will deliver within the first week, and 70 to 80 percent will do so after 2 to 5 weeks (American College of Obstetricians and Gynecologists, 2020f). Average latency is 2 weeks (Hunter, 2012; Kibel, 2016). Significant maternal complications attend previable PPROM and include uterine infection, sepsis, placental abruption, postpartum hemorrhage, and retained placenta (Dotters-Katz, 2017b; Waters, 2009). In one study, 56 percent of women suffered one or more of these complications (van der Marel, 2016). With significant bleeding or fever, the uterus should be evacuated. Surgical evacuation or medication options for this vary by gestational age and surgeon skill. Methods mirror those for second-trimester elective abortion, described later (p. 213).

For cases in which previable delivery is inevitable or elected, neonatal consultation aids decision-making and helps form expectations for the family. For fetuses with a life-limiting

condition, such as extreme prematurity, *perinatal palliative care* is a strategy that emphasizes comfort (American College of Obstetricians and Gynecologists, 2019c). Care team members can include obstetric and neonatal professionals, chaplaincy, and mental health specialists.

In cases without bleeding or fever, expectant management is an option in the well-counseled patient. Many will choose termination due to the earlier-described maternal risks and tenuous neonatal outcomes. Early fetal mortality stems from pulmonary hypoplasia, severe intraventricular hemorrhage, and sepsis. Of those managed expectantly with PPROM at <20 weeks, the percentage of infants who are discharged home ranges from 12 to 23 percent (Hunter, 2012; Sim, 2020; van der Martel, 2016). Common neonatal morbidities are respiratory distress syndrome, bronchopulmonary hypoplasia or dysplasia, necrotizing enterocolitis, and sepsis. Overall, prognosis is improved if previable PPROM occurs at a later gestation, latency is longer, and oligohydramnios is absent. With the last, poor lung development and fetal skeletal deformations can result from scant amnionic fluid.

If expectant care is elected, initial hospital evaluation, diminished physical activity, and observation for fever or labor are reasonable. After 24 hours, if there is no bleeding, cramping, or fever, a woman may resume ambulation and is discharged home. She is instructed to watch for fever, contractions, or bleeding. Antibiotics are considered and given for 7 days to extend latency (Dotters-Katz, 2017a). However, lung-maturing corticosteroids, magnesium sulfate neuroprophylaxis, group B streptococcus antibiotic prophylaxis, cesarean delivery, and tocolytics are not recommended before 22 weeks' gestation (American College of Obstetricians and Gynecologists, 2019d). Once a viable age is reached, readmission until delivery is our practice. PPROM care at viable gestational ages is described in Chapter 45 (p. 799).

In procedure-related PPROM, iatrogenic leaks are typically higher in the uterus and tend to self-seal. For leaks from amniocentesis, management is typically conservative, and brief bedrest yields high pregnancy continuation rates. For rupture after fetal surgery, investigational treatments can address surgical leaks (Chmait, 2017). One is an occlusive plug—termed an amniopatch—that forms following intraamnionic instillation of autologous platelets and cryoprecipitate. Another is amnioinfusion to counter the effects of oligohydramnios but is not robustly supported by current data (Roberts, 2014; van Kempen, 2019).

In subsequent pregnancies, the risk for recurrent preterm birth is great in women with prior previable PPROM. In one cohort study, 46 percent delivered their next pregnancy before 37 weeks, and 17 percent delivered before reaching 24 weeks (Monson, 2016).

Septic Abortion

With spontaneous or induced abortion, organisms may invade myometrial tissues and extend to cause parametritis, peritonitis, and septicemia. This may complicate both medication and surgical methods. Classic clinical findings include fever, lower abdominal pain, uterine tenderness, and foul vaginal discharge. Vaginal bleeding and sonographic evidence of retained uterine tissue are others. Urinary tract infection should be excluded by urinalysis, and a complete blood count assesses leukocytosis.

Most bacteria causing septic abortion are part of the normal vaginal flora. Thus, vaginal culture is not informative, however, we obtain blood cultures for those with sepsis. Particularly worrisome are severe necrotizing infections and toxic shock syndrome (TSS) caused by group A streptococcus—*S pyogenes* (Daif, 2009). Maternal deaths from *Clostridium perfringens* or *C sordellii* also have been described. With TSS, women show severe endothelial injury, capillary leakage, hemoconcentration, hypotension, tachycardia, and marked leukocytosis but may not be febrile initially.

With septic abortion, management includes prompt administration of broad-spectrum antibiotics as discussed in Chapter 37 (p. 651). If products are retained, suction evacuation is performed. Most women respond to this treatment within 1 to 2 days and are discharged when afebrile. Additional oral antibiotics are likely unnecessary (Savaris, 2011). In a very few women, severe sepsis syndrome develops, and intensive supportive care is essential. Although rare, widespread peritonitis despite curettage and clinical decline in the patient should raise concerns. Imaging that shows intraabdominal free air or air within the uterine wall typically prompts laparotomy (Eschenbach, 2015). If the uterus is necrotic, hysterectomy is indicated.

Anti-D Immunoglobulin

With spontaneous or induced abortion, 2 percent of D-negative women will become alloimmunized if not provided passive isoimmunization. With surgical dilation and curettage, this rate may reach 5 percent. The American College of Obstetricians and Gynecologists (2019e) recommends a 300-μg intramuscular dose of anti-Rho (D) immunoglobulin for all gestational ages. Doses can also be graduated. Namely, a 50-μg or 120-ug dose is given for pregnancies ≤12 weeks and a 300-μg one for those ≥13 weeks. This is administered immediately following surgical evacuation. For medication abortion or expectant management, the injection is given within 72 hours of pregnancy failure diagnosis.

With *threatened* abortion, immunoglobulin prophylaxis is controversial because of sparse evidence-based data (Hannafin, 2006). It is reasonable to administer anti-D immunoglobulin for a threatened abortion, and this is our practice.

RECURRENT MISCARRIAGE

Affecting approximately 1 percent of fertile couples, recurrent pregnancy loss (RPL) is classically defined as three or more consecutive pregnancy losses at <20 weeks' gestation or with a fetal weight <500 g. However, data show the risk for a subsequent loss to be similar whether a woman has two or three prior miscarriages (Bhattacharya, 2010). The American Society for Reproductive Medicine (2020) now defines RPL as two or more failed pregnancies confirmed by sonographic or histopathological examination. *Primary RPL* refers to multiple losses in a woman who has never delivered a liveborn, and *secondary RPL* refers to multiple pregnancy losses in a patient with a prior live birth. Remarkably, chances for a successful pregnancy are >50 percent even after five miscarriages (Table 11-3) (Brigham, 1999). RPL evaluation addresses its major causes, described next.

TABLE 11-3. Predicted Success Rate of Subsequent Pregnancy According to Age and Number of Previous Miscarriages

Age (yrs)	No. of Previous Miscarriages: Predicted Success of Subsequent Pregnancy (%)			
	2	3	4	5
20	92	90	88	85
25	89	86	82	79
30	84	80	76	71
35	77	73	68	62
40+	65	59	53	47

Etiology

Widely accepted causes of RPL include some parental chromosomal abnormalities, antiphospholipid antibody syndrome, specific endocrinopathies, and certain structural uterine abnormalities. Thus, current RPL evaluation includes karyotyping of both parents; measuring antiphospholipid antibody levels; assessing HbA_{1c}, thyroid-stimulating hormone (TSH), and prolactin levels; and performing saline-infusion sonography (SIS) or hysterosalpingography (American Society for Reproductive Medicine, 2012).

The timing of recurrent loss can offer clues, and in some women, each miscarriage may occur near the same gestational age (Heuser, 2010). Approximately 50 percent of women have idiopathic RPL (Habayeb, 2004).

Parental Chromosomal Abnormalities

In first-trimester RPL, the incidence of genetic abnormalities is significantly lower than in sporadic miscarriage (Stephenson, 2002). A notable exception is a parent that carries a reciprocal translocation or Robertsonian translocation (Fan, 2016). Their genesis and reproductive sequelae are discussed in Chapter 16 (p. 316). These account for only 2 to 4 percent of RPL cases, but karyotyping of both parents is a recognized part of RPL evaluation.

After thorough genetic counseling, couples with an abnormal karyotype can be offered in vitro fertilization (IVF) followed by preimplantation genetic testing (PGT) or offered donor gametes (Chap. 17, p. 348). However, birth rates with IVF plus PGT are not superior to expectant management for this cause of RPL (Murugappan, 2016). Importantly, in couples with RPL who are *chromosomally normal,* PGT is not recommended solely for the indication of RPL.

Anatomical Factors

Several genital tract abnormalities have been implicated in RPL, but direct linkage is not robust. According to Devi Wold and associates (2006), 15 percent of women with ≥3 consecutive miscarriages will have a congenital or acquired uterine anomaly. Thus, SIS and hysteroscopy are primary evaluation tools.

Uterine leiomyomas are common, and some may cause miscarriage, especially if located near the placental implantation site. However, data suggesting a significant link to RPL are not convincing and poor quality (Saravelos, 2011). The American Society for Reproductive Medicine (2017) notes that hysteroscopic excision of large submucosal leiomyomas in women with RPL can be considered.

Uterine synechiae, often called *Asherman syndrome,* result from broad destruction of endometrium and subsequent scarring, which can follow uterine curettage or hysteroscopic surgeries. With SIS, multiple hypoechoic bridging bands are seen to span the endometrial cavity, which is filled with anechoic saline. Treatment is hysteroscopic adhesiolysis, but success rates are lower with more severe initial disease.

Uterine polyps have been found more frequently in women with RPL, but causality is unclear. These are seen during hysteroscopy or SIS as a mass lesion extending from the uterine wall into the endometrial cavity. Application of color Doppler during SIS classically reveals a single feeder vessel reaching the mass. Hysteroscopic polypectomy can be considered.

For all these acquired lesions, correction can be considered for those with significant uterine cavity distortion. However, evidence supporting improved birth rates is not robust (American Society for Reproductive Medicine, 2012). Moreover, reproductive benefits are balanced against intrauterine adhesions that may form after any intracavitary surgery.

Congenital uterine anomalies often originate from abnormal müllerian duct formation. Depending on their anatomy, some may raise risks for miscarriage or preterm delivery. Of these, septate uterus is most closely linked with miscarriage. Hysteroscopic resection has been associated with improved live birth rates in some but not all studies (Rikken, 2017). It can be considered for RPL (American Society for Reproductive Medicine, 2016). Chapter 3 (p. 42) contains a fuller discussion of uterine abnormalities and their other obstetrical effects.

Immunological Factors

Miscarriages are more common in women with systemic lupus erythematosus (SLE) (Clowse, 2008). Many of these women and also some without SLE carry *antiphospholipid antibodies*. These are a family of autoantibodies that bind to phospholipid-binding plasma proteins and are associated with RPL (Alijotas-Reig 2019). As shown in Table 11-4, the *antiphospholipid antibody syndrome (APS)* is defined by these antibodies in combination with various forms of reproductive loss or vascular thrombosis (American College of Obstetricians and Gynecologists, 2019a). Chapter 62 (p. 1114) describes pregnancy loss with APS and treatment.

Endocrine Factors

Of recurrent miscarriages, 8 to 12 percent are caused by endocrine factors (Arredondo, 2006). First, the well-known abortifacient action of uncontrolled diabetes mellitus is detailed in Chapter 60 (p. 1070). Optimal periconceptional glycemic control will mitigate many of these losses.

Overt hypothyroidism and severe iodine deficiency also raise miscarriage rates (Chap. 61, p. 1094). Correction with supplementation reverses these actions. Subclinical hypothyroidism, however, does not appear to increase miscarriage rates (Dong, 2020). Antithyroid antibodies are a common associate of subclinical hypothyroidism or overt hypothyroidism. A recent

TABLE 11-4. Clinical and Laboratory Criteria for Diagnosis of Antiphospholipid Antibody Syndrome[a]

Clinical Criteria

Obstetrical:

≥3 unexplained consecutive spontaneous miscarriages <10 weeks' gestation

or

≥1 unexplained fetal death(s) ≥10 weeks' gestation

or

Severe preeclampsia or placental insufficiency necessitating delivery before 34 weeks

Vascular: ≥1 episode(s) of arterial, venous, or small-vessel thrombosis in any tissue

Laboratory Criteria[b]

Presence of lupus anticoagulant according to guidelines of the International Society on Thrombosis and Hemostasis

or

Medium or high serum levels of IgG or IgM anticardiolipin antibodies

or

Anti-β_2 glycoprotein-I IgG or IgM antibody

[a]At least one clinical and one laboratory criteria must be present for diagnosis.
[b]These tests must be positive on two or more occasions at least 12 weeks apart.
IgG = immunoglobulin G; IgM = immunoglobulin M.
Modified from Branch, 2010; Miyakis, 2006.

metaanalysis found positive associations between these antibodies and a greater risk for sporadic and recurrent miscarriages (Xie, 2020). However, levothyroxine supplementation in this group does not improve subsequent pregnancy outcomes (Sun, 2020). For evaluation of RPL, measuring levels of serum TSH, but not antithyroid antibodies, is reasonable.

Other endocrinopathies are inconclusively implicated. One is progesterone deficiency caused by a luteal-phase defect. Progesterone supplementation, compared with placebo, did not improve the live birth rate in those with RPL in one large trial (Coomarasamy, 2015). Limited data implicate hyperprolactinemia (Hirahara, 1998). Obesity, polycystic ovarian syndrome, and insulin resistance are also linked to RPL (Cavalcante, 2019; Craig, 2002; Mayrhofer, 2020). However, the interplay between these makes assigning individual causality difficult.

SECOND-TRIMESTER ABORTION

Etiology

The timespan that defines a midtrimester fetal loss extends from the end of the first trimester until the fetus weighs <500 g or gestational age reaches 20 weeks. The spontaneous loss rate in the second trimester is much lower than in the first.

Unlike earlier miscarriages that frequently stem from chromosomal aneuploidies, causes of these later fetal losses are more diverse (Table 11-5). Their ultimate presentations may be miscarriage, PPROM, or fetal demise prior to labor (Morris, 2016). Some second-trimester abortions are induced because of fetal abnormalities or patient choice.

Second-trimester losses are subclassified similarly to first-trimester ones (p. 200). Management is similar in many regards to that used for second-trimester induced abortion, described on page 214. One exception is cervical cerclage, which may be employed for cervical insufficiency.

Cervical Insufficiency

Previously called incompetent cervix, this is characterized classically by painless cervical dilation in the second trimester. It can be followed by prolapse and ballooning of the amnionic membranes into the vagina, and ultimately, expulsion of an immature fetus. This sequence often repeats in future pregnancies.

Of causes, prior cervical trauma is implicated. One cohort study of more than 15,000 women with prior cervical conization found a fourfold risk of pregnancy loss before 24 weeks' gestation (Albrechtsen, 2008). However, in women solely with prior conization but no prior preterm birth, outcomes are not improved by prophylactic cerclage (Zeisler, 1997). In other instances, abnormal cervical development, including that from diethylstilbestrol (DES), may play a role (Hoover, 2011). Marfan and Ehlers-Danlos syndromes also carry increased risk of cervical insufficiency (Meijboom, 2006; Spiegel, 2020).

Surgical Indications

For women with an unequivocal history of second-trimester painless delivery, prophylactic cerclage placement is an option and reinforces a weak cervix by an encircling suture. However,

TABLE 11-5. Some Causes of Midtrimester Spontaneous Pregnancy Losses

Fetal Anomalies	**Placental Causes**
Structural	Abruption, previa
Chromosomal	Vasculopathy
	Chorioamnionitis
Maternal Disorders	**Uterine Defects**
Autoimmune	Congenital
Infections	Leiomyomas
Metabolic	Incompetent cervix

some women have a history and clinical findings that make it difficult to verify—*classic* cervical insufficiency. In one randomized trial of almost 1300 women, cerclage was found to be beneficial—13 versus 17 percent—to prolong pregnancy past 33 weeks (MacNaughton, 1993).

The physical finding of early dilation of the internal cervical os and visible membranes is another indicator of insufficiency. In one systematic review, cerclages that were placed based on such examination findings provided superior perinatal outcomes compared with expectant management (Ehsanipoor, 2015).

Last, some use TVS to determine cerclage need. In those with any prior spontaneous preterm birth, the Society for Maternal-Fetal Medicine (2016) recommends transvaginal cervical length screening. The American College of Obstetricians and Gynecologists (2021) also recommends this screening. Surveillance extends between 16 and 24 weeks' gestation, and examinations, described in Chapter 14 (p. 254), are performed every 1 to 4 weeks. In those without prior preterm birth or in those with multifetal gestation, cervical length is not specifically measured. The cervix should be viewed during the sonographic anatomical anatomy examination at 18 to 22 weeks' gestation. Chapter 45 (p. 794) discusses recommendations for cerclage placement based on cervical length to prevent preterm birth.

Presurgical Preparation

Contraindications to cerclage include bleeding, contractions, or ruptured membranes, any of which substantially raise the likelihood of labor and failure. Prophylactic *elective cerclage* before dilation is preferable, and timing between 12 and 14 weeks' gestation allows early intervention. Still, it avoids surgery in the first trimester, which is when most predestined spontaneous losses occur, and screening for aneuploidy and malformation is completed. Cervical neoplasia screening in suitable candidates and gonorrhea and chlamydial infection testing are done. Obvious cervical infection is treated.

At times, the cervix instead is found to be dilated, effaced, or both, and an *emergency cerclage* is performed. Notably, in more-advanced pregnancy, the risk of stimulating preterm labor or of rupturing membranes with the surgery is greater. At Parkland Hospital, cerclage procedures are not done after 23 to 24 weeks' gestation. Others, however, describe placement later than this (Caruso, 2000; Terkildsen, 2003).

When outcomes of cerclage are evaluated, women with similar clinical presentations are ideally compared. In a study of elective cerclage by Owen and associates (2009), approximately a third of women delivered before 35 weeks, and complications were few. By contrast, in a 10-year review of 75 women undergoing emergency cerclage, only half were delivered after 36 weeks (Chasen, 1998). Importantly, only 44 percent of those with bulging membranes at the time of cerclage reached 28 weeks. Terkildsen and associates (2003) had similar experiences. Our experiences at Parkland Hospital are that emergency cerclage has a high failure rate, and women are counseled accordingly.

If the clinical indication for cerclage is questionable, a woman may instead be observed. Most undergo cervical examinations weekly or every 2 weeks to assess effacement and dilation. Unfortunately, rapid effacement and dilation can develop despite such precautions (Witter, 1984).

Vaginal Cerclage

Of the two vaginal cerclage operations, most use the simpler procedure developed by McDonald (1963) (Fig. 11-3). The more complicated operation is a modification of the procedure

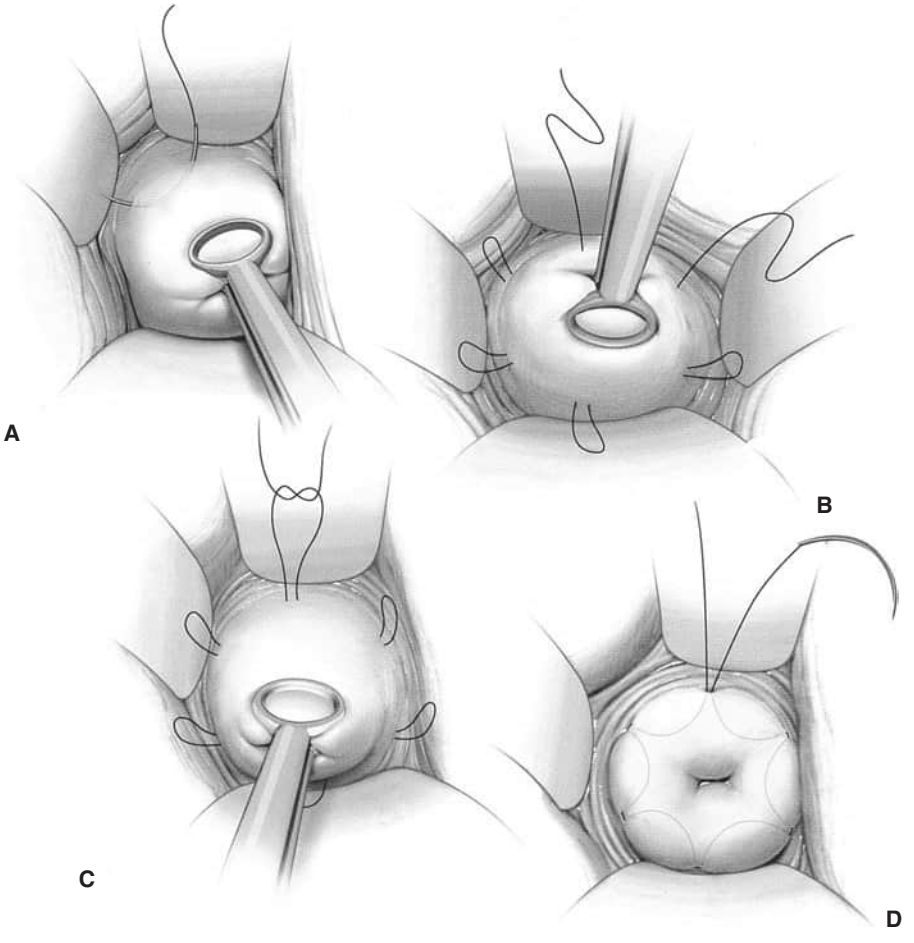

FIGURE 11-3 McDonald cerclage procedure for incompetent cervix. **A.** Start of the cerclage procedure with a no. 2 monofilament suture being placed in the body of the cervix very near the level of the internal os. **B.** Continuation of suture placement in the body of the cervix so as to encircle the os. **C.** Encirclement completed. **D.** The suture is tightened around the cervical canal sufficiently to reduce the diameter of the canal to 5 to 10 mm, and then the suture is tied. The effect of the suture placement on the cervical canal is apparent. A second suture placed somewhat higher may be of value if the first is not in close proximity to the internal os.

described by Shirodkar (1955) (Fig. 11-4). When either technique is performed electively, women with a classic history of cervical insufficiency have good outcomes (Caspi, 1990; Kuhn, 1977). For either vaginal or abdominal cerclage, evidence is insufficient to recommend perioperative antibiotic prophylaxis (American College of Obstetricians and Gynecologist, 2020a). Few data are available and do not support prophylactic tocolysis (Smith, 2015).

Regional analgesia is suitable and preferred. After this, the woman is placed in standard lithotomy position. The vagina and perineum are cleaned for surgery, and the bladder is drained. Some operators do not use potentially irritating antiseptic solution if amnionic membranes are exposed and instead use warm saline (Pelosi, 1990). Although steps are described here, a thorough and illustrated review of technique is provided by Hawkins (2017).

For suturing, options include a no. 1 or 2 nylon or polypropylene monofilament suture or 5-mm Mersilene tape. During placement, the suture is placed as cephalad along the cervical length as possible, is anchored into the dense cervical stroma, yet avoids the bladder. Two tandem cerclage suture rings are not more effective than one (Giraldo-Isaza, 2013).

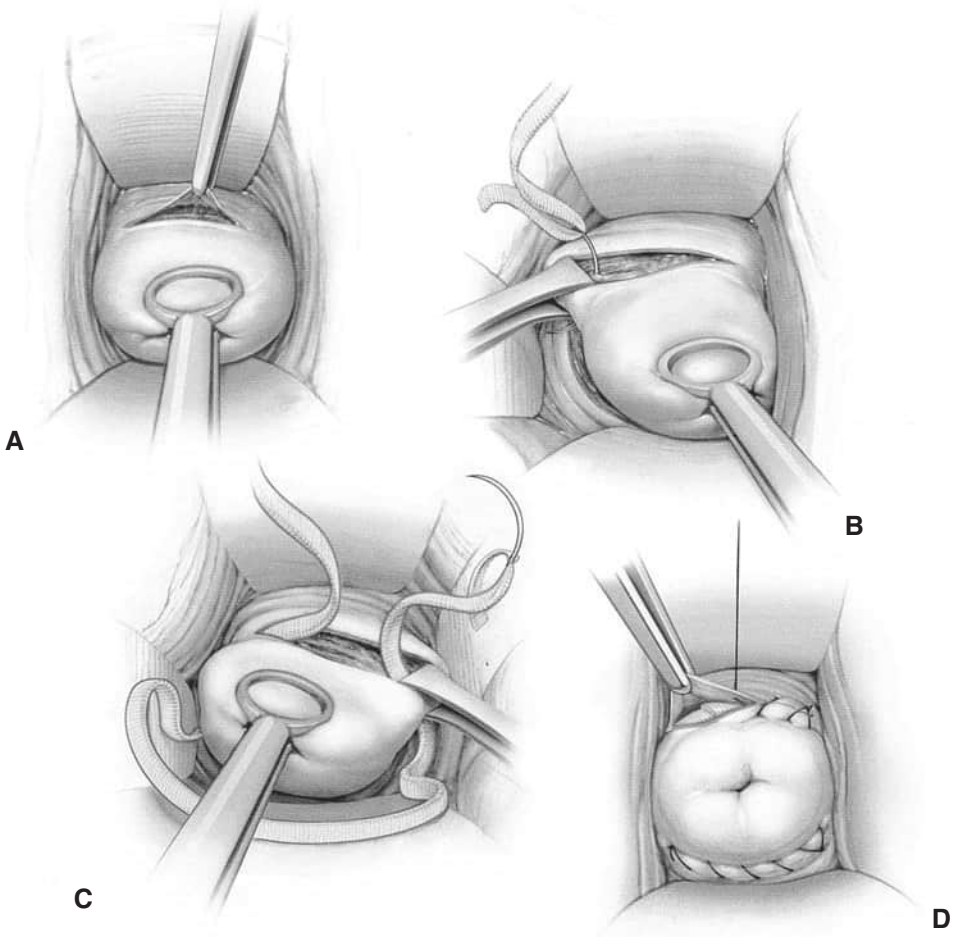

FIGURE 11-4 Modified Shirodkar cerclage for incompetent cervix. **A.** A transverse incision is made in the mucosa overlying the anterior cervix, and the bladder is pushed cephalad. **B.** A 5-mm Mersilene tape on a swaged-on or Mayo needle is passed anterior to posterior. **C.** The tape is then directed posterior to anterior on the other side of the cervix. Allis clamps are placed so as to bunch the cervical tissue. This diminishes the distance that the needle must travel submucosally and aids tape placement. **D.** The tape is snugly tied anteriorly, after ensuring that all slack has been taken up. The cervical mucosa is then closed with continuous stitches of chromic suture.

Emergency cerclage placement with a thinned dilated cervix is more difficult, and tissue tearing and membrane puncture are risks. Gentle replacement of the prolapsed amnionic sac back into the uterus can aid suturing. Options include steep Trendelenburg or filling the bladder with 600 mL of saline through a Foley catheter in the bladder. However, these steps may carry the cervix cephalad and away from the operating field. Instead, membranes can be pushed inward by a wide, moist sponge stick. A Foley catheter can instead be inserted through the cervix, and inflation of the 30-mL balloon can deflect the amnionic sac inward. The balloon is gradually deflated as the cerclage suture is tightened around the catheter tubing, which is then removed. With any of these, simultaneous gentle outward traction created by ring forceps placed on the cervical edges may be helpful.

For uncomplicated pregnancies without labor, the cerclage is usually snipped and removed at 37 weeks' gestation. This balances the risk of preterm birth against that of cervical laceration from a cerclage in place with labor contractions. Transvaginally placed cerclages are typically removed even with cesarean delivery to avoid rare long-term foreign-body complications (Hawkins, 2014). With scheduled cesarean delivery, the cerclage may be removed at 37 weeks or deferred until the time of regional analgesia and delivery. Again, the risk of labor ensuing before delivery must be considered. During extraction, particularly with a Shirodkar cerclage or a cerclage using Mersilene tape, analgesia aids patient comfort and adequate visualization.

Transabdominal Cerclage

At times, suture at the uterine isthmus is placed abdominally. Performed less often than transvaginal methods, selected indications include prior transvaginal cerclage failure or severe cervical anatomical defects. The cerclage is left until childbearing completion, and thus cesarean delivery is required. With the cerclage in place, conception rates still approximate 75 percent (Moawad, 2018). If needed for a fetal loss, dilation and evacuation can be performed with the suture in place (Dethier, 2020).

With the procedure, after abdomen entry, sharp dissection in the vesicocervical space allows the bladder to be pushed caudally. At the level of the internal os, a window is made in free space *medial* to the uterine vessels. This avoids vessel compression by the tightened cerclage. The nearby ureter is identified and avoided. One end of the ligating suture is passed into the right window, and the other is threaded into the left. Per surgeon preference, the knot is tied either in the front or back. The vesicouterine peritoneum is closed with absorbable suture in a running fashion.

In the MAVRIC trial, 111 women with a prior failed vaginal cerclage were randomly assigned to transabdominal, McDonald, or Shirodkar methods. Almost half of the transabdominal ones were placed prior to conception. The preterm birth rate before 32 weeks was 8 percent in the transabdominal group and 38 percent in each of the transvaginal cerclage groups (Shennan, 2020).

Of morbidity, rates of bleeding, adjacent organ injury, uterine perforation, and infection can be greater with transabdominal compared with transvaginal methods. Transabdominal cerclage performs suitably whether laparotomy or laparoscopy is used to place the sutures (Moawad, 2018).

Complications

With cerclage in general, PPROM, preterm labor, hemorrhage, or infection is a potential risk. All are uncommon with prophylactic cerclage. In the trial by MacNaughton and associates (1993), membrane rupture complicated only 1 of more than 600 procedures done before 19 weeks. In our view, clinical infection mandates immediate removal of the suture with labor induced or augmented. Similarly, with imminent abortion or delivery, the suture should be removed to avoid cervical laceration.

Following cerclage, sonographic surveillance does not improve outcomes (Dijkstra, 2000). Evidence does not support a subsequent reinforcing cerclage procedure (Baxter, 2005). Membrane rupture during suture placement or within the first 48 hours after surgery is considered by some to be an indication for cerclage removal to avoid serious fetal or maternal infection (Kuhn, 1977). In those with later PPROM but without infection or labor, options include observation alone or cerclage removal and observation. In these cases, data are contradictory regarding prolonged gestational latency and infection rates with retention or removal (Jenkins, 2000; Pergialiotis, 2015). In the absence of infection or labor, we allow cerclage retention with close clinical surveillance.

INDUCED ABORTION

Definitions

The term *induced abortion* is defined as termination of pregnancy with medication or surgery before fetal viability. The *abortion ratio* is the number of abortions per 1000 live births, and *abortion rate* is the number per 1000 women aged 15 to 44 years. For 2018, approximately 620,000 elective abortions were reported (Kortsmit, 2020). Of these, 78 percent were pregnancies aged ≤9 weeks' gestation, and 92 percent of abortions were completed before ≤13 weeks. The abortion ratio was 189 per 1000 live births, and the abortion rate was 11.3.

Therapeutic abortion refers to pregnancy termination for medical reasons, and suitable maternal or fetal indications are described in respective chapters. In cases of rape or incest, many consider termination. The most frequent therapeutic indication currently is to prevent birth of a fetus with a significant anatomical, metabolic, or mental deformity.

The term *elective abortion* or *voluntary abortion* describes the interruption of pregnancy before viability at the request of the woman, but not for medical reasons. Most abortions done today are elective.

Legal Influence

The legality of elective abortion was established by the United States Supreme Court in the case of *Roe v. Wade*. The Court defined the extent to which states might regulate abortion and ruled that first-trimester procedures must be left to the medical judgment of the physician. After this, the state could regulate abortion procedures in ways reasonably related to maternal health. Last, subsequent to viability, the state could promote its interest in the potential of human life and regulate abortion, except for preservation of the mother's health.

Other legislation followed. The 1976 Hyde Amendment forbids use of federal funds to provide abortion services except in cases of rape, incest, or life-threatening circumstances. The Supreme Court in 1992 reviewed *Planned Parenthood v. Casey* and upheld the fundamental right to abortion, but established that regulations are constitutional as long as they do not impose an "undue burden" on the woman. Subsequently, many states introduced counseling requirements, waiting periods, parental consent for minors, facility requirements, and funding restrictions. Such limits are often called targeted regulation of abortion providers (TRAP) laws. One major choice-limiting decision was the 2007 Supreme Court decision that reviewed *Gonzales v. Carhart* and upheld the 2003 Partial-Birth Abortion Ban Act. In 2016, some TRAP laws were dialed back by the Supreme Court ruling in the case of *Whole Woman's Health v. Hellerstedt*. With this, the justices noted that abortion laws must confer health safety benefits that outweigh burdens on access.

Provider Availability

Major women's health organizations support the legal right of women to obtain an abortion (Espey, 2019). The Accreditation Council for Graduate Medical Education mandates that obstetrics and gynecology residency education must include access to experience with induced abortion. The Kenneth J. Ryan Residency Training Program was established in 1999 to work with residency programs to improve abortion and contraceptive training. Moreover, postresidency training in these techniques is available in formal 2-year Family Planning fellowships. Other residency programs have a less-codified abortion curriculum. Instead, residents learn technical aspects through their management of miscarriage and pregnancy interruption for medical indications.

The American College of Obstetricians and Gynecologists (2019g) respects the need and responsibility of health-care providers to determine their individual positions on induced abortion. It also advocates for counseling and timely referral if providers have individual beliefs that preclude pregnancy termination. Knowledgeable and compassionate counseling objectively describes and provides information to the woman to permit informed decision-making.

FIRST-TRIMESTER METHODS

Abortions can be completed with either medication or surgery. In the absence of serious maternal disorders, abortion procedures do not require hospitalization (Guiahi, 2012). However, outpatient facilities should be able to provide emergency resuscitation and immediate transfer to a hospital (Levy, 2019).

■ Surgical Abortion

Preoperative Preparation

Surgical evacuation is performed transvaginally through an appropriately dilated cervix. For this, preoperative cervical ripening is typically associated with easier intraoperative cervical dilation, less pain, a technically easier procedure, and shorter operative times (Kapp, 2010; Webber, 2015). On balance, this preparation adds a surgical delay and potential side effects. Thus, cervical priming in the first trimester may be reserved for those with anticipated challenges to dilation. Examples are those with cervical stenosis or adolescents, who overall may experience higher associated pain (Allen, 2016). Surgical steps presented here apply to both induced abortion and miscarriage.

For ripening, hygroscopic dilators, also called osmotic dilators, are devices that draw water from surrounding tissues and expand gradually to dilate the endocervical canal. One type is derived from various species of *Laminaria* algae that are harvested from the ocean floor (Fig. 11-5). These come in different diameters, which allow the number and diameters of inserted devices, also called tents, to be customized to a given cervix. Another device is *Dilapan-S,* which is composed of an acrylic-based gel. Each type expands to an ultimate diameter three to four times that of its dry state.

With hygroscopic dilators, shallow insertion yields insufficient dilation or tent expulsion. Overly deep placement risks dislodgement into the uterine cavity. Once tents are inserted, several gauze sponges placed at the external os help prevent spontaneous tent expulsion. Patients can ambulate, void, or stool without limitation. The numbers of sponges and dilators inserted are carefully counted and recorded in the chart.

Schneider and coworkers (1991) described 21 cases in which women who had a hygroscopic dilator placed changed their minds. Of 17 women who chose to continue their pregnancy, 14 delivered at term, two delivered preterm, and one miscarried 2 weeks later. None suffered infection-related morbidity, including three untreated women with cervical cultures positive for *Chlamydia trachomatis*.

Instead, misoprostol is often used for cervical ripening. The typical dose is 400 μg administered sublingually, buccally, or

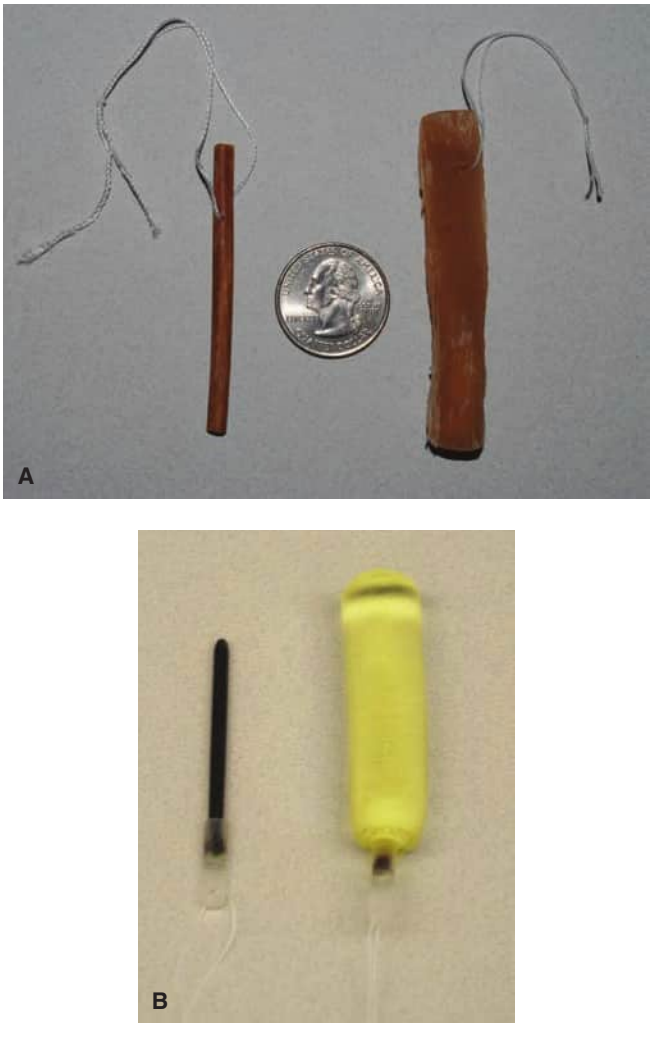

FIGURE 11-5 Hygroscopic dilators. With each type, the dry unit (*left*) expands exponentially when exposed to water (*right*) as in the endocervical canal. **A.** Laminaria. **B.** Dilapan-S.

placed into the posterior vaginal fornix at least 3 to 4 hours prior to surgery. Oral ingestion is less effective (Allen, 2016). Another option is a 200-mg oral mifepristone dose given 24 to 48 hours before surgery (Ashok, 2000). However, misoprostol is typically favored, because of mifepristone's greater delay to the procedure, cost, and limited access within the FDA's REMS program (p. 202).

Of options, hygroscopic dilators provide equal or slightly greater dilation than misoprostol. Other surgical parameters do not vary significantly (Bartz, 2013; MacIsaac, 1999). On balance, the ripening time required for hygroscopic dilators extends the total procedure time and can be uncomfortable, whereas misoprostol can cause fever, bleeding, and gastrointestinal side effects.

If not done as part of early prenatal care, hemoglobin level and Rh status are assessed prior to abortion. Screening for gonorrhea, for syphilis, and for human immunodeficiency virus, hepatitis B, and chlamydial infections also is completed. Obvious cervical infections are treated and resolved before elective procedures. To prevent postabortal infection after a first- or second-trimester surgical evacuation, a 200-mg oral prophylactic dose

of doxycycline is given 1 hour before. For those electing local anesthesia, evidence also supports adding an oral or intramuscular dose of a nonsteroidal antiinflammatory drug 30 to 60 minutes prior to surgery (Allen, 2018). Prophylaxis specifically for infective endocarditis prevention in those with valvular heart disease is not required in the absence of active infection (American College of Obstetricians and Gynecologists, 2020g,i). No recommendations specifically address venous thromboembolism prophylaxis for suction curettage in low-risk gravidas. At our hospital, we encourage early ambulation.

Vacuum Aspiration

Also called *suction curettage* or *suction dilation and curettage*, vacuum aspiration is a transcervical approach, in which the cervix is first dilated and tissue is then evacuated. For this, a rigid cannula is attached either to an electric-powered vacuum source or to a handheld 60-mL syringe for its vacuum source. These are *electric vacuum aspiration (EVA)* or *manual vacuum aspiration (MVA)*, respectively. *Sharp dilation and curettage (D & C)* in which contents are mechanically scraped out *solely* by a sharp curette is currently not recommended for pregnancy evacuation due to greater blood loss, pain, and procedural time (National Abortion Federation, 2020; World Health Organization, 2012). Importantly, this practice is distinguished from brief final sharp curettage following initial aspiration.

To begin, the surgeon performs a bimanual examination to confirm uterine size and orientation. A speculum is inserted, and the cervix is swabbed with povidone-iodine or equivalent solution. The anterior cervical lip is grasped with a toothed tenaculum. The cervix, vagina, and uterus are richly supplied by nerves of the Frankenhäuser plexus, which lies within connective tissue lateral to the uterosacral and cardinal ligaments. Thus, vacuum aspiration at minimum requires intravenously or orally administered sedatives or analgesics, and some add a paracervical or intracervical block (Allen, 2009; Renner, 2012). For a pudendal block, 5 mL of 1- or 2-percent lidocaine is injected into the uterosacral ligaments at their insertion into the uterus at 4 and 8 o'clock. Instead, an intracervical block with 5-mL aliquots of 1-percent lidocaine injected at 12, 3, 6, and 9 o'clock was reported to be equally effective (Mankowski, 2009). General or regional anesthesia may instead be elected.

First, a Sims uterine sound is passed into the uterus to measure the depth and inclination of the cavity. This provides parameters for subsequent instrument insertion. If required, the cervix is further dilated with Hegar, Hank, or Pratt dilators until a suction cannula can be inserted. As a rough rule, the degree of required cervical dilation in millimeters approximates gestational age. Hegar sizes reflect their diameter in millimeters. Pratt and Hank dilators are sized in French units, which can be converted to millimeters by dividing the French value by three.

With dilation, the fourth and fifth fingers of the introducing hand should rest on the perineum and buttocks as the instrument is guided through the internal os (Fig. 11-6). This technique minimizes forceful insertion and helps prevent uterine perforation.

Following dilation, for most first-trimester aspiration procedures, an 8- to 12-mm Karman cannula is appropriate. Small cannulas carry the risks of a longer surgery and of missed

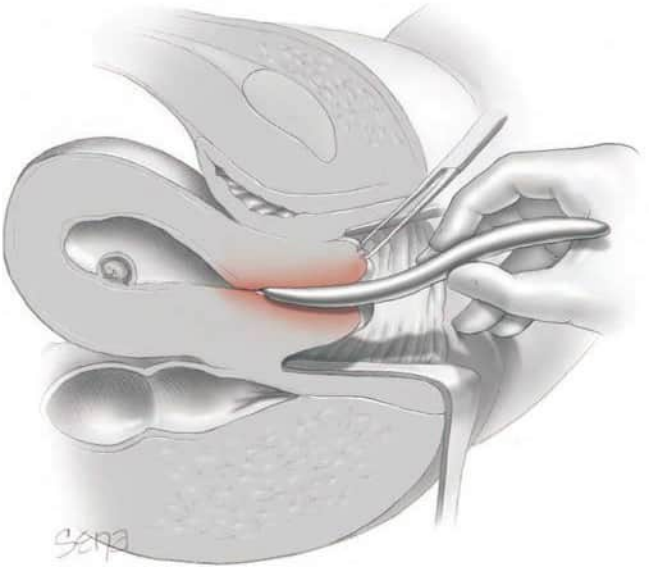

FIGURE 11-6 Dilation of cervix with a Hegar dilator. Note that the fourth and fifth fingers rest against the perineum and buttocks, lateral to the vagina. This maneuver is an important safety measure because if the cervix relaxes abruptly, these fingers prevent a sudden and uncontrolled thrust of the dilator, a common cause of uterine perforation.

intrauterine tissue. Large cannulas risk cervical injury and more discomfort. For evacuation, the cannula is slowly moved toward the fundus until resistance is met. Suction is then activated. The cannula is gradually pulled back toward the os and is simultaneously slowly turned circumferentially to cover the entire uterine cavity surface (Fig. 11-7). This is repeated until no more tissue is aspirated. A gentle sharp curettage can follow to remove any remaining tissue fragments (Fig. 11-8). Strong and consistent evidence supports the high efficacy, safety, and patient acceptability for both MVA and EVA (Lichtenberg, 2013).

For abortion done at ≤6 weeks' gestation, a distinct drawback is that the pregnancy may be small and missed by the curette. To identify placenta, the aspirated contents are rinsed in a strainer to remove blood, and then placed in a clear plastic container with saline and examined with back lighting (MacIsaac, 2000). Placental tissue macroscopically appears feathery. A magnifying lens, colposcope, or microscope can augment viewing. With gestations <6 weeks, the failed abortion rate approximates 2 percent (Paul, 2002). Thus, if products are not clearly identified, serial serum β-hCG levels can be informative (Dean, 2015).

Abortion Complications

Legally induced abortion in the United States has a low associated mortality rate, and from 2013 to 2017, the rate was 0.4 deaths in 100,000 procedures (Kortsmit, 2020). Early abortions are safer. The mortality rate was 0.3 deaths in 100,000 procedures performed ≤8 weeks' gestation but rose to 2.5 at 14 to 17 weeks and to 6.7 at ≥18 weeks (Zane, 2015). Notably, maternal mortality rates are 14-fold greater for pregnancies that are continued (Raymond, 2012).

Uterine perforation and lower-genital-tract laceration are uncommon but potentially serious, and rates also rise with

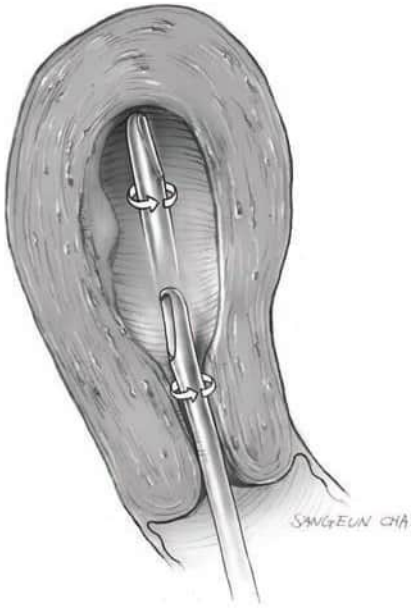

FIGURE 11-7 A suction curette has been placed through the cervix into the uterus. The figure shows the rotary motion used to aspirate the contents. (Figures 11-7 and 11-8: Reproduced with permission from Hoffman BL, Hamid CA, Corton MM: Surgeries for benign gynecologic disorders. In Hoffman BL, Schorge JO, Halvorson LM, et al (eds): Williams Gynecology, 4th ed. New York, McGraw Hill Education, 2020.)

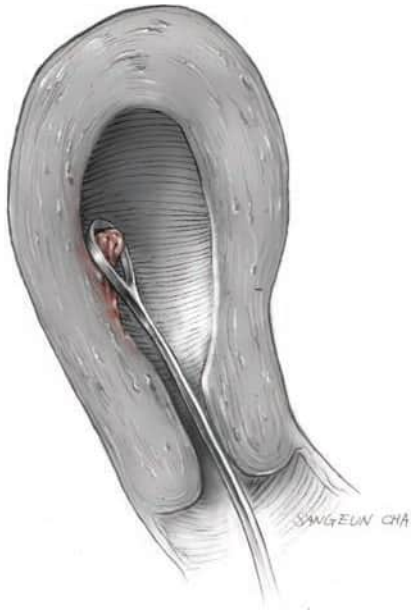

FIGURE 11-8 A sharp curette is advanced into the uterine cavity while the instrument is held with the thumb and forefinger as shown in Figure 11-6. Upon reaching the fundus, the curette is placed flush against the uterine wall. Firm pressure against the wall as the instrument is dragged out will scrape away adhered tissue fragments. With movement of the curette, only the strength of these two fingers should be used to help avoid perforation.

gestational age. In one systematic review of first-trimester abortion, the uterine perforation and laceration rates were each ≤1 percent (White, 2015). Perforation is usually recognized when the instrument passes without resistance deep into the pelvis. Risk factors include operator inexperience, prior cervical surgery or anomaly, adolescence, multiparity, and advanced gestational age (Allen, 2016; Grimes, 1984). If the uterine perforation is small and fundal, as when produced by a uterine sound or narrow dilator, observation for vital sign changes or uterine bleeding is usually sufficient.

If a suction cannula or sharp curette passes into the peritoneal cavity, considerable intraabdominal damage can ensue. Laparotomy or laparoscopy to thoroughly examine the abdominal contents is often the safest course. After potential injuries are resolved, intraoperatively, curettage can be completed under the direct guidance provided by laparoscopy or laparotomy (Owen, 2017).

Following curettage, uterine synechiae may form, and the risk of synechiae increases with procedure number. Most cases are mild and of unclear reproductive significance (Hooker, 2014). However, of Asherman syndrome cases, one series found that two thirds were linked to first-trimester curettage (Schenker, 1982).

Other first-trimester abortion complications are germane to both surgical and medication abortion techniques. First, hemorrhage with abortion is variably defined. One supported by the Society for Family Planning is bleeding that prompts a clinical response or bleeding in excess of 500 mL (Kerns, 2013). For first-trimester surgical abortions, hemorrhage complicates ≤1 percent (White, 2015). Atony, abnormal placentation, and coagulopathy are frequent sources, whereas surgical trauma is a rare cause. With medication abortion, bleeding is more common. In one study of more than 42,000 Finnish women undergoing pregnancy termination with pregnancies less 63 days, hemorrhage complicated 15 percent of medication abortion but only 2 percent of surgical cases (Niinimäki, 2009).

Infection is another risk. One review found a cumulative rate of 0.5 percent in those given prophylaxis compared with 2.6 percent in those given placebo (Achilles, 2011). In another review, the postoperative infection rate was <0.3 percent for either surgical or medication abortion (Upadhyay, 2015).

Incomplete abortion may require reevacuation. For medication abortion, this neared 5 percent in one systematic review (Raymond, 2013). Reaspiration rates following surgical abortion are typically <2 percent (Ireland, 2015; Niinimaki, 2009).

In sum, surgical abortion offers higher efficacy rates (96 to 100 percent) than medication abortion (83 to 98 percent) in the first trimester. Medication abortion also carries a greater cumulative risk of complications, although differences are small (Lichtenberg, 2013). These are balanced against the greater privacy of medication abortion and the more invasive steps of curettage.

■ Medication Abortion

Agents Used

For many women, outpatient medication abortion is an acceptable option for pregnancies with a menstrual age ≤70 days. Although suitable at later gestational ages, successful evacuation rates are lower.

Among abortions performed at ≤9 weeks' gestation, 39 percent were completed with medication in the United States

in 2018 (Kortsmit, 2020). One regimen provides mifepristone plus misoprostol, but another provides misoprostol alone. Of actions, mifepristone augments uterine contractility by reversing progesterone-induced myometrial quiescence. Misoprostol directly stimulates the myometrium. Both also ripen the cervix (Mahajan, 1997; Tang, 2007).

Contraindications have evolved from exclusion criteria that were used in clinical trials. Cautions include suspected ectopic pregnancy; in-situ intrauterine device; severe anemia, coagulopathy, or anticoagulant use; long-term systemic corticosteroid therapy; chronic adrenal failure; inherited porphyria; or allergy to agents used (American College of Obstetricians and Gynecologists, 2020c). Of note, misoprostol is suitable for early pregnancy failure in those with prior uterine surgery (Chen, 2008).

Misoprostol is a teratogen that is associated with transverse limb reduction or with the Mobius sequence, which is manifest by cranial nerve palsy. *Thus, a commitment to abortion completion is essential once this drug is given* (Vauzelle, 2013). With mifepristone, for women who choose to continue their pregnancies after exposure, the ongoing pregnancy rate ranges from 10 to 46 percent (Grossman, 2015). The associated major malformation rate was 5 percent in one series of 46 exposed pregnancies (Bernard, 2013).

Administration

Several dosing schemes are effective (Table 11-6). Because of its greater efficacy, mifepristone plus misoprostol combinations are favored. For gestations ≤70 days, the most widely accepted regimen is mifepristone, 200 mg given orally on day 0. This is followed in 24 to 48 hours by an 800-μg misoprostol dose that is administered vaginally, buccally, or sublingually (American College of Obstetricians and Gynecologists, 2020c). Oral ingestion has lower efficacy rates. If desired, mifepristone and misoprostol may be self-administered at home (Gambir, 2020). Associated infection rates approximate 0.3 percent, and antibiotic prophylaxis is not currently recommended (Achilles, 2011).

Symptoms following misoprostol are common within 3 hours and include vomiting, diarrhea, fever, and chills. Bleeding and cramping with medication abortion typically is significantly worse than that with menses. Thus, oral analgesics are provided. If bleeding soaks two or more pads in an hour for at least 2 hours, the woman is instructed to contact her provider.

Reappointment is 1 to 2 weeks following drug administration, and bimanual pelvic examination is recommended. Abortion completion may be assessed with β-hCG levels. Expected rates of decline at 1 week can be extrapolated from Table 11-1 and can guide care. However, specific β-hCG values lack suitable sensitivity (Rørbye, 2004). Moreover, routine postabortal sonographic examination is typically unnecessary (Clark, 2010). If done, it performs comparably to β-hCG level assessment (Dayananda, 2013). If sonography is done due to concern for failed abortion or for bleeding, unnecessary surgery can be avoided if scans are interpreted appropriately. If no gestational sac is seen and no heavy bleeding is noted, intervention is unnecessary. This is true even when, as is common, the uterus contains sonographically evident debris (Reeves, 2008).

TABLE 11-6. Various Regimens for Medical Termination of Pregnancy

First Trimester
Mifepristone/Misoprostol Mifepristone, 200 mg orally, and after 24 hr provide misoprostol[a] 800 μg
Misoprostol[a] Alone 800 μg and then may repeat every 3 hr for 3 total doses
Second Trimester
Mifepristone/Misoprostol Mifepristone, 200 mg orally, and after 24 hr provide misoprostol[a] 400 μg every 3 hr up to 5 total doses[b]
Misoprostol[a] Alone 400 μg every 3 hr up to 5 total doses[b]
Dinoprostone 20 mg vaginal suppository every 4 hr
Concentrated Oxytocin 50 units oxytocin in 500 mL of normal saline and infuse during 3 hr; then 1-hr diuresis (no oxytocin); then escalate sequentially in a similar fashion through 150, 200, 250, and finally 300 units oxytocin, each in 500 mL normal saline

[a]With misoprostol, efficacy is similar for vaginal, buccal, and sublingual routes, whereas oral ingestion is less effective.
[b]If abortion not completed by fifth dose, the cycle may be repeated following a 24-hour rest period.
American College of Obstetricians and Gynecologists, 2019f, 2020c; Raymond, 2019; Schreiber, 2018; Whitehouse, 2020; World Health Organization, 2018.

SECOND-TRIMESTER METHODS

In the second trimester, fetal anomaly or death, maternal health complications, inevitable abortion, or desired termination may be indications for uterine evacuation. As in the first trimester, medication or surgery is an option. In the second trimester, *dilation and evacuation (D & E)* rather than suction D & C is needed because of larger fetal size and bones.

Of options, D & E is a common means in the United States. Of all induced abortions in 2018, nearly 8 percent were performed by D & E at gestational ages >13 weeks (Kortsmit, 2020). Many of the surgical and medication steps for second-trimester abortion mirror those in the first trimester, and differences are emphasized here.

■ Dilation and Evacuation

Preparation

With D & E, wide mechanical cervical dilation is needed for evacuation of fetal parts. The degree needed rises with fetal gestational age, and inadequate dilation risks cervical trauma, uterine perforation, or tissue retention (Peterson, 1983). Thus, presurgical cervical preparation is advised, and main options include hygroscopic dilators or misoprostol (p. 209).

With laminaria, overnight preparation offers optimal cervical dilation (Fox, 2014). Uncommonly, laminaria may fail to adequately dilate the cervix, and serial insertions over several days with an increasing number of tents is an option. Dilapan-S also is suitable. It may be preferable for same-day procedures, as this device achieves its maximal effect in 4 to 6 hours (Newmann, 2014). Supplementing laminaria with mifepristone can aid procedures for gestations >19 weeks (Diedrich, 2020; Goldberg, 2015). In contrast, misoprostol supplementation to hygroscopic dilators failed to add benefits in one metaanalysis (Cahill, 2020).

If a patient changes abortion plans after hygroscopic dilator removal, preterm delivery and PPROM rates are substantial. In one series of 12 such cases, 50 percent ended with miscarriage or perinatal death (Mark, 2019).

Misoprostol alone can be used for cervical preparation. The typical dose is 400 μg given vaginally or buccally 3 to 4 hours prior to D & E. Randomized trial results vary regarding the ability of misoprostol to achieve results equal to that with hydroscopic dilators (Bartz, 2013; Goldberg, 2005; Sagiv, 2015). In women with one prior hysterotomy, the risk of uterine rupture was not elevated by misoprostol cervical ripening in one review but rose to 2.5 percent in those with ≥2 cesarean deliveries (Andrikopoulou, 2016).

With mifepristone alone for cervical ripening, fewer studies provide data. In one, mifepristone alone provided less dilation than hydroscopic dilators (Borgatta, 2012). In another trial, mifepristone given 48 hours before misoprostol created greater cervical dilation compared with misoprostol alone (Carbonell, 2007).

In sum, hygroscopic dilators soften and dilate the cervix before D & E. Sequential insertions or layering agents may be most helpful for later gestations or for an inadequate response to initial hygroscopic dilators alone. Yet, layering adds cost and potential side effects.

With elective abortion, some choose to induce fetal demise prior to D & E to avert a live birth. For this, an intracardiac potassium chloride or lidocaine injection or an intraamnionic or intrafetal digoxin injection is used prior to cervical ripening (Tufa, 2020).

Technique

During D & E, sonography can be used as an adjunct in all cases or selectively in more challenging ones. Perioperative antibiotic prophylaxis mirrors that for first-trimester procedures (p. 209). To reduce postprocedure bleeding, dilute vasopressin can be injected intracervically or as part of a paracervical block (Kerns, 2013; Schulz, 1985). Once adequate cervical dilation is achieved, the initial surgical step drains amnionic fluid with an 11- to 16-mm suction cannula or with amniotomy. This reduces the risk of amnionic fluid embolism and brings the fetus into the lower uterine segment for removal (Owen, 2017; Prager, 2009).

For pregnancies >16 weeks' gestation, the fetus is extracted, often in parts, using Sopher forceps or other destructive instruments. With complete removal of the fetus, a large-bore vacuum curette is used to remove the placenta.

Major complications are infrequent with D & E, and rates range from 1 to 2 percent in large series (Lederle, 2015; Peterson, 1983). These include uterine perforation, cervical laceration, uterine bleeding, and postabortal infection. Prior *cesarean delivery* is not a contraindication for D & E and may be preferred over prostaglandins for those with multiple prior hysterotomies (Ben-Ami, 2009).

Other Surgical Considerations

Placenta previa or the placenta accreta syndrome (PAS) can raise D & E risks. Once diagnosed, PAS typically prompts hysterectomy (Matsuzaki, 2015). For *placenta previa,* D & E is preferred to quickly evacuate the placenta, but the ability to transfuse blood products and perform possible hysterectomy must be available (American College of Obstetricians and Gynecologists, 2019f; Perriera, 2017). Medication abortion may be elected, but the risk for transfusion is greater than with D & E (Nakayama, 2007). Data are conflicting regarding the value of predelivery uterine artery embolization to lessen bleeding risks (Wang, 2019).

In some cases of failed second-trimester medication abortion, hysterotomy may be considered. In other cases, if comorbid uterine pathology is significant, such as numerous large myomas, hysterectomy may provide ideal treatment. Some women with second-trimester pregnancies desire sterilization following evacuation. Because the contracted uterine fundus will lie lower, any laparotomy incision must be placed to allow fallopian tube access.

■ Medication Abortion

Principal among noninvasive methods is a mifepristone plus misoprostol regimen or misoprostol alone (see Table 11-6). Of these two options, the combined regimen yields a shorter termination duration (Kapp, 2007; Ngoc, 2011). Hygroscopic dilators may speed the time to delivery with this combined regimen

(Mazouni, 2009; Vincienne, 2018). In selecting misoprostol routes, oral administration leads to a longer time to delivery compared with vaginal or sublingual routes (Dickinson, 2014). Prophylactic antibiotics are not typically given, and infection surveillance during labor is instead applied (Achilles, 2011).

Another induction agent, PGE_2, shows similar efficacy and side effects compared with misoprostol (Jain, 1994; Jansen, 2008). Simultaneous administration of an antiemetic such as metoclopramide (Reglan), an antipyretic such as acetaminophen, and an antidiarrheal such as diphenoxylate/atropine (Lomotil) will help prevent or treat symptoms. Dinoprostone (Prostin) is an available PGE_2 in the United States. However, its greater cost and poor pharmacologic stability at room temperature may make it less attractive than misoprostol.

During medication abortion, the uterine rupture rate is 0.4 percent with misoprostol and one prior low transverse cesarean delivery (Berghella, 2009). Both misoprostol and PGE_2 appear to pose similar risk (le Roux, 2001; Reichman, 2007). Few data guide their use for medication abortion in those with ≥2 prior cesarean deliveries.

Of other agents, high-dose intravenous oxytocin in saline will result in second-trimester abortion in 80 to 90 percent of cases (see Table 11-6). However, by comparison, misoprostol leads to higher successful induction rates and faster delivery times (Alavi, 2013).

Rarely used in the United States, ethacridine lactate is an organic antiseptic that activates myometrial mast cells to release prostaglandins (Olund, 1980). The solution is instilled either intraamnionically or extraovularly, that is, into the potential space between the uterine wall and amnion. Compared with misoprostol, it is associated with longer times to delivery and lower success rates (Hou, 2011).

Fetal and Placental Evaluation

For second-trimester pregnancies being terminated for maternal health or fetal indications, either D & E or medication abortion is suitable. Thus, patient input and clinical indication both guide selection. Perinatal palliative care can be instituted (p. 203) (Marc-Aurele, 2020).

Evaluation of a stillborn fetus is described in Chapter 35 (p. 626). One component is autopsy, which can also be valuable for second-trimester terminations due to anomalies (Hauerberg, 2012; Man, 2016). Fragmented D & E specimens may provide less information than intact fetuses (Lal, 2014).

ELECTIVE ABORTION CONSEQUENCES

Data relating abortion to overall maternal health and to subsequent pregnancy outcome are limited. Rates of infertility or ectopic pregnancy are not increased (Burkman, 1988; Frank, 1993). Exceptions may stem from postabortal infections, especially those caused by *C trachomatis*. Of subsequent adverse pregnancy outcomes, several studies note an approximate 1.5-fold greater incidence of preterm delivery following surgical evacuation (Lemmers, 2016; Saccone, 2016). This risk accrues with the number of terminations (Klemetti, 2012). Subsequent pregnancy outcomes are similar if a prior induced abortion was completed with medication or by surgery (Männistö, 2013; Virk, 2007).

POSTABORTAL CONTRACEPTION

After early abortion, woman may ovulate after 8 days, but the average is 3 weeks (Lahteenmaki, 1978; Stoddard, 2011). Unless another pregnancy is imminently desired, contraception, either hormonal or nonhormonal, can be started immediately after abortion (Curtis, 2016). In candidates, defined in Chapter 38 (p. 667), an intrauterine device can be inserted immediately after surgery or medication abortion is completed (Bednarek, 2011; Korjamo, 2017).

For women who desire another pregnancy, conception need not be delayed. From studies, groups conceiving within 3 months of a first-trimester loss had lower subsequent miscarriage rates compared with groups with later conceptions (Schliep, 2016).

CHAPTER 12

Ectopic Pregnancy

Following fertilization and fallopian tube transit, the blastocyst normally implants in the endometrial lining of the uterine cavity. Implantation elsewhere is considered ectopic. In the United States, numbers from an insurance database and from Medicaid claims showed ectopic pregnancy rates of 1.54 percent and 1.38 percent, respectively, in 2013 (Tao, 2017). Ectopic implantation accounts for 3 percent of all pregnancy-related deaths (Creanga, 2017). Fortunately, beta-human chorionic gonadotropin (β-hCG) assays and transvaginal sonography (TVS) aid earlier diagnosis, maternal survival, and fertility conservation.

TUBAL PREGNANCY

Classification

Of ectopic pregnancies, nearly 95 percent implant in the fallopian tube's various segments (Fig. 2-13, p. 26). The ampulla (70 percent) is the most frequent site (Fig. 12-1). The rate for isthmic implantation is 12 percent; fimbrial, 11 percent; and interstitial, 2 percent (Bouyer, 2002). Nontubal ectopic pregnancies compose the remaining 5 percent and implant in the ovary, peritoneal cavity, cervix, or prior cesarean scar. Occasionally, a multifetal pregnancy contains one conceptus with normal uterine implantation and the other implanted ectopically. This is termed a *heterotopic pregnancy* (p. 231).

For all ectopic pregnancy sites, management is influenced by pregnancy viability, gestational age, maternal health, desires for

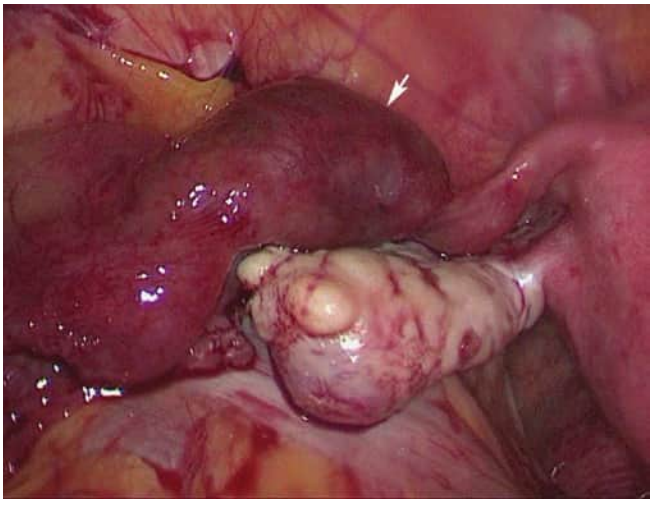

FIGURE 12-1 Ampullary tubal pregnancy (*arrow*) seen during laparoscopy. (Reproduced with permission from Dr. Lisa Chao.)

the index pregnancy and for future fertility, physician skill, and available resources. Regardless of location, D-negative women with an ectopic pregnancy are given anti-D immunoglobulin. In first-trimester pregnancies, a single intramuscular 50- or 120-μg dose is appropriate. Later gestations are given 300 μg (American College of Obstetricians and Gynecologists, 2019b).

Risks

Abnormal fallopian tube anatomy underlies most cases of tubal ectopic pregnancy. Surgeries for a prior tubal pregnancy, for fertility restoration, or for sterilization confer the highest risk. After one prior ectopic pregnancy, the chance of another nears 10 percent (de Bennetot, 2012). Previous tubal infection, which can distort normal tubal anatomy, is another risk. Specifically, one episode of salpingitis can be followed by a subsequent ectopic pregnancy in up to 9 percent of women (Westrom, 1992). Peritubal adhesions that form from salpingitis, appendicitis, or endometriosis also raise chances.

Infertility and the use of assisted reproductive technologies (ART) to overcome it are linked to increased ectopic pregnancy rates (Li, 2015; Perkins, 2015). Newer techniques aim to lower this rate with ART (Londra, 2015; Zhang, 2017). Smoking is another known association, although the underlying mechanism is unclear (Hyland, 2015). Last, with any form of contraception, the absolute number of ectopic pregnancies declines because pregnancy is effectively prevented. However, some methods more efficiently prevent intracavity implantation and with their failure, ectopic implantation is favored. These methods are tubal sterilization, intrauterine devices (IUDs), and progestin-only contraceptives.

Pathogenesis and Potential Outcomes

With tubal pregnancy, because the fallopian tube lacks a submucosal layer, the fertilized ovum promptly burrows through the epithelium. The zygote comes to lie near or within the muscularis, which is invaded by rapidly proliferating trophoblast. Potential outcomes from this include tubal rupture, tubal abortion, or pregnancy failure with resolution.

With rupture, the invading and expanding conceptus can tear the fallopian tube. Tubal ectopic pregnancies usually rupture spontaneously but may occasionally burst following coitus or bimanual examination. Hemorrhage usually persists and can become life threatening.

Tubal abortion describes the pregnancy's passage out the fallopian tube's distal end. Subsequently, hemorrhage may cease, and symptoms eventually disappear. However, bleeding instead can progress to induce symptoms as long as products remain in the tube. Blood slowly issues from the tubal fimbria into the peritoneal cavity and pools in the rectouterine cul-de-sac. If the fimbriated extremity is occluded, the fallopian tube may gradually distend with blood to form a hematosalpinx. Rarely, an aborted fetus will secondarily implant on a peritoneal surface and become an abdominal pregnancy (p. 231).

Last, *spontaneous failure* reflects ectopic pregnancy death and subsequent reabsorption. These are now more regularly identified by current sensitive β-hCG assays and surveillance.

Distinctions between *acute* ectopic pregnancy, just described, and *chronic* ectopic pregnancy also can be drawn. Acute ectopic pregnancies are more common, produce a high serum β-hCG level, and grow rapidly, leading to a timely diagnosis. These carry a greater risk of rupture (Barnhart, 2003c). With chronic ectopic pregnancy, abnormal trophoblasts die early, and thus serum β-hCG levels are negative or are low and static. Chronic ectopic pregnancies typically rupture late, if at all, but commonly form a persistent complex pelvic mass. This sonographic finding, rather than patient symptoms, often is the reason that prompts diagnostic surgery (Tempfer, 2019).

Clinical Manifestations

Sources of abdominal pain during pregnancy are extensive. Uterine conditions include miscarriage, infection, degenerating or enlarging leiomyomas, or round-ligament pain. Adnexal pain may reflect ectopic pregnancy or ovarian masses that are hemorrhagic, ruptured, or torsed. Appendicitis, renal stone, cystitis, and gastroenteritis are some nongynecological reasons for lower abdominal pain in early pregnancy. Thus, an initial urine β-hCG assay, urinalysis, and measure of hemoglobin or hematocrit are routine. A complete blood count (CBC) to assess the white blood cell count may be preferred if serious infection is a possible diagnosis. A positive urine pregnancy test result should prompt a serum β-hCG assay for those with pain or bleeding.

Before rupture, symptoms and signs of ectopic pregnancy are often subtle or absent. The classic triad is amenorrhea that is followed by pain and vaginal bleeding. With tubal rupture, lower abdominal and pelvic pain is usually severe and frequently described as sharp, stabbing, or tearing. Some degree of vaginal spotting or bleeding is reported by most women with tubal pregnancy. Although profuse vaginal bleeding suggests an incomplete abortion, such bleeding occasionally is seen with tubal gestations. Moreover, tubal pregnancy can lead to significant intraabdominal hemorrhage. Neck or shoulder pain, especially on inspiration, develops in women with diaphragmatic irritation from a sizable hemoperitoneum. Vertigo and syncope may reflect hemorrhage-related hypovolemia.

Of physical findings, abdominal palpation elicits tenderness. Bimanual pelvic examination may reveal a mass and tenderness, but this examination should be limited and gentle to avoid iatrogenic rupture. The uterus itself can be slightly enlarged due to hormonal stimulation. Responses to moderate bleeding include no change in vital signs, a slight rise in blood pressure, or a vasovagal response with bradycardia and hypotension. Blood pressure will fall and pulse will rise only if bleeding continues and hypovolemia becomes significant.

Of laboratory findings, hemoglobin or hematocrit readings may at first show only a slight reduction, even after substantive hemorrhage. Thus, after acute hemorrhage, a trending decline in hemoglobin or hematocrit levels over several hours is a more valuable index of blood loss than is the initial level. In approximately half of women with a ruptured ectopic pregnancy, varying degrees of leukocytosis may reach 30,000/μL.

Decidua is endometrium that is hormonally prepared for pregnancy. The degree to which the endometrium is converted with ectopic pregnancy varies. Thus, in addition to bleeding,

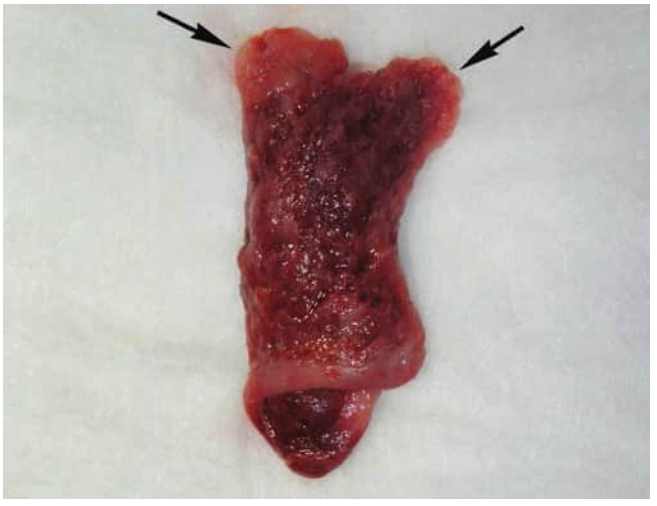

FIGURE 12-2 This 7-cm decidual cast was passed by a patient with a tubal ectopic pregnancy. The cast mirrors the shape of the endometrial cavity, and each arrow marks the portion of decidua that lined the cornua.

women with ectopic tubal pregnancy may pass a *decidual cast.* This is the entire sloughed endometrium that takes the form of the endometrial cavity (Fig. 12-2). Importantly, decidual sloughing may also occur with miscarriage. Thus, tissue is carefully examined by the provider and then submitted to evaluate for histological evidence of a conceptus. If no clear gestational sac is seen by inspection or if no villi are identified histologically, the possibility of ectopic pregnancy must still be considered.

TUBAL PREGNANCY DIAGNOSIS

For ectopic pregnancy, physical findings, serum β-hCG level measurement, TVS, and at times diagnostic surgery are tools for diagnosis. Women with evidence of tubal rupture undergo prompt surgery. For all other hemodynamically stable women without a clearly identified pregnancy, diagnostic strategies use these tools to identify ectopic pregnancy.

Strategies involve trade-offs. Those that maximize ectopic pregnancy detection may terminate a normal intrauterine pregnancy (IUP). Conversely, those that reduce the potential interruption of a normal IUP can delay ectopic pregnancy diagnosis. Patient desires for the index pregnancy are sought and influence these trade-offs.

■ Beta-Human Chorionic Gonadotropin

Rapid and accurate determination of pregnancy is a fundamental step. hCG is a glycoprotein produced by placental trophoblast and can be detected in serum in early pregnancy. Current pregnancy tests are immunoassays that seek the beta subunit of hCG. Lower limits of detection are 20 to 25 mIU/mL for urine and ≤5 mIU/mL for serum (Greene, 2015). Different assays can have results that vary by 5 to 10 percent. Thus, serial values are more reliable when performed by the same laboratory (Desai, 2014).

For women with a positive pregnancy test result plus bleeding or pain, an initial TVS is typically performed to locate the gestation. The initial β-hCG level sets expectations for anticipated TVS finding. With values above a discriminatory threshold, a normal IUP is expected to be seen within the uterus. Some institutions set their discriminatory threshold at ≥1500 mIU/mL, whereas others use ≥2000 mIU/mL. Connolly and associates (2013) suggested an even higher threshold. They noted that with live IUPs, a gestational sac was seen 99 percent of the time in those with a discriminatory level >3510 mIU/mL.

■ Transvaginal Sonography

Pregnancy of Unknown Location

If a yolk sac, embryo, or fetus is found within the uterus or within the adnexa, a diagnosis is made. However, if no evidence of an IUP is seen with TVS, the diagnosis is a *pregnancy of unknown location (PUL).* Most PULs reflect: (1) a failing IUP, (2) recent completed abortion, (3) early IUP, or (4) ectopic pregnancy.

Without clear evidence for ectopic pregnancy, serial β-hCG level assessment is reasonable, and a second level is obtained 48 hours after the first. This practice averts unnecessary methotrexate therapy and avoids harming an early, normal IUP.

With early, normal IUPs, Barnhart and coworkers (2004b) reported a 53-percent minimum rise over 48 hours. Seeber and colleagues (2006) found an even more conservative minimal 35-percent rise in normal IUPs. With multifetal gestation, this same anticipated rate of rise is expected (Chung, 2006).

With a PUL ultimately diagnosed as a failed IUP, a pattern of β-hCG level decline also can be anticipated, and levels drop rapidly (Table 11-1, p. 202) (Barnhart, 2004a). Sometimes, PULs fail before their location is identified. With failing PULs, Butts and coworkers (2013) found rates of decline that ranged from 35 to 50 percent at 48 hours and 66 to 87 percent at 7 days for starting hCG values between 250 and 5000 mIU/mL.

Despite these benchmarks, a third of women with an ectopic pregnancy can also have a 53-percent rise at 48 hours (Silva, 2006). Overall, approximately half of ectopic pregnancies show declining β-hCG levels, whereas the other half have rising levels. Importantly, despite a declining β-hCG level, a resolving ectopic pregnancy may rupture. Rupture at low values likely reflects partial disruption of the vascular connection between trophoblast and maternal vessels. Here, although β-hCG is produced, it is unable to enter circulation and be detected.

After the initial two β-hCG tests during PUL assessment, additional levels are drawn every 2 to 7 days. In general, testing is typically more frequent if symptoms or β-hCG level trends reflect a higher ectopic pregnancy risk (American College of Obstetricians and Gynecologists, 2019c). TVS also may be repeated. This serial assessment to reach a diagnosis is balanced against the rupture risk if the pregnancy is indeed ectopic. Dilation and curettage (D & C) is an option (Barnhart, 2021). It may give a faster diagnosis but may interrupt a normal IUP. Before curettage, a second TVS examination may be indicated and may display new informative findings.

As noted, ectopic pregnancies can rupture even at low β-hCG levels. Thus, serum β-hCG values are usually followed until they lie below the negative-result threshold for the given assay.

Endometrial Findings

In a woman in whom ectopic pregnancy is suspected, TVS is performed to look for findings indicative of an IUP or ectopic

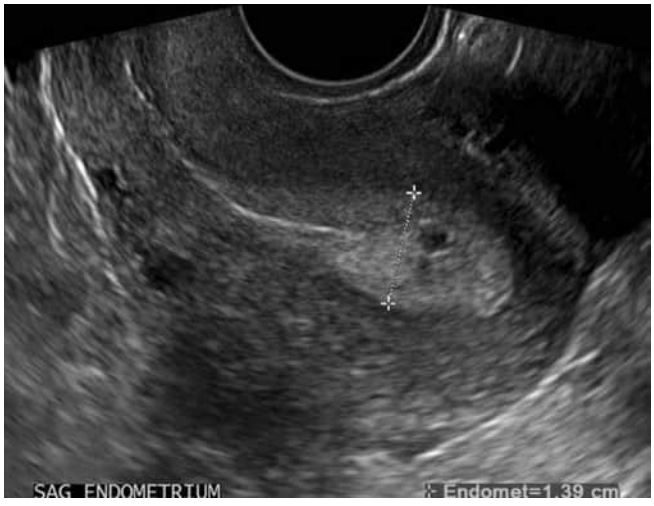

FIGURE 12-3 Transvaginal sonography of a pseudogestational sac within the endometrial cavity. Its central location is characteristic of these anechoic fluid collections. The endometrium is marked by calipers, and distal to this fluid, the endometrial thickness has a trilaminar pattern. This pattern is common with ectopic pregnancy. (Reproduced with permission from Jason McWhirt, ARDMS.)

pregnancy. During endometrial cavity evaluation, an intrauterine gestational sac is usually visible between 4½ and 5 weeks. The yolk sac appears between 5 and 6 weeks, and a fetal pole with cardiac activity is first detected at 5½ to 6 weeks (Fig. 14-1, p. 248). With transabdominal sonography, these structures are visualized slightly later.

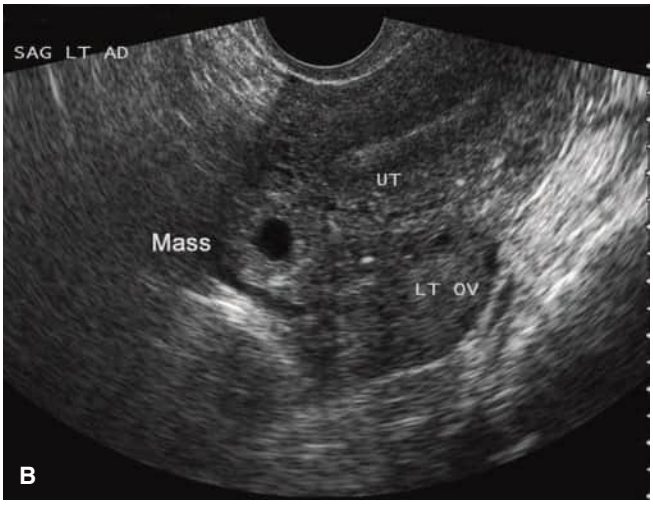
In contrast, with ectopic pregnancy, a trilaminar endometrial pattern is characteristic (Fig. 12-3). Its specificity is 94 percent, but with a sensitivity of only 38 percent (Hammoud, 2005). In addition, Moschos and Twickler (2008) determined in women with a PUL at presentation that no normal IUPs had an endometrial stripe thickness <8 mm.

Anechoic fluid collections, which might normally suggest an early intrauterine gestational sac, may also be seen with ectopic pregnancy. These include pseudogestational sac and decidual cyst. First, a pseudosac is a fluid collection between the endometrial layers and conforms to the cavity shape (see Fig. 12-3). If a pseudosac is noted, the risk of ectopic pregnancy is increased (Hill, 1990). Second, a decidual cyst is identified as an anechoic area lying within the endometrium but remote from the canal and often at the endometrial–myometrial border. This may represent early decidual breakdown that precedes cast formation (Ackerman, 1993b).

These two findings contrast with the intradecidual sign seen with IUPs. With this sign, the early gestational sac is an anechoic sac eccentrically located within one of the endometrial stripe layers (Dashefsky, 1988). The American College of Obstetricians and Gynecologists (2020) advises caution in diagnosing an IUP if a definite yolk sac or embryo is not seen.

Adnexal Findings

The sonographic diagnosis of ectopic pregnancy rests on seeing an adnexal mass separate from the ovary (Fig. 12-4). If an extrauterine yolk sac, embryo, or fetus is identified, ectopic



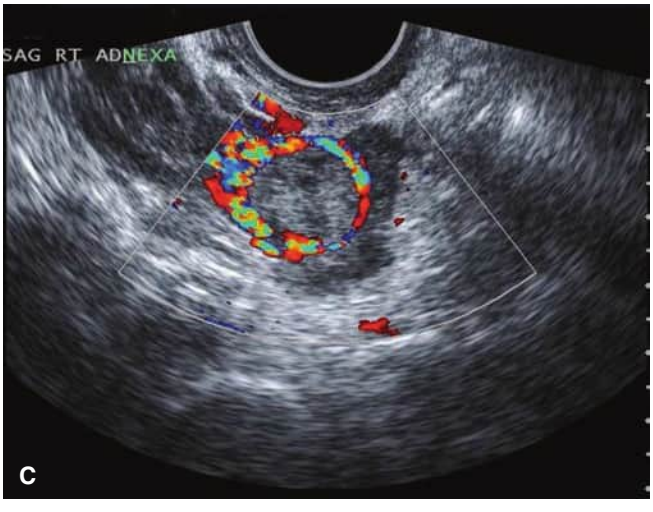


FIGURE 12-4 Various transvaginal sonographic findings with ectopic tubal pregnancies. For sonographic diagnosis, an ectopic mass should be seen in the adnexa separate from the ovary and may be seen as: **(A)** a yolk sac (shown here) and/or fetal pole with or without cardiac activity within an extrauterine sac, **(B)** an empty extrauterine sac with a hyperechoic ring, or **(C)** an inhomogeneous adnexal mass. In this last image, color Doppler shows a classic "ring of fire," which reflects increased vascularity typical of ectopic pregnancies. LT OV = left ovary; SAG LT AD = sagittal left adnexal; UT = uterus.

pregnancy is clearly confirmed. In other cases, a hyperechoic halo or tubal ring surrounding an anechoic gestational sac is seen. Alternatively, hemorrhage within the ectopic pregnancy can form a solid, complex adnexal mass. Overall, 60 percent of ectopic pregnancies are a complex mass; 20 percent are a hyperechoic ring; and 13 percent have an obvious gestational sac with a yolk sac or embryo (Condous, 2005). Importantly, not all adnexal masses represent an ectopic pregnancy. In this case, integration of sonographic findings with other clinical information is necessary.

Placental blood flow within the periphery of the complex adnexal mass—the *ring of fire*—can be seen with application of color Doppler. A corpus luteum cyst often displays a similar vascular pattern, and differentiation can be challenging.

Hemoperitoneum

In affected women, blood in the peritoneal cavity is most often identified using TVS (Fig. 12-5). A small amount of peritoneal fluid is physiologically normal. However, with hemoperitoneum, anechoic or hypoechoic fluid initially collects in the dependent retrouterine cul-de-sac. It then additionally surrounds the uterus as blood fills the pelvis. With significant intraabdominal hemorrhage, blood will track up the pericolic gutters to fill Morison pouch near the liver. Free fluid in this pouch typically is not seen until accumulated volumes reach 400 to 600 mL (Branney, 1995; Rodgerson, 2001). Diagnostically, peritoneal fluid in conjunction with an adnexal mass and a positive pregnancy test result are highly predictive of ectopic pregnancy (Nyberg, 1991). Ascites from cancer is a notable mimic.

If sonography is unavailable, culdocentesis is a simple technique and was used commonly in the past. The cervix is pulled outward and upward toward the symphysis with a tenaculum, and a long, 18-gauge needle is inserted through the posterior vaginal fornix into the retrouterine cul-de-sac. If present, fluid can be aspirated. However, no fluid is interpreted only as unsatisfactory entry into the cul-de-sac. Bloody fluid or fluid with old clot fragments suggests hemoperitoneum. If the blood sample clots, it may reflect an adjacent blood vessel puncture or brisk bleeding from ectopic pregnancy rupture.

Serum Progesterone

Although not our practice, this hormone is used by some to aid ectopic pregnancy diagnosis when serum β-hCG levels and TVS findings are inconclusive (Stovall, 1992). A single value is sufficient. From studies, a serum progesterone level <6 ng/mL (<20 nmol/L) has a pooled specificity of 98 percent to predict a nonviable pregnancy in women with a PUL (Verhaegen, 2012). A value >25 ng/mL suggests a live IUP and excludes ectopic pregnancy with 97-percent sensitivity (Carson, 1993). With most ectopic pregnancies, progesterone levels range between 10 and 25 ng/mL and thus have limited diagnostic utility (American College of Obstetricians and Gynecologists, 2019c). Serum progesterone levels can be used to buttress a clinical impression, but again they cannot reliably identify location (Guha, 2014).

Endometrial Sampling

Several endometrial changes accompany ectopic pregnancy, and all lack coexistent chorionic villi. Decidual reaction is found in 42 percent of samples, secretory endometrium in 22 percent, and proliferative endometrium in 12 percent (Lopez, 1994). Some recommend that lack of chorionic villi be confirmed by D & C before methotrexate treatment is given. Chung and associates (2011) found that the presumptive diagnosis of ectopic pregnancy is inaccurate in 27 percent of cases without histological exclusion of a spontaneous pregnancy loss. Nevertheless, the risks of D & C are weighed against the limited maternal risks of methotrexate.

Endometrial biopsy with a Pipelle catheter or endometrial aspiration was studied as an alternative to surgical curettage and found inferior (Barnhart, 2003b; Insogna, 2017). Instead, frozen section of curettage fragments to identify products of conception is accurate in 95 percent of cases (Li, 2014).

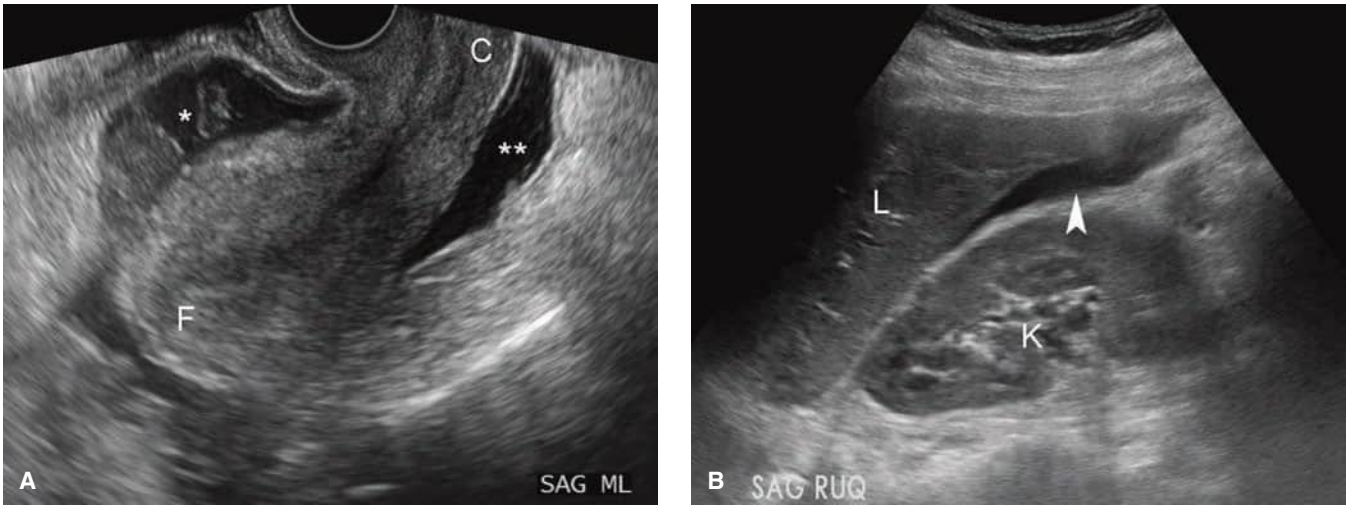

FIGURE 12-5 Hemoperitoneum. **A.** This transvaginal sagittal view of the pelvis shows anechoic fluid initially pooling in the retrouterine cul-de-sac (**). Large accumulations will also extend into the anterior cul-de-sac (*). **B.** In this right upper quadrant sonogram, anechoic fluid is seen in Morison pouch (*arrowhead*). Laparoscopy

Direct visualization of the fallopian tubes and pelvis by laparoscopy offers a reliable diagnosis in most cases of suspected ectopic pregnancy. This also permits a ready transition to definitive operative therapy, which is discussed subsequently.

MEDICAL MANAGEMENT

Regimen Options

For most ectopic pregnancies, medical therapy is preferred, if feasible, to avoid surgical risks. Disqualifying criteria are a ruptured fallopian tube and drug contraindications. Other considerations include reasonably close access to emergency care and a commitment to surveillance laboratory testing.

Medical therapy traditionally involves the antimetabolite methotrexate (MTX). This drug is a folic acid antagonist. It tightly binds to dihydrofolate reductase, blocking the reduction of dihydrofolate to tetrahydrofolate, which is the active form of folic acid. As a result, de novo purine and pyrimidine production is halted, which then arrests DNA, RNA, and protein synthesis. Thus, MTX is highly effective against rapidly proliferating trophoblast. However, gastrointestinal mucosa, bone marrow, and respiratory epithelium also can be harmed.

To help select suitable candidates, laboratory tests are obtained. First, MTX is renally cleared, and significant renal dysfunction, reflected by an elevated serum creatinine level, precludes its use. Second, MTX can be hepato- and myelotoxic, and CBC and liver function tests (LFTs) help establish a baseline. Last, blood type and Rh status are determined. All except blood typing are considered surveillance laboratory tests and are repeated prior to additional MTX doses.

With administration, women are counseled to avoid several aggravating agents until treatment is completed. These are: (1) folic acid-containing supplements, which can competitively reduce MTX binding to dihydrofolate reductase; (2) nonsteroidal antiinflammatory drugs, which reduce renal blood flow and delay drug excretion; (3) alcohol, which can predispose to concurrent hepatic enzyme elevation; (4) sunlight, which can provoke MTX-related dermatitis; and (5) sexual activity, which can rupture the ectopic pregnancy (American College of Obstetricians and Gynecologists, 2019c).

MTX is a potent teratogen, and MTX embryopathy is notable for craniofacial and skeletal abnormalities and fetal-growth restriction (Nurmohamed, 2011). MTX is excreted into breast milk and may accumulate in neonatal tissues and interfere with neonatal cellular metabolism (American Academy of Pediatrics, 2001; Briggs, 2017). Based on all these findings, a list of contraindications and pretherapy laboratory testing is found in Table 12-1.

For ease and efficacy, intramuscular MTX administration is used most often for ectopic pregnancy treatment, and single-dose and multidose MTX protocols are available. With single-dose therapy, the dose is 50 mg/m^2 body surface area (BSA), and BSA can be derived using various Internet-based BSA calculators. At our institution, patients are observed for 30 minutes following MTX injection to exclude an adverse reaction.

With the multidose regimen, leucovorin is added to blunt MTX toxicity. Leucovorin is *folinic acid* and has folic acid activity. Thus, it allows some purine and pyrimidine synthesis to buffer side effects.

Comparing these two protocols, trade-offs are recognized. Single-dose therapy offers simplicity, less expense, and less intensive posttherapy monitoring. However, some but not all studies report a higher success rate for the multidose regimen (Barnhart, 2003a; Lipscomb, 2005; Tabatabaii, 2012). Overall, ectopic tubal pregnancy resolution rates approximate 90 percent with MTX use. At our institution, we use single-dose MTX.

TABLE 12-1. Medical Treatment Protocols for Ectopic Pregnancy

	Single Dose	Multidose
Dosing	One dose; repeat if necessary	Up to four doses of both drugs until serum β-hCG declines by 15%
Medication Dosage		
Methotrexate	50 mg/m^2 BSA (day 1)	1 mg/kg, days 1, 3, 5, and 7
Leucovorin	NA	0.1 mg/kg days 2, 4, 6, and 8
Serum β-hCG level	Days 1 (baseline), 4, and 7	Days 1 (baseline), 3, 5, and 7
Indication for additional dose	If serum β-hCG level does not decline by 15% from day 4 to day 7 Less than 15% decline during weekly surveillance	If serum β-hCG level declines <15%, give additional dose; repeat serum β-hCG in 48 hours and compare with previous value; maximum four doses
Surveillance	Once 15% decline achieved, then weekly serum β-hCG levels until undetectable	
Methotrexate Contraindications		
MTX sensitivity	Intrauterine pregnancy	Immunodeficiency
Tubal rupture	Peptic ulcer disease	Hepatic, renal, or hematologic dysfunction
Breastfeeding	Active pulmonary disease	

BSA = body surface area; β-hCG = β-human chorionic gonadotropin; MTX = methotrexate; NA = not applicable.

Patient Selection

The best candidate for medical therapy is the woman who is asymptomatic, motivated, and compliant. With medical therapy, some classic predictors of success include a low initial serum β-hCG level, small ectopic pregnancy size, and absent fetal cardiac activity. Of these, initial serum β-hCG level is the best prognostic indicator with single-dose MTX. Reported failure rates are 1.5 percent if the initial serum β-hCG concentration is <1000 mIU/mL; 5.6 percent at 1000 to 2000 mIU/mL; 3.8 percent at 2000 to 5000 mIU/mL; and 14.3 percent for levels between 5000 and 10,000 mIU/mL (Menon, 2007).

Many early trials also used large size as an exclusion criterion. Lipscomb and colleagues (1998) reported a 93-percent success rate with single-dose MTX when the ectopic mass was ≤3.5 cm. This compared with success rates between 87 and 90 percent when the mass was >3.5 cm. These authors also found ectopic pregnancies measuring ≤4 cm and lacking cardiac activity to be suitable candidates. Failure rates rise if cardiac activity is seen, with an 87-percent success rate in such cases.

Side Effects

These regimens are associated with minimal laboratory changes and symptoms, but rarely toxicity may be severe. Kooi and Kock (1992) reviewed 16 studies and reported that adverse effects were resolved by 3 to 4 days after MTX was discontinued. The most frequent were liver involvement—12 percent; stomatitis—6 percent; and gastroenteritis—1 percent. One woman had bone marrow depression. More commonly, 65 to 75 percent of women given MTX will have increasing pain beginning several days after therapy. Thought to reflect separation of the ectopic pregnancy from the tubal wall, this pain generally is mild and relieved by analgesics. In a series of 258 women treated with MTX by Lipscomb and colleagues (1999), 20 percent had pain that merited evaluation in a clinic or emergency department to exclude tubal rupture.

Long term, MTX treatment does not diminish ovarian reserve (Ohannessian, 2014). However, after successful MTX therapy, pregnancy is ideally delayed for at least 3 months, because this drug may persist in human tissues for months after a single dose (Hackmon, 2011). Although data are very limited, conception before this waiting period appears reassuring. In one study, 45 women who conceived <6 months after MTX had similar pregnancy outcomes compared with 80 women who conceived >6 months after MTX (Svirsky, 2009).

Surveillance

As shown in Table 12-1, monitoring single-dose therapy calls for serum β-hCG determinations at days 4 and 7 following initial MTX injection on day 1. After single-dose MTX, mean serum β-hCG levels may rise or fall during the first 4 days and then should gradually decline. If the level fails to drop by ≥15 percent between days 4 and 7, a second MTX dose is recommended. This is necessary in 20 percent of women treated with single-dose therapy (Cohen, 2014). In such cases, a CBC, creatinine level, and LFTs are rechecked. If these surveillance tests are normal, a second equivalent dose is administered. The date of this second injection will become the new day 1, and the protocol is restarted.

Multidose therapy provides MTX (1 mg/kg) treatment with leucovorin (0.1 mg/kg) therapy on alternating days. After this first pair of injections, a serum β-hCG concentration is obtained. Values between days 1 and 3 are anticipated to drop by ≥15 percent. If not and if surveillance tests are normal, an additional MTX/leucovorin pair is given. A serum β-hCG level is repeated 2 days later. Up to four doses may be given if required (Stovall, 1991).

With either dosing regimen, once a decline ≥15 percent is achieved, weekly serum β-hCG level testing then begins until values are undetectable. Lipscomb and colleagues (1998) used single-dose MTX to successfully treat 287 women and reported that the average time to resolution—defined as a serum β-hCG level <15 mIU/mL—was 34 days. The longest time was 109 days.

SURGICAL MANAGEMENT

Options

Before surgery, future fertility desires are discussed. In women desiring sterilization, the unaffected tube can be ligated or removed. This is done concurrently with salpingectomy for the ectopic-containing tube.

Laparoscopy is the preferred surgical approach for ectopic pregnancy unless a woman is hemodynamically unstable. This is supported first by comparable subsequent uterine pregnancy rates and tubal patency rates in those undergoing salpingostomy completed either by laparoscopy or by laparotomy (Hajenius, 2007). Second, laparoscopy has lower infection, adhesion, and thromboembolism risks and faster recovery times than laparotomy. Moreover, as experience has accrued, cases previously managed by laparotomy—for example, those with hemoperitoneum—can safely be managed laparoscopically by those with suitable expertise. However, the lowered venous return and cardiac output associated with pneumoperitoneum must be factored into the selection of minimally invasive surgery for a hypovolemic woman.

Two procedures—salpingostomy or salpingectomy—are options. In the past, some favored salpingostomy to preserve future fertility. However, two randomized trials compared laparoscopic outcomes between the two procedures in women with a normal contralateral fallopian tube. The European Surgery in Ectopic Pregnancy (ESEP) study randomized 231 women to salpingectomy and 215 to salpingostomy. After surgery, the subsequent cumulative rates of ongoing pregnancy by natural conception did not differ significantly between groups—56 versus 61 percent, respectively (Mol, 2014). Again, in the DEMETER trial, the subsequent 2-year rate for achieving an IUP did not differ between groups—64 versus 70 percent, respectively (Fernandez, 2013). However, for women with an *abnormal-appearing* contralateral tube, salpingostomy of the ectopic-containing tube may be preferred if feasible to help preserve fertility.

Of the two procedures, salpingectomy may be used for both ruptured and unruptured ectopic pregnancies. With one

laparoscopic technique, the affected fallopian tube is lifted and held with atraumatic grasping forceps. One of several suitable bipolar grasping devices is placed across the fallopian tube at the uterotubal junction. Once desiccated, the tube is cut from its uterine attachment. The bipolar device is then advanced across the mesosalpinx to free the entire tube.

Salpingostomy is typically used to remove a small unruptured pregnancy. A 10- to 15-mm linear incision is made on the antimesenteric border of the fallopian tube and over the pregnancy. The products usually will extrude from the incision. These can be carefully extracted or can be flushed out using high-pressure irrigation that more thoroughly removes the trophoblastic tissue. Small bleeding sites are controlled with needlepoint electrosurgical coagulation, and the incision is left unsutured to heal by secondary intention (Tulandi, 1991). With either procedure and after specimen removal, the pelvis and abdomen are irrigated and suctioned free of blood and tissue debris to remove all trophoblastic tissue.

■ Persistent Trophoblast

After trophoblast removal during surgery, β-hCG levels usually fall quickly. Persistent trophoblast is rare following salpingectomy but complicates 5 to 15 percent of salpingostomy cases (Pouly, 1986; Seifer, 1993). Incomplete trophoblast removal can be identified by stable or rising β-hCG levels (Hajenius, 1995). Monitoring approaches are not codified. Weekly measures are reasonable following salpingostomy (Mol, 2008). Following uncomplicated salpingectomy, we do not repeat β-hCG levels in women without pain or symptoms of hemoperitoneum.

With stable or increasing β-hCG levels, additional surgical or medical therapy is necessary. In those without evidence for tubal rupture, standard therapy for persistent trophoblast is single-dose MTX, 50 mg/m^2 × BSA. Tubal rupture and bleeding require a second surgery.

■ Medical versus Surgical Therapy

Of options, multidose MTX treatment and laparoscopic salpingostomy have been compared in one randomized trial of 100 patients. The authors found no differences for rates of tubal preservation, primary treatment success, and subsequent fertility (Dias Pereira, 1999; Hajenius, 1997).

For single-dose MTX, its efficacy compared with laparoscopic salpingostomy shows conflicting results. In one randomized trial, single-dose MTX was less successful in pregnancy resolution, whereas in the other, single-dose MTX was equally effective (Saraj, 1998; Sowter, 2001). Krag Moeller and associates (2009) reported during a median surveillance period of 8.6 years that ectopic-resolution success rates and cumulative spontaneous IUP rates were not significantly different between those managed by laparoscopic salpingostomy and those treated with single-dose MTX.

Salpingectomy effectively removes the entire conceptus and yields high resolution rates. It thus outperforms MTX in this regard. Yet, when future fertility and ectopic pregnancy recurrence rates are analyzed, both salpingectomy and MTX therapy show comparable results (de Bennetot, 2012; Irani, 2017). In another study, surgery, MTX, or expectant management all yielded statistically similar subsequent spontaneous IUP rates (Demirdag, 2017).

In sum, medical or surgical management offer similar outcomes in women who are hemodynamically stable, have serum β-hCG concentrations <5000 mIU/mL, and have a small pregnancy with no cardiac activity. Despite lower success rates with medical therapy for women with larger tubal size, higher serum β-hCG levels, and fetal cardiac activity, medical management can be offered to the motivated woman who understands the risks of emergency surgery in the event of treatment failure.

■ Expectant Management

In select asymptomatic women, observation of a very early tubal pregnancy that is associated with stable or falling serum β-hCG levels is reasonable. A commitment to surveillance visits and relative proximity to emergency care are other safeguards. Importantly, this differs from expectant management of a PUL during its evaluation.

Predictive factors for success include a low initial serum β-hCG concentration, a significant drop in levels over 48 hours, and a sonographic inhomogeneous mass rather than a tubal halo or other gestational structures. For example, initial values <175 mIU/mL predict spontaneous resolution in 88 to 96 percent of attempts (Elson, 2004; Kirk, 2011). Initial values <1000 mIU/mL have success rates ranging from 71 to 92 percent (Jurkovic, 2017; Mavrelos, 2013; Silva, 2015).

With expectant management, subsequent rates of tubal patency and intrauterine pregnancy are comparable with surgery (Helmy, 2007). That said, compared with the established safety of medical or surgical therapy, the prolonged surveillance and risks of tubal rupture support the practice of expectant therapy only in appropriately selected and counseled women.

INTERSTITIAL PREGNANCY

■ Diagnosis

An interstitial pregnancy is one that implants within the tubal segment that lies within the muscular uterine wall (Fig. 12-6). Incorrectly, they may be called cornual pregnancies, but this term describes a conception that develops in the rudimentary horn of a uterus with a müllerian anomaly. Risk factors are similar to others discussed for tubal ectopic pregnancy, although previous ipsilateral salpingectomy is a specific one for interstitial pregnancy (Lau, 1999). Undiagnosed interstitial pregnancies usually rupture following 8 to 16 weeks of amenorrhea, which is later than for more distal tubal pregnancies. The myometrium covering the interstitial fallopian tube segment permits greater distention before rupture. Because of the proximity of these pregnancies to the uterine and ovarian arteries, hemorrhage can be severe and associated with mortality rates as high as 2.5 percent (Tulandi, 2004).

In many cases, these pregnancies are identified early, but diagnosis can still be challenging. These pregnancies sonographically

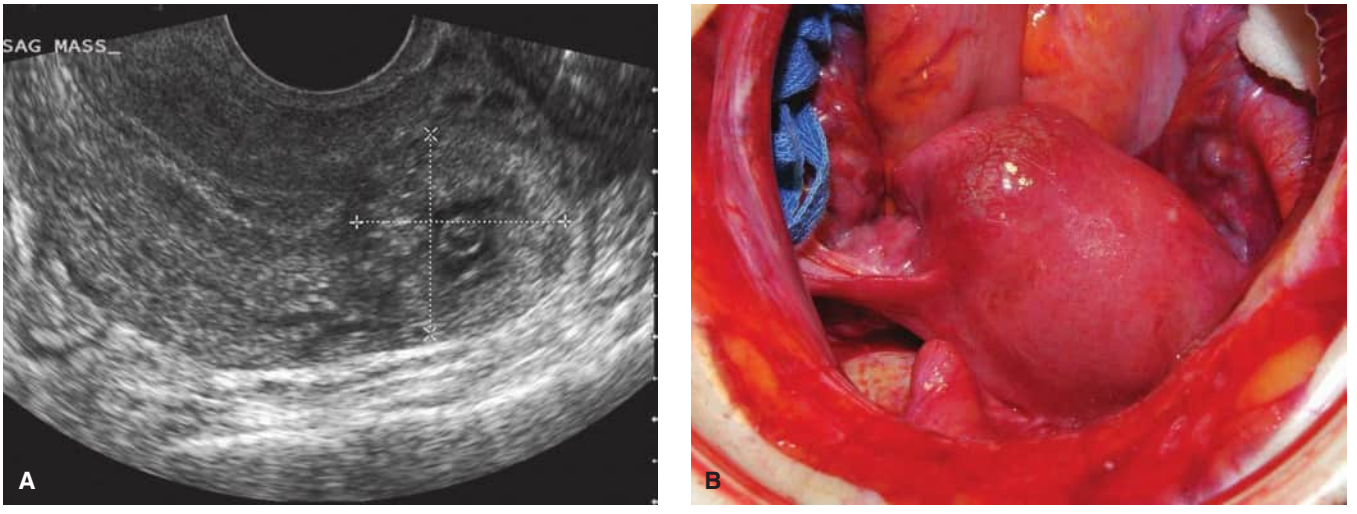

FIGURE 12-6 Interstitial ectopic pregnancy. **A.** This parasagittal view using transvaginal sonography shows an empty uterine cavity and a mass that is cephalad and lateral to the uterine fundus (*calipers*). **B.** Intraoperative photograph during laparotomy and before cornual resection of the same ectopic pregnancy. In this frontal view, the bulging right-sided interstitial ectopic pregnancy is lateral to the round ligament insertion and medial to the isthmic portion of the fallopian tube. (Reproduced with permission from Drs. David Rogers and Elaine Duryea.)

can appear similar to an eccentrically implanted IUP, especially in a uterus with a müllerian anomaly. Criteria that may aid differentiation include: an empty uterus, a gestational sac seen separate from the endometrium and >1 cm away from the most lateral edge of the uterine cavity, and a thin, <5-mm myometrial mantle surrounding the sac (Timor-Tritsch, 1992). Moreover, an echogenic line, known as the *interstitial line sign*, extending from the gestational sac to the endometrial cavity most likely represents the interstitial portion of the fallopian tube and is highly sensitive and specific (Ackerman, 1993a). In unclear cases, three-dimensional (3-D) sonography, magnetic resonance (MR) imaging, or diagnostic laparoscopy can help clarify anatomy. Laparoscopically, a myometrial protuberance is seen to lie lateral to the round ligament and coexists with normal distal tubes and ovaries.

■ Management

Surgically, either cornual resection or cornuostomy may be performed via laparotomy or laparoscopy, depending on patient hemodynamic stability and surgeon expertise. With either approach, intraoperative intramyometrial vasopressin injection may limit surgical blood loss. Cornual resection removes the gestational sac and surrounding cornual myometrium by means of a wedge excision (Fig. 12-7). Alternatively, cornuostomy involves incision of the cornual myometrium and suction or instrument extraction of the pregnancy. Both instances require layered myometrial closure. β-hCG levels are monitored postoperatively to exclude remnant trophoblast.

With early diagnosis, medical management may be considered. However, consensus regarding MTX regimens is lacking because of small study numbers. Jermy and coworkers (2004) reported a 94-percent success with systemic MTX using a dose of 50 mg/m^2 × BSA. Others employ a traditional multidose MTX regimen (Hiersch, 2014). Direct MTX injection into the gestational sac also offers comparable success (Framarino-dei-Malatesta, 2014). Last, a uterine artery MTX infusion followed by uterine artery embolization (UAE) is termed *chemoembolization* by some. This combined with systemic MTX has shown promise (Krissi, 2014).

The risk of uterine rupture with subsequent pregnancies following either medical or surgical management is undefined. Thus, elective cesarean delivery after $37^{0/7}$ weeks' gestation, which is timed similarly to those with prior at-risk myomectomy, is reasonable (American College of Obstetricians and Gynecologists, 2021).

Distinct from interstitial pregnancy, the term *angular pregnancy* is used by some to describe eccentric implantation near

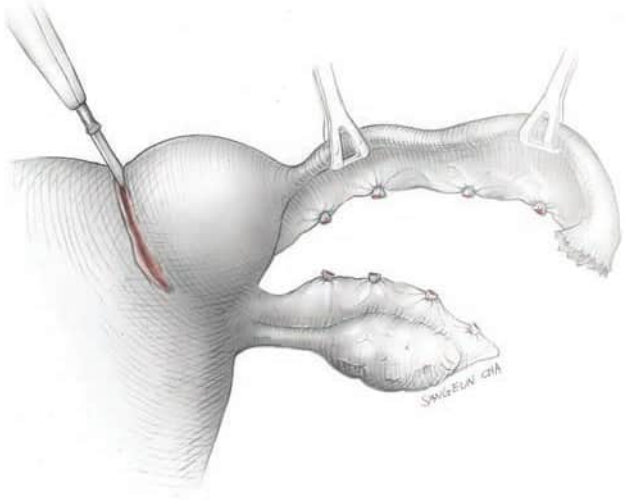

FIGURE 12-7 During cornual resection, the pregnancy, surrounding myometrium, and ipsilateral fallopian tube are excised en bloc. The incision is angled inward as it is deepened. This creates a wedge shape into the myometrium, which is then closed in layers with delayed-absorbable suture. The serosa is closed with subcuticular style suturing. (Reproduced with permission from Hoffman BL, Hamid CA, Corton MM: Surgeries for benign gynecologic conditions. In Hoffman BL, Schorge JO, Halvorson LM, et al: Williams Gynecology, 4th ed. New York, NY: McGraw Hill; 2020.)

one cornu but within the endometrial cavity. In one prospective case series of 42 such pregnancies, 80 percent progressed to a viable age, and abnormal placentation or uterine rupture did not develop (Bollig, 2020). These eccentrically implanted early IUPs are managed as normal pregnancies at our institution.

CESAREAN SCAR PREGNANCY

Diagnosis

This term describes implantation within the myometrium of a prior cesarean delivery scar. Its incidence approximates 1 case in 2000 normal pregnancies and has increased along with the cesarean delivery rate (Rotas, 2006).

Women with symptomatic cesarean scar pregnancy (CSP) usually present early, and pain and bleeding are common. Still, up to 40 percent of women are asymptomatic, and the diagnosis is made during routine sonographic examination (Rotas, 2006). Sonographic criteria are described in Figure 12-8 (Timor-Tritsch, 2012). Further, CSP implantation can be divided into *endogenic* and *exogenic* patterns. Endogenic CSPs implant on the scar and expand toward the uterine cavity, whereas exogenic ones implant deeply within the scar niche and grow toward the bladder or abdominal cavity. In one small study of CSPs that continued to viability, endogenic CSPs yielded variable obstetric outcomes, whereas all exogenic CSPs underwent hysterectomy with placenta accreta spectrum (PAS) at delivery (Kaelin Agten, 2017).

Sonographically, differentiating between an IUP implanted at the cervicoisthmic junction and a CSP can be difficult. Investigators in one study marked the midpoint of the uterine length (cervix to fundus) in sagittal views. If the center of the gestational sac lay distal to this midpoint, a CSP was diagnosed (Timor-Tritsch, 2016). A spontaneous expelling abortus is another mimic. Color Doppler will show the intense placental vascularity around a CSP, whereas as the aborting sac is avascular. Moreover, gentle pressure applied to the cervix by the vaginal probe will fail to move an implanted gestation—a negative sliding sign. Instead, an aborted sac will slide against the endocervical canal (Jurkovic, 2003). TVS is the typical first-line imaging tool, but MR imaging is useful for inconclusive cases.

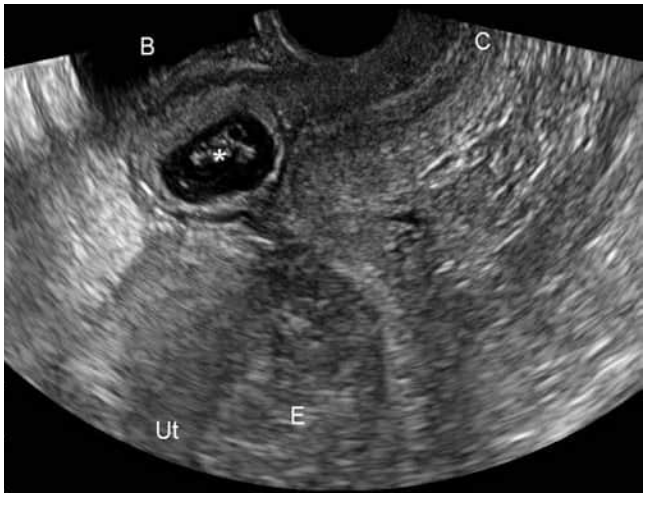

FIGURE 12-8 Transvaginal sonogram of a uterus with a cesarean scar pregnancy in a sagittal plane. Diagnostic criteria include: (1) an empty uterine cavity (*E*) and empty endocervical canal, (2) placenta or gestational sac (*asterisk*) embedded in the hysterotomy scar niche, (3) a thin myometrial mantle between the gestational sac and bladder (*B*), and (4) a prominent vascular pattern at the scar. C = cervix; Ut = anterior uterine wall.

Management

Insights into the pathogenesis of CSPs are expanding management options. Namely, growing evidence suggests that some of these pregnancies will not behave as a typical ectopic pregnancy, and rupture rates are lower. CSPs are thought by some to be a precursor of PAS (Timor-Tritsch, 2014). As such, a significant percentage of affected pregnancies will progress to a viable-aged neonate, albeit with the complications associated with PAS (Calì, 2018; Timor-Tritsch, 2015b).

Patients may prefer to avoid rupture and PAS risks and seek pregnancy termination. From one literature review, the most successful operations include: (1) laparoscopic uterine isthmic resection; (2) transvaginal isthmic resection through an anterior colpotomy, created similarly to anterior entry during vaginal hysterectomy; (3) UAE, followed by D & C with or without hysteroscopy; and (4) hysteroscopic resection (Birch Petersen, 2016; Wang, 2014). The Society for Maternal-Fetal Medicine (SMFM) (2020) considers sonography-guided vacuum aspiration alone, but not sharp curettage, to be suitable. In some instances, hysterectomy is required or may be elected in those not desiring future fertility.

Medical management is an option for those hoping to avoid surgery. However, compared with surgery, pregnancy resolution rates are more varied and lengthier. In one review, local MTX injection into the gestational sac alone provided a success rate of 60 percent, and systemic plus local MTX raised the rate to nearly 80 percent (Maheux-Lacroix, 2017). The SMFM (2020) recommends against systemic MTX alone.

With local MTX, doses of 1 mg/kg or 50-mg doses have been described. Prior to local MTX, fetal death can be induced in more advanced gestations by potassium chloride (KCL) injection into the sac (Grechukhina, 2018). One option is 1 mL of 2 mEq/mL KCL. Also, if associated bleeding complicates medical management, a Foley balloon catheter can be placed and expanded (Timor-Tritsch, 2015a). Recently, a novel double-balloon catheter, in which the balloons lie in tandem, has been used with MTX to resolve CSPs (Monteagudo, 2019). The cephalad balloon is filled within the endometrial cavity to prevent device expulsion. The lower balloon is tightly inflated to interrupt the CSP via mechanical pressure and tamponades potential bleeding.

Following conservative treatment, subsequent pregnancies have good outcomes, but PAS and recurrent CSP are risks (Gao, 2016; Wang, 2015). In one series of 30 CSPs, five subsequent pregnancies developed normally, whereas four were recurrent CSPs (Grechukhina, 2018). Uterine arteriovenous malformations are a potential long-term complication (Timor-Tritsch, 2015b).

CSPs have also been expectantly managed. The Society for Maternal–Fetal Medicine (2020) recommends against this practice. Exceptions may be early CSPs with evidence of pregnancy failure. One review of 69 patients continuing their gestation found that uterine rupture or dehiscence complicated 10 percent of all

cases (Calì, 2018). During the first or second trimester, hysterectomy was performed in 15 percent. For the 40 patients progressing to the third trimester, 17 had placenta percreta, 23 patients underwent hysterectomy, and two patients had uterine rupture or dehiscence. For all trimesters, 60 percent of cases ultimately underwent hysterectomy. More reassuringly, in early pregnancies without cardiac activity, 70 percent had uncomplicated miscarriage, whereas 30 percent required surgical or medical intervention. Of these early demises, none required hysterectomy.

Women accepting expectant care are ideally well counseled on these potential obstetric complications. If not prompted by earlier complications, repeat cesarean delivery is recommended at $34^{0/7}$ and $35^{6/7}$ weeks' gestation, and this timing recognizes the PAS and uterine rupture risks associated with CSP. Betamethasone to hasten lung maturity is recommended prior to delivery (Society for Maternal–Fetal Medicine, 2020).

CERVICAL PREGNANCY

Diagnosis

This rare ectopic pregnancy is defined first by cervical glands noted histologically opposite the placental attachment site. Second, all or part of the placenta lies at a level below the entrance of the uterine vessels or below the peritoneal reflection on the anterior uterus. Trophoblast invades the endocervix, and the pregnancy develops in the fibrous cervical wall. Risk factors include ART and prior uterine curettage (Ginsburg, 1994).

Painless vaginal bleeding is reported by 90 percent of women with a cervical pregnancy, and it can be severe (Ushakov, 1997). As pregnancy progresses, a distended, thin-walled cervix with a partially dilated external os may be evident. Above the cervical mass, a slightly enlarged uterine fundus is felt. Typical sonographic findings are shown and described in Figure 12-9. In some cases, MR imaging and 3-D TVS can aid diagnosis.

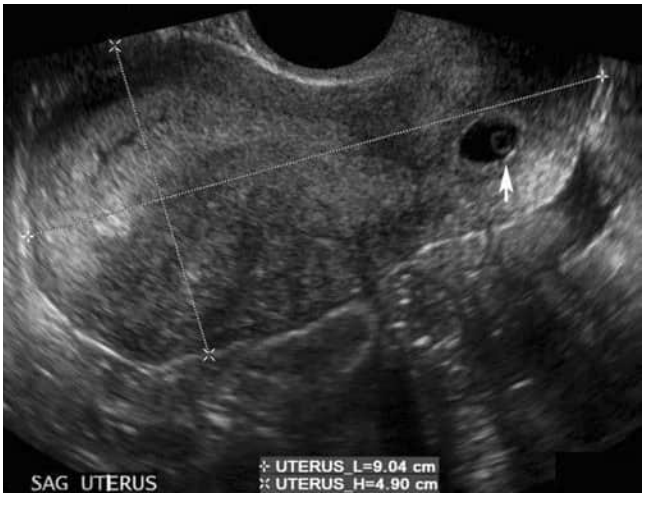

FIGURE 12-9 Cervical pregnancy. Transvaginal sonographic findings may include: (1) an hourglass uterine shape and ballooned cervix; (2) gestational tissue at the level of the cervix (*arrow*); (3) absent intrauterine gestational tissue; and (4) a portion of the endocervical canal seen interposed between the gestation and the endometrial canal. (Reproduced with permission from Dr. Angela Seasely.)

At times, cervical ectopic pregnancy can mimic a miscarriage in transit through the cervix. Similar to CSPs and described in that section, color Doppler will show the intense vascularity of cervical implantation, and gentle pressure applied to the cervix by the vaginal probe will fail to move an implanted gestation—a negative sliding sign.

Management

Cervical pregnancy may be treated medically or surgically. In many centers, including ours, MTX is first-line therapy in hemodynamically stable women. Of options, single- or multidose systemic MTX and dosing found in Table 12-1 are suitable (Murji, 2015). Alternatively, 50 mg of MTX can be injected directly into the gestational sac (Jeng, 2007; Yamaguchi, 2017). Others describe chemoembolization with MTX and UAE, as described for interstitial pregnancy (p. 228).

With MTX regimens, resolution and uterine preservation are achieved for gestations <12 weeks in 91 percent of cases (Kung, 1997). To select appropriate candidates, Hung and colleagues (1996) noted higher risks of systemic MTX treatment failure in those with a gestational age >9 weeks, β-hCG levels >10,000 mIU/mL, crown-rump length >10 mm, and fetal cardiac activity. For this reason, feticidal KCL can be injected into the fetus or gestational sac (Verma, 2009). Notably, during posttherapy surveillance, sonographic resolution lags far behind serum β-hCG level regression (Song, 2009).

Although conservative management is feasible for many women with cervical pregnancies, suction evacuation or hysterectomy may be selected. Moreover, hysterectomy may be required with bleeding uncontrolled by conservative methods (Fowler, 2021). *During hysterectomy, because of the close proximity of the ureters to the ballooned cervix, urinary tract injury rates are a concern.*

If suction evacuation of the cervix is planned, intraoperative bleeding may be lessened by preoperative UAE, by intracervical vasopressin injection, or by a cerclage placed at the internal cervical os to compress feeding vessels (Chen, 2015; Fylstra, 2014; Wang, 2011). Cervical branches of the uterine artery can effectively be ligated with vaginal placement of hemostatic cervical sutures on the lateral aspects of the cervix at 3 and 9 o'clock (Bianchi, 2011).

As an adjunct to medical or surgical therapy, UAE has been described either as a response to bleeding or as a preprocedural prevention (Hirakawa, 2009; Zakaria, 2011). Also, in the event of hemorrhage, a 26F Foley catheter with a 30-mL balloon can be placed intracervically and inflated to effect hemostasis by vessel tamponade and to monitor bloody drainage. The balloon remains inflated for 24 to 48 hours and is gradually decompressed over a few days (Ushakov, 1997).

ABDOMINAL PREGNANCY

Diagnosis

These rare ectopic pregnancies are defined as an implantation in the peritoneal cavity exclusive of tubal, ovarian, or

intraligamentous implantations. Most are thought to follow early tubal rupture or tubal abortion with reimplantation.

Clinically, symptoms may be absent or vague. Laboratory tests are typically uninformative, although maternal serum alpha-fetoprotein levels can be elevated. With later gestations, abnormal fetal positions may be palpated, or the cervix is displaced (Zeck, 2007). Sonographically, clues are a fetus or placenta seen eccentrically positioned within the pelvis or separate from the uterus; lack of myometrium between the fetus and the maternal anterior abdominal wall or bladder; or bowel loops surrounding the gestational sac (Allibone, 1981; Chukus, 2015). Oligohydramnios is common but nonspecific. Often needed, MR imaging can aid diagnosis and provide placental information.

Management

Abdominal pregnancy treatment depends on the gestational age at diagnosis. Conservative expectant management carries a maternal risk for sudden, dangerous hemorrhage. Moreover, Stevens (1993) reported fetal malformations and deformations in 20 percent. Thus, we believe that termination generally is indicated once the diagnosis is made. Certainly, before 24 weeks' gestation, conservative treatment rarely is justified. Despite this, some describe waiting until fetal viability with close surveillance (Harirah, 2016).

Principal surgical objectives are delivery of the fetus and careful assessment of placental implantation without provoking hemorrhage. Unnecessary exploration is avoided because the anatomy is commonly distorted and surrounding areas are extremely vascular. Importantly, placental removal may precipitate torrential hemorrhage because the normal hemostatic mechanism of myometrial contraction to constrict hypertrophied blood vessels is lacking. If it is obvious that the placenta can be safely removed or if the implantation site is already bleeding, then removal begins immediately. Blood vessels supplying the placenta are ideally ligated first. For early gestations, locally injected dilute vasopressin also can be employed.

Some advocate leaving the placenta in place as the lesser of two evils. It decreases the chance of immediate life-threatening hemorrhage, but at the expense of long-term sequelae. Placental embolization may play a role prior to or following fetal extraction (Frischhertz, 2019; Marcelin, 2018). If left in the abdominal cavity, the placenta can form abscesses, adhesions, intestinal or ureteral obstruction, and wound dehiscence (Bergstrom, 1998; Martin, 1988). In many of these cases, surgical removal becomes inevitable. If the placenta is left, its involution can be monitored using serum β-hCG levels and color Doppler sonography or MR imaging (France, 1980; Martin, 1990). Placental function usually declines rapidly. The placenta is eventually resorbed, but this can take months or years with advanced gestations (Valenzano, 2003).

If the placenta is left, postoperative MTX is often given to hasten involution. Accelerated placental destruction with accumulation of necrotic tissue follows (Deng, 2017). Infection with abscess formation can be a complication (Rahman, 1982). Similar to persistent trophoblastic tissue, early gestations may benefit most (Ansong, 2019).

OVARIAN PREGNANCY

Ectopic implantation of the fertilized egg in the ovary is rare and is diagnosed if four clinical criteria are met. These were outlined by Spiegelberg (1878): (1) the ipsilateral tube is intact and distinct from the ovary; (2) the ectopic pregnancy occupies the ovary; (3) the ectopic pregnancy is connected by the uteroovarian ligament to the uterus; and (4) ovarian tissue can be demonstrated histologically amid the placental tissue. Risk factors are similar to those for tubal pregnancies, but ART or IUD failure are prominent (Zhu, 2014). Presenting complaints and findings mirror those for tubal ectopic pregnancy. Although the ovary can accommodate the expanding pregnancy more easily than the fallopian tube, rupture at an early stage is the usual consequence (Melcer, 2016).

Sonographically, an internal anechoic area is surrounded by a wide echogenic ring, which in turn is surrounded by ovarian cortex (Comstock, 2005). In one review of 49 cases, the diagnosis was not be made until surgery, and many cases were presumed to be a tubal ectopic pregnancy (Choi, 2011). Moreover, at surgery, an early, unrecognized ovarian pregnancy may instead be considered and managed as a hemorrhagic corpus luteum.

Evidence-based management accrues mainly from case reports (Hassan, 2012). Classically, management for ovarian pregnancies has been surgical. Selection of laparoscopy or laparotomy are influenced by gestational age, hemoperitoneum, and hemodynamic status. Small lesions can be managed by ovarian wedge resection or cystectomy, whereas larger lesions require oophorectomy (Elwell, 2015; Melcer, 2015). With conservative surgery, β-hCG levels should be monitored to exclude remnant trophoblast.

HETEROTOPIC PREGNANCY

This pairing of an IUP and an ectopically located pregnancy is rare, and the most common dyad is an IUP and an ampullary tubal pregnancy. The natural incidence of these *heterotopic pregnancies* approximates 1 case per 30,000 pregnancies (Reece, 1983). However, with ART, their incidence is higher and is 9 cases in 10,000 pregnancies (Perkins, 2015). Initial clinical symptoms usually reflect those from the ectopic. Because an IUP is seen sonographically and the ectopic pregnancy may not be visualized, rates of rupture are higher in heterotopic pregnancy (Dendas, 2017).

In patients wishing to preserve the IUP, management initially is dictated by bleeding. In those with hemorrhage, treatment of the ectopic pregnancy is surgical. Depending on the ectopic location, resection or suction aspiration is the most common method (Wu, 2018). Of note, adjunctive UAE and vasopressin and their effects on uterine blood flow are less desirable for the ongoing IUP. With a rare comorbid ovarian ectopic pregnancy, early excision of the corpus luteum merits progesterone supplementation (Chap. 66, p. 1170).

In those without significant bleeding, medical steps to disrupt the ectopic pregnancy typically involve gestational-sac injection of KCl or of hyperosmolar glucose. This may be followed by later aspiration evacuation of the ectopic gestation. Because of toxicity to the IUP, MTX is avoided.

With ongoing pregnancy, adverse neonatal outcome rates are not appreciably elevated (Clayton, 2007). However, initial sonographic surveillance of fetal growth seems reasonable. Route of ultimate delivery is influenced mainly by myometrial integrity following ectopic treatment (Dendas, 2017; OuYang, 2014).

CHAPTER 13

Gestational Trophoblastic Disease

Gestational trophoblastic disease (GTD) is the term used to encompass a group of tumors typified by abnormal trophoblast proliferation. Trophoblast produces human chorionic gonadotropin (hCG). Thus, the measurement of this peptide hormone in serum is essential for GTD diagnosis, management, and surveillance. GTD histologically is divided into hydatidiform moles, which are characterized by the presence of villi, and nonmolar trophoblastic malignant neoplasms, which lack villi.

Hydatidiform moles are excessively edematous immature placentas (Benirschke, 2012). These include the benign *complete hydatidiform mole* and *partial hydatidiform mole* (Table 13-1). The third member is the malignant *invasive mole* (Hui, 2014b). Invasive mole is deemed malignant because of its marked penetration into and destruction of the myometrium and its ability to metastasize.

Nonmolar trophoblastic neoplasms include choriocarcinoma, placental site trophoblastic tumor, and epithelioid trophoblastic tumor (Hui, 2014a). These three are differentiated by the trophoblast type that they contain.

Under the GTD umbrella term, the malignant forms of GTD are termed *gestational trophoblastic neoplasia (GTN).* These include invasive mole, choriocarcinoma, placental site trophoblastic tumor, and epithelioid trophoblastic tumor. These malignancies develop weeks or years following any type of pregnancy, but more frequently follow hydatidiform mole.

Each GTN malignancy type is histologically distinct and varies in its propensity to invade and metastasize. However, these diagnoses are infrequently identified from an actual histological specimen. Instead, measurement of serum hCG levels and clinical findings are more often used to diagnose and treat this malignancy. Accordingly, GTN is often managed as a single composite clinical entity. With chemotherapy, most tumors currently are highly curable.

TABLE 13-1. Modified WHO Classification of GTD

Molar Pregnancies
Hydatidiform mole

HYDATIDIFORM MOLE

Classic histological findings of molar pregnancy include trophoblast proliferation and villi with stromal edema (Fig. 13-1). The degree of histological changes, karyotype and immunostaining differences, and the absence or presence of embryonic elements are used to classify them as either *complete* or *partial hydatidiform moles* (Table 13-2). These two also vary in their associated risks for developing medical comorbidities and postevacuation GTN. Of the two, GTN more frequently follows complete hydatidiform mole.

Grossly, complete moles have abnormal chorionic villi that appear as a mass of clear vesicles. These vary in size and often hang in clusters from thin pedicles. In contrast, partial molar pregnancies have focal and less advanced hydatidiform changes and contain some fetal tissue. Both forms of moles usually fill the uterine cavity, but they rarely may be ectopic (Sebire, 2005; Yamada, 2016).

TABLE 13-2. Features of Partial and Complete Hydatidiform Moles

Feature	Partial Mole	Complete Mole
Karyotype[a]	69,XXX or 69,XXY	46,XX
Clinical presentation		
Diagnosis	Missed abortion	Molar gestation
Uterine size	Small for dates	Large for dates
Theca-lutein cysts	Rare	25–30% of cases
Initial hCG levels	<100,000 mIU/mL	>100,000 mIU/mL
Medical complications[b]	Rare	Uncommon
Rate of subsequent GTN	1–5% of cases	15–20% of cases
Pathology		
Embryo-fetus	Often present	Absent
Amnion, fetal erythrocytes	Often present	Absent
Villous edema	Focal	Widespread
Trophoblastic proliferation	Focal, slight to moderate	Slight to severe
Trophoblast atypia	Mild	Marked
$p57^{KIP2}$ immunostaining	Positive	Negative

[a]Typical karyotypes.
[b]These include anemia, hyperthyroidism, hyperemesis gravidarum, preeclampsia, and infection.
GTN = gestational trophoblastic neoplasia; hCG = human chorionic gonadotropin.

Epidemiology and Risk Factors

Ethnic predisposition is seen with hydatidiform mole, and prevalences are higher in Asians, Hispanics, and American Indians (Choi, 2015; Drake, 2006). The incidence in the United States and Europe has been relatively constant at 1 per 1000 deliveries (Eysbouts, 2016; Melamed, 2016).

The strongest risk factors are age and a prior hydatidiform mole. Women at both extremes of reproductive age are most vulnerable (Savage, 2013; Sebire, 2002a). With a prior complete mole, the risk of another mole is 0.9 percent, and with a previous partial mole, the rate is 0.3 percent. After two prior complete moles, approximately 20 percent of women have a third mole (Eagles, 2015).

Pathogenesis

Molar pregnancies typically arise from chromosomally abnormal fertilizations. Complete moles most often have a diploid chromosomal composition. These usually are 46,XX and result from *androgenesis,* meaning both sets of chromosomes are paternal. The chromosomes of the ovum are either absent or inactivated. As shown in Figure 13-2A, an ovum is fertilized by a haploid sperm, which then duplicates its own chromosomes after meiosis. Less commonly, the chromosomal pattern may be 46,XY or 46,XX and due to fertilization by two sperm, that is, *dispermic fertilization* or *dispermy* (Lawler, 1991; Ohama, 1981).

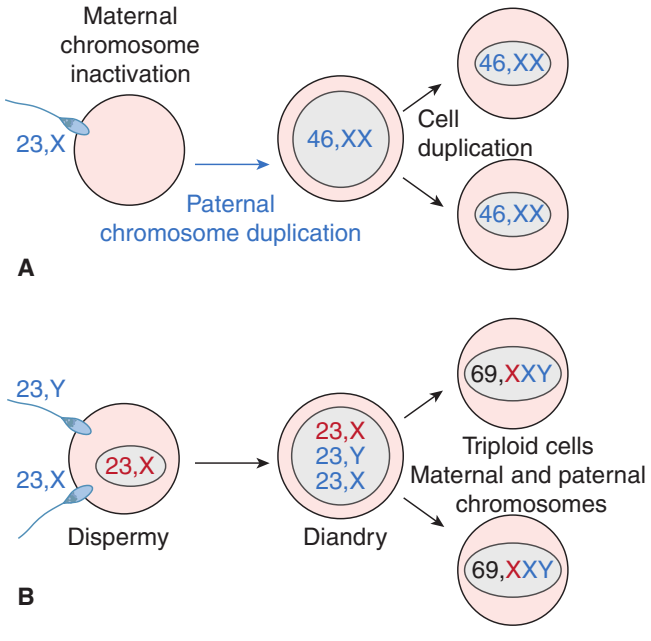

FIGURE 13-2 Typical pathogenesis of complete and partial moles. **A.** A 46,XX complete mole may be formed if a 23,X-bearing haploid sperm penetrates a 23,X-containing haploid egg whose genes have been "inactivated." Paternal chromosomes then duplicate to create a 46,XX diploid complement solely of paternal origin. **B.** A partial mole may be formed if two sperm—either 23,X- or 23,Y-bearing—both fertilize (*dispermy*) a 23,X-containing haploid egg whose genes have not been inactivated. The resulting fertilized egg is triploid with two chromosome sets being donated by the father (*diandry*).

Partial moles have a triploid karyotype, which is 69,XXX, 69,XXY, or much less commonly, 69,XYY. These are each composed of two paternal haploid sets of chromosomes contributed by dispermy and one maternal haploid set (see Fig. 13-2B). Less frequently, a similar haploid egg may be fertilized by an unreduced diploid 46,XY sperm. These triploid zygotes result in some embryonic development, however, it ultimately is a lethal fetal condition (Joergensen, 2014; Lakovschek, 2011). Fetuses that reach advanced ages have severe growth restriction, multiple congenital anomalies, or both.

Twin Pregnancy

Rarely, in some twin pregnancies, one chromosomally normal fetus is paired with a complete diploid molar pregnancy. Importantly, these cases must be distinguished from a single partial molar pregnancy with its associated abnormal fetus. Other potential diagnoses include placental mesenchymal dysplasia, subchorionic hematoma, or chorioangioma (Chap. 6, p. 112) (Cavoretto, 2020). To help distinguish among these, chorionic villus sampling, amniocentesis, or fetal cord blood sampling coupled with fetal karyotyping aid confirmation (Lee, 2010).

Several unique pregnancy problems complicate such twin pregnancies. Thyrotoxicosis is common, but the most worrisome are preeclampsia or hemorrhage. These frequently necessitate preterm delivery. Thus, many women may choose to terminate the gestation, if diagnosed early. In those with continuing pregnancy, survival of the normal fetus varies and depends on associated comorbidity from the molar component. Wee and Jauniaux (2005) reviewed outcomes in 174 women, of whom 82 chose termination. Of the remaining 92 pregnancies, 42 percent either miscarried or had a perinatal death; approximately 60 percent delivered preterm; and 40 percent delivered at term.

Another concern for those continuing their pregnancy is the risk for developing subsequent GTN. Most evidence indicates no significant difference between women who continue or terminate their pregnancy (Lin, 2017; Sebire 2002b).

Clinical Findings

Molar pregnancy is diagnosed sooner than in the past because prenatal care is sought much earlier and sonography is virtually universal. For example, in 194 women with a complete mole, evacuation was completed at a median gestational age of 9 weeks and at 12 weeks for 172 patients with a partial mole (Sun, 2015). As a result, most molar pregnancies are treated before complications ensue.

Typically, 1 to 2 months of amenorrhea precede the diagnosis. As gestation advances, symptoms tend to be more pronounced with complete compared with partial moles (Niemann, 2007). Untreated molar pregnancies will almost always cause uterine bleeding that varies from spotting to profuse hemorrhage. Bleeding may presage spontaneous molar abortion, but more often, it follows an intermittent course for weeks to months.

In more advanced moles with considerable concealed uterine hemorrhage, moderate iron-deficiency anemia develops. Nausea and vomiting also may be significant. Of physical findings, many women have uterine growth exceeding that expected, and the enlarged uterus is comparatively softer. Fetal heart motion is absent with complete moles. The ovaries can be fuller and cystic

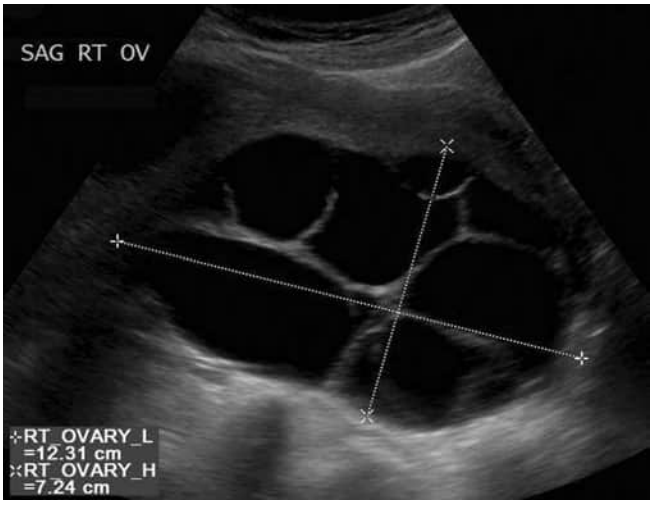

FIGURE 13-3 Sonogram of an ovary with multiple theca-lutein cysts in a woman with a complete hydatidiform mole.

from multiple theca-lutein cysts (Fig. 13-3). These are more common with a complete mole and likely result from ovarian overstimulation by excessive hCG levels. Remember that hCG and luteinizing hormone share the same receptor, and both can stimulate the theca layer that surrounds follicles. Because theca-lutein cysts regress following pregnancy evacuation and subsequent hCG level decline, expectant management is preferred. Occasionally, a larger cyst may undergo torsion, infarction, and hemorrhage. However, oophorectomy is not performed unless extensive infarction persists after untwisting.

The thyrotropin-like effects of hCG frequently cause serum free thyroxine (fT_4) levels to be elevated and thyroid-stimulating hormone (TSH) levels to be decreased (Chap. 61, p. 1089). Despite this, clinically apparent thyrotoxicosis is unusual and in our experience can be mimicked by bleeding and sepsis from infected products. Moreover, the serum free T_4 levels rapidly normalize after uterine evacuation. Despite this, cases of presumed "thyroid storm" have been reported (Kofinas, 2015).

Severe preeclampsia and eclampsia are relatively common with advanced molar pregnancies. However, these are seldom seen today because of early diagnosis and evacuation. An exception is the case of a normal fetus coexisting with a complete mole, described earlier. In continuing twin gestations, severe preeclampsia frequently mandates preterm delivery.

Diagnosis

Serum β-HCG Measurements

Most women initially have irregular bleeding that almost always prompts pregnancy testing and sonography. Less often, women will spontaneously pass molar tissue.

With a complete molar pregnancy, serum β-hCG levels are commonly elevated above those expected for gestational age. With more advanced moles, values in the millions are not unusual. Importantly, these high values can lead to erroneous false-negative *urine* pregnancy test results. Termed a *hook effect*, excessive β-hCG hormone levels oversaturate the assay's targeting antibody and create a false-negative reading (Cormano, 2016). In these cases, *serum* β-hCG determinations with or without sample dilution will yield a positive result. With a partial mole, β-hCG levels may also be significantly elevated, but more commonly concentrations are in ranges expected for gestational age.

Sonography

Although this is the mainstay of trophoblastic disease diagnosis, not all cases are confirmed initially. In a large series of more than 1000 patients with molar pregnancy, sonography's sensitivity was 44 percent, and its specificity was 74 percent (Fowler, 2006). With grayscale sonography, a complete mole appears as an echogenic uterine mass filling the endometrial cavity and is surrounded by normal myometrium. The mass is composed of numerous anechoic cystic spaces of different sizes and shapes, but without a fetus or amnionic sac. The appearance is often described as a "snowstorm" (Fig. 13-4). Application of color Doppler displays marked surrounding myometrial vascularity.

FIGURE 13-4 Sonograms of hydatidiform moles. **A.** Transverse view of a uterus with a complete hydatidiform mole. The characteristic "snowstorm" appearance reflects an echogenic uterine mass, marked by calipers, that has numerous anechoic cystic spaces. Notably, a fetus or amnionic sac is absent. **B.** In this sagittal image of a partial hydatidiform mole, the fetal head (*arrow*) lies adjacent to an enlarged, multicystic placenta.

However, absent internal flow reflects the avascular villi of complete moles.

A partial mole has features that include a thick, multicystic placenta plus a fetus or fetal tissue. Thin septa can be found within the gestational sac (Savage, 2017). Affected fetuses usually die in the first trimester. Those advancing further often show growth restriction, oligohydramnios, and limb or CNS defects (Cavoretto, 2020).

In early pregnancy, however, these sonographic characteristics are seen in fewer than half of hydatidiform moles. At earlier gestations, a complete mole may appear as a polypoid hyperechoic mass that lacks internal cysts and is surrounded by anechoic fluid (Jauniaux, 2018).

The most common mimics are incomplete or missed abortion. In these cases, histological evaluation, described next, ultimately is diagnostic. Occasionally, molar pregnancy may be confused for a multifetal pregnancy or a uterine leiomyoma with cystic degeneration.

Pathology

Because of the risk for subsequent GTN following molar pregnancy, postevacuation surveillance is indicated. Thus, moles must be distinguished from other pregnancy types that are not molar but that have hydropic placental degeneration. Most often, these are hydropic abortuses formed by the traditional union of one haploid egg and one haploid sperm but are pregnancies that have failed. Their placentas display hydropic degeneration, in which villi are edematous and swollen, and thus mimic some villous features of hydatidiform moles. These mimics do not require postevacuation surveillance. Some distinguishing histological characteristics are shown in Table 13-2.

In pregnancies before 10 weeks, classic molar histological changes may not be apparent. Villi may not be enlarged, and molar stroma may not yet be edematous and avascular. Histopathologic evaluation can be enhanced by immunohistochemical staining for p57 expression and by molecular genotyping (Banet, 2014). $p57^{KIP2}$ is a nuclear protein whose gene is paternally imprinted and maternally expressed. This means that the gene product is produced only in tissues containing a maternal allele. Because complete moles contain only paternal genes, the $p57^{KIP2}$ protein is absent in complete moles, and tissues do not pick up this stain (Merchant, 2005). In contrast, this nuclear protein is strongly expressed in normal placentas, in spontaneous pregnancy losses with hydropic degeneration, and in partial hydatidiform moles (Castrillon, 2001). Accordingly, immunostaining for $p57^{KIP2}$ is an effective means to isolate complete mole from the diagnostic list. For distinction of a partial mole from a nonmolar hydropic abortus, both of which express $p57^{KIP2}$, molecular genotyping can be used (Ronnett, 2018). Molecular genotyping determines the parental source of alleles. Thereby, it can distinguish among a diploid diandric genome (complete mole), a triploid diandric-monogynic genome (partial mole), or biparental diploidy (nonmolar abortus) (Xing, 2021).

■ Management

Maternal deaths from molar pregnancies are rare because of early diagnosis, timely evacuation, and vigilant postevacuation surveillance for GTN (Sun, 2016). Preoperative evaluation strives to identify potential complications, such as preeclampsia, hyperthyroidism, anemia, electrolyte depletions from hyperemesis, and metastatic disease (Table 13-3). Most recommend chest radiography, whereas computed tomography (CT) and magnetic resonance (MR) imaging are not routinely done unless a chest radiograph shows lung lesions or unless other extrauterine disease is suspected.

Molar Pregnancy Termination

Regardless of uterine size, molar evacuation by suction curettage usually is the preferred treatment. Preoperative cervical dilation with an osmotic dilator is recommended if the cervix is minimally dilated. Intraoperative bleeding can be greater with molar pregnancy than with a comparably sized uterus containing nonmolar products. Thus with large moles, adequate anesthesia, sufficient intravenous access, and blood-banking support is imperative.

A step by step description of dilation and curettage is found in Chapter 11 (p. 213). For molar evacuation, the cervix is mechanically dilated to preferably allow insertion of a large Karman suction cannula. Depending on uterine size, a 10- to 14-mm diameter is typical. As evacuation is begun, oxytocin is infused to limit bleeding. Intraoperative sonography is often recommended to help ensure complete uterine cavity emptying and minimize perforation risk. When the myometrium has contracted, a thorough but gentle curettage with a sharp large-loop Sims curette may be performed. If bleeding continues despite uterine evacuation and oxytocin infusion, other uterotonic agents are given (see Table 13-3). Uncommonly, pelvic arterial embolization, uterine packing, or hysterectomy may be necessary (Chap. 44, p. 779) (Tse, 2007).

Some volume of trophoblast is deported into the pelvic venous system during molar evacuation (Hankins, 1987). With large moles, the amount of tissue may be sufficient to produce clinically apparent respiratory insufficiency, pulmonary edema, or even embolism (Delmis, 2000). In our earlier experiences with substantial moles, these and their chest radiographic manifestations clear rapidly without specific treatment.

Following curettage, anti-D immunoglobulin (Rhogam) is given to Rh D-negative women because fetal tissues with a partial mole may include red cells with D-antigen (Chap. 18, p. 356). Those with suspected complete mole are similarly treated because a definitive diagnosis of complete versus partial mole may not be confirmed until histological evaluation of the evacuated products.

Following evacuation, the long-term prognosis for women with a hydatidiform mole is not improved with prophylactic chemotherapy. Moreover, chemotherapy toxicity can be significant, and thus it is not recommended routinely (Gueye, 2014; Wang, 2017).

Methods other than suction curettage can be considered for select cases. Hysterectomy with ovarian preservation may be preferable for women who have finished childbearing and who carry complete moles with high-risk features. Of women aged 40 to 49 years, up to 50 percent will subsequently develop GTN, and hysterectomy markedly reduces this likelihood (Elias, 2012; Zhao, 2019). During hysterectomy, theca-lutein cysts do not require removal, and they spontaneously regress following molar termination. Last, labor induction or hysterotomy is seldom

TABLE 13-3. Some Considerations for Management of Hydatidiform Mole

Preoperative
Laboratory
Hemogram; serum β-hCG, creatinine, and hepatic aminotransferase levels
TSH, free T_4 levels
Type and Rh; group & screen or crossmatch depending on uterine size
Chest radiograph
Consider hygroscopic dilators
Intraoperative
Large-bore intravenous catheter(s)
Regional or general anesthesia
Oxytocin (Pitocin): 20 units in 1000 mL Ringer lactate for continuous infusion
One or more other uterotonic agents may be added as needed:
Methylergonovine (Methergine): 0.2 mg = 1 mL = 1 ampule IM every 2 h prn
Carboprost tromethamine ($PGF_{2\alpha}$) (Hemabate): 250 μg = 1 mL = 1 ampule IM every 15–90 min prn
Misoprostol (PGE_1) (Cytotec): 200 mg tablets for rectal administration, 800–1000 mg once
Karman cannula: size 10 or 14 mm
Consider sonography machine
Postevacuation
Anti-D immune globulin (Rhogam) if Rh D-negative
Initiate effective contraception[a]
Review pathology report
Serum hCG levels: within 48 h of evacuation, weekly until undetectable, then monthly for 6 months

[a]Intrauterine devices are not suitable during surveillance.
hCG = human chorionic gonadotropin; IM = intramuscular; PG = prostaglandin; T_4 = thyroxine; TSH = thyroid-stimulating hormone.

used for molar evacuation in the United States. Both will likely increase blood loss and theoretically may raise the incidence of persistent trophoblastic disease (Tidy, 2000).

Postevacuation Surveillance

Close biochemical surveillance for persistent gestational neoplasia follows each hydatidiform mole evacuation. Serial measurement of serum β-hCG levels aim to detect persistent or renewed trophoblastic proliferation. As a glycoprotein, hCG shows structural heterogeneity and exists in different isoforms. Thus, for surveillance, an hCG assay that can detect all forms of hCG should be used (Harvey, 2010; Ngan, 2018). These are different from those used for routine pregnancy testing (de Medeiros, 2009). The initial β-hCG level is obtained within 48 hours after evacuation. This serves as the baseline, which is compared with β-hCG quantification done thereafter every 1 to 2 weeks. Levels are followed until they become undetectable.

The median time for such resolution is 6 weeks for partial moles and 7 weeks for complete moles. Of patients, 95 percent have normal β-hCG levels by 14 weeks postevacuation and 99 percent by 25 weeks (Eysbouts, 2017a). Once β-hCG is undetectable, this is confirmed with monthly determinations for another 6 months (Lurain, 2010; Sebire, 2007).

Concurrently, reliable contraception is imperative to avoid confusion caused by rising β-hCG levels from a new pregnancy. Most recommend combination hormonal contraception, injectable depot medroxyprogesterone acetate, or progestin implant. The latter two are particularly useful if poor patient compliance is anticipated. Intrauterine devices are not used until β-hCG levels are undetectable because of the risk of uterine perforation if an invasive mole is present. After these 6 months, monitoring is discontinued and pregnancy allowed. Although not recommended, if a woman conceives during surveillance, live-birth and congenital anomalies rates appear to mirror general population rates (Tuncer, 1999b).

During β-hCG levels surveillance, increasing or persistently plateaued levels mandate evaluation for GTN. If the woman has not become pregnant, these levels signify trophoblast proliferation that is most likely malignant. Several factors predispose a patient to GTN following molar evacuation. Complete moles have a 15 to 20 percent incidence of malignant sequelae, compared with 1 to 5 percent following partial moles. Surprisingly, with much earlier recognition and evacuation of molar pregnancies, the risk for GTN has not dropped (Sun, 2015). Other GTN risk factors are older maternal age, preevacuation β-hCG levels >100,000 mIU/mL, uterine size that is large-for-gestational age, theca-lutein cysts >6 cm, and a slow decline in β-hCG levels (Berkowitz, 2009; Kang, 2012; Wolfberg, 2005).

GESTATIONAL TROPHOBLASTIC NEOPLASIA

This group includes invasive mole, choriocarcinoma, placental site trophoblastic tumor, and epithelioid trophoblastic tumor. These tumors almost always develop with or after some form

TABLE 13-4. Criteria for Diagnosis of Gestational Trophoblastic Neoplasia

1. Plateau of β-hCG level (± 10 percent) for four measurements during a period of 3 weeks or longer—days 1, 7, 14, 21
2. Rise of serum β-hCG level >10 percent during three weekly consecutive measurements or longer, during a period of 2 weeks or more—days 1, 7, 14
3. Serum β-hCG level remains detectable for 6 months or more
4. Histological criteria for choriocarcinoma

of recognized pregnancy. Half follow hydatidiform mole, a fourth follow miscarriage or tubal pregnancy, and another fourth develop after a preterm or term pregnancy (Goldstein, 2012). These four tumor types are histologically distinct but are usually diagnosed solely by persistently elevated serum β-hCG levels because tissue is infrequently available for study. Criteria to diagnose postmolar GTN are shown in Table 13-4.

Diagnosis, Staging, and Prognostic Scoring

Clinically, these placental tumors are characterized by their aggressive invasion into the myometrium and propensity to metastasize. The most common finding with GTN is irregular bleeding associated with uterine subinvolution. The bleeding may be continuous or intermittent and sometimes may be sudden and massive. Myometrial perforation from trophoblastic growth can cause intraperitoneal hemorrhage. In some women, lower genital tract metastases are evident. In others, only distant metastases, with no trace of uterine tumor, are found.

Consideration for the possibility of GTN is the most important factor in its recognition. Unusually persistent bleeding after any type of pregnancy should prompt serum β-hCG level measurement. Uterine size is assessed, and careful examination seeks lower genital tract metastases, which usually are bluish vascular masses (Cagayan, 2010). Tissue biopsy of such masses is unnecessary and may cause significant bleeding.

Once the diagnosis is verified, a baseline serum β-hCG level and hemogram are obtained. A search for local disease and metastases includes tests of liver and renal function, transvaginal sonography, chest CT or radiography, and brain and abdominopelvic CT scan or MR imaging. Less often, positron-emission tomographic (PET) scanning and cerebrospinal fluid β-hCG level determination are used to identify metastases (Lurain, 2011).

If no extrauterine disease is found, a second curettage or hysterectomy may be considered. After either, β-hCG levels are then measured every 2 weeks until three consecutively lie in undetectable range. Levels are subsequently repeated monthly for 6 months. In contrast, if β-hCG levels persist after curettage or hysterectomy or if initial extrauterine disease is found, patients undergo staging and chemotherapy is instituted (Koh, 2018; Osborne, 2016).

GTN is staged clinically using the system of the International Federation of Gynecology and Obstetrics (FIGO) (2009). This includes a modification of the World Health Organization (WHO) (1983) prognostic index score, with which scores of 0 to 4 are given for each of the categories shown in Table 13-5. Women with WHO scores of 0 to 6 are considered to have

TABLE 13-5. International Federation of Gynecology and Obstetrics (FIGO) Staging and Diagnostic Scoring System for Gestational Trophoblastic Neoplasia

Anatomical Staging	
Stage I	Disease confined to the uterus
Stage II	GTN extends outside of the uterus but is limited to the genital structures (adnexa, vagina, broad ligament)
Stage III	GTN extends to the lungs, with or without known genital tract involvement
Stage IV	All other metastatic sites

Modified World Health Organization (WHO) Prognostic Scoring System[a]

Scores[b]	0	1	2	4
Age (years)	<40	≥40	—	—
Antecedent pregnancy	Mole	Abortion	Term	—
Interval after index pregnancy (mo)	<4	4–6	7–12	>12
Pretreatment serum β-hCG (mIU/mL)	$<10^3$	10^3 to 10^4	10^4 to 10^5	$\geq 10^5$
Largest tumor size (including uterus)	<3 cm	3–4 cm	≥5 cm	—
Site of metastases		Spleen, kidney	GI	Liver, brain
Number of metastases	—	1–4	5–8	>8
Previous failed chemotherapy drugs	—	—	1	≥2

[a]Adapted by FIGO.
[b]Low risk = WHO score of 0 to 6; high risk = WHO score of ≥7.
β-hCG = beta human chorionic gonadotropin; GI = gastrointestinal; GTN = gestational trophoblastic neoplasia.

low-risk disease, whereas those with scores ≥7 are considered in the high-risk group.

Histological Classification

Clinical staging is assigned without regard to histological findings, even if available. Still, distinct histological types are recognized.

Invasive Mole

These are a common trophoblastic neoplasm, and almost all invasive moles arise from partial or complete moles. Previously known as *chorioadenoma destruens*, invasive mole is characterized by extensive tissue invasion by trophoblast and whole villi. Trophoblastic cells penetrate deep into the myometrium and sometimes involve the peritoneum, adjacent parametrium, or vaginal vault. Although locally aggressive, invasive moles are less prone to metastasize.

Gestational Choriocarcinoma

This is the most common trophoblastic neoplasm to follow a term pregnancy or a miscarriage, and only a fourth of cases follow a molar gestation (Soper, 2021). Choriocarcinoma is composed of cells reminiscent of early cytotrophoblast and syncytiotrophoblast, however, it contains no villi. This rapidly growing tumor invades both myometrium and blood vessels to create hemorrhage and necrosis. Myometrial tumor may spread outward and become visible on the uterine surface as dark, irregular nodules. Metastases often develop early and are generally blood-borne. The most common sites are the lungs and vagina, but tumor may travel to the vulva, kidneys, liver, brain, ovaries, and bowel. With choriocarcinomas, ovarian theca-lutein cysts commonly coexist.

Placental Site Trophoblastic Tumor

This uncommon tumor arises from *intermediate trophoblasts* at the placental site. These tumors have associated serum β-hCG levels that may be only modestly elevated (Gadducci, 2019). However, they produce variant forms of hCG, and identifying a high proportion of free β-hCG favors this diagnosis (Horowitz, 2017). Treatment of placental site trophoblastic tumor by hysterectomy is preferred because these locally invasive tumors are usually resistant to chemotherapy. For higher-risk stage I and for later stages, adjuvant multidrug chemotherapy also is given (Koh, 2018; Schmid, 2009).

Epithelioid Trophoblastic Tumor

This rare tumor develops from *chorionic-type intermediate trophoblast*. The uterus is mainly involved, and bleeding but low hCG levels are typical findings (Gadducci, 2019). Primary treatment is hysterectomy because this tumor is relatively resistant to chemotherapy. Metastatic disease is common, and combination chemotherapy is employed (Frijstein, 2019; Koh, 2018).

Treatment

Women with GTN are best managed by oncologists, and some evidence supports treatment in centers specializing in GTN (Kohorn, 2014). Chemotherapy alone is usually the primary treatment. In some GTN cases without extrauterine disease, a second uterine evacuation may be an adjuvant therapeutic option to avoid or minimize chemotherapy (Hemida, 2019; Koh, 2018; Pezeshki, 2004). In other cases, suction curettage may infrequently be needed to resolve bleeding or remove a substantial amount of retained molar tissue. In specific cases, hysterectomy may be primary or adjuvant treatment (Bolze, 2018; Eysbouts, 2017b).

Single-agent chemotherapy protocols are usually sufficient for nonmetastatic or low-risk metastatic neoplasia (Lawrie, 2016; Koh, 2018). In their review of 108 women with low-risk disease, Abrão and colleagues (2008) reported that monotherapy protocols with either methotrexate or actinomycin D were equally effective compared with a regimen containing both. In general, methotrexate is less toxic than actinomycin D (Chan, 2006; Seckl, 2010). Regimens are repeated until serum β-hCG levels are undetectable.

Combination chemotherapy is given for high-risk disease, and reported cure rates approximate 90 percent (Lurain, 2011). Several regimens are successful. One is *EMA-CO,* which includes etoposide, methotrexate, actinomycin D, cyclophosphamide, and vincristine (Oncovin). In selected cases, adjuvant surgical and radiotherapy also may be employed (Hanna, 2010). Despite chemotherapy successes in general, frequent causes of death include hemorrhage from metastatic sites, respiratory failure, sepsis, and multiorgan failure due to widespread chemoresistant disease (Lybol, 2012; Neubauer, 2015).

With either low- or high-risk disease, once serum β-hCG levels are undetectable, serosurveillance is continued for 1 year. During this time, effective contraception is crucial to avoid teratogenic effects of chemotherapy to the fetus and to mitigate confusion from rising β-hCG levels caused by superimposed pregnancy.

A few women during surveillance, despite no evidence of metastases, will be found to have very low β-hCG levels that plateau. This phenomenon is called *quiescent hCG* and presumably stems from dormant trophoblast. Close observation without therapy is recommended, but 20 percent will eventually have recurrent active and progressive GTN (Ngu, 2014).

SUBSEQUENT PREGNANCY

Women with prior hydatidiform mole generally do not have impaired fertility, and their pregnancy outcomes are usually normal (Joneborg, 2014; Matsui, 2001; Sebire, 2003). One concern is the 1-percent risk for developing trophoblastic disease in a subsequent pregnancy (p. 237). Sonographic evaluation is recommended in early pregnancy, and subsequently as needed.

Women with GTN who have successfully completed chemotherapy are advised to delay pregnancy for 1 year. Most relapses develop within this time period (Tranoulis, 2019). Also, methotrexate may persist in human tissues for months (Hackmon, 2011). Despite this, women who become pregnant within 1 year postchemotherapy for GTN can be reassured of a likely favorable outcome (Woolas, 1998). Risk of miscarriage or GTN relapse is not increased compared with women conceiving after the suggested 1-year surveillance (Williams, 2014). However, these gravidas are advised that the diagnosis

of a tumor relapse may be delayed during pregnancy (Blagden, 2002; Tuncer, 1999a).

In general, fertility and pregnancy outcomes following GTN treatment are typically normal, and congenital anomaly rates are not increased (Berkowitz, 2000; Tse, 2012). One exception is a higher stillbirth rate of 1.5 percent compared with a background rate of 0.8 percent (Vargas, 2014).

For those with prior hydatidiform mole or GTN treatment, the placenta or products of conception in a subsequent pregnancy are sent for pathological evaluation at delivery. A serum β-hCG level also is measured 6 weeks postpartum (Lurain, 2010; Royal College of Obstetricians and Gynaecologists, 2010). This assay may be less valuable for those solely with a prior mole compared with those previously treated for GTN (Earp, 2019).

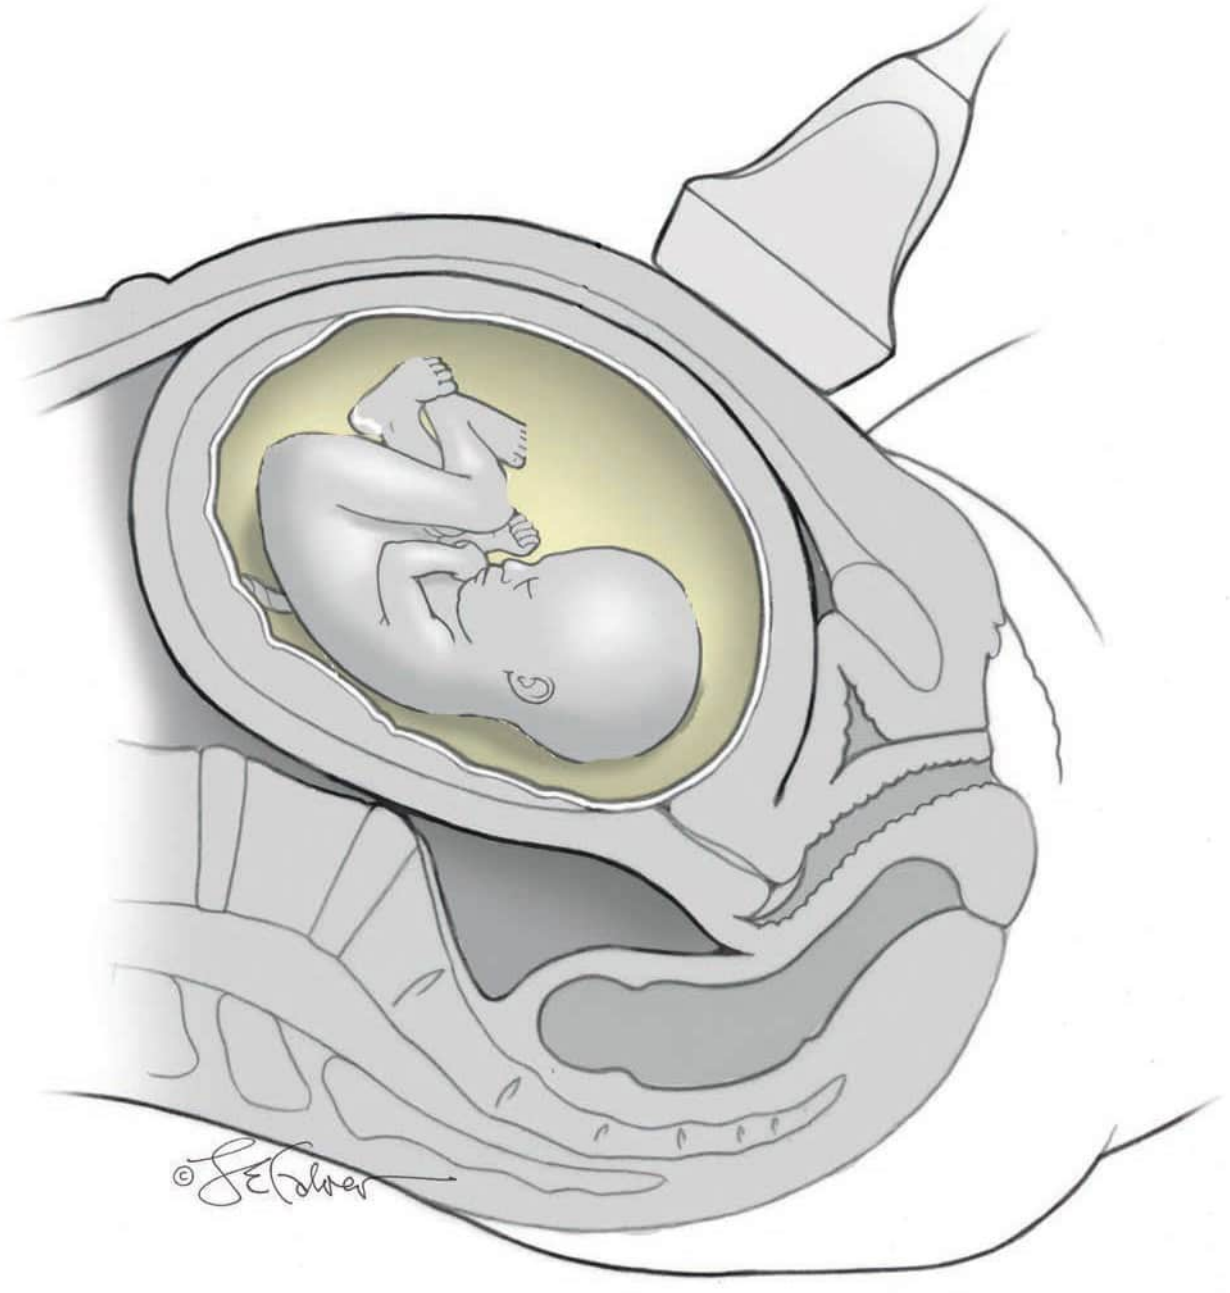
SECTION 6

THE FETAL PATIENT



CHAPTER 14

Obstetrical Imaging

Obstetrical ultrasound is fundamental to prenatal care. It is used to confirm gestational age and viability; to detect and characterize abnormalities of the fetus, amnionic fluid, and placenta; and to assist with diagnostic and therapeutic procedures.

Ultrasound practice continues to evolve. The number of components included in the second-trimester standard and detailed fetal anatomical surveys has expanded. With improved image resolution, fetal abnormalities are increasingly identified in the late first trimester. This has prompted the requirement for a limited anatomical survey during the standard first-trimester examination and has led to the development of a new detailed first-trimester examination. Detailed placental evaluation is a new specialized examination to aid detection and characterization of placenta accreta spectrum.

Across the United States, pregnant women receive ultrasound examinations in various practice settings staffed by obstetrician–gynecologists, maternal–fetal medicine specialists, and radiologists. Ideally, examinations are performed by registered diagnostic medical sonographers or physicians with certification in their area(s) of practice and in units accredited by the American Institute of Ultrasound in Medicine (AIUM) or American College of Radiology. Components of accreditation include evidence of physician training, sonographer credentialing, continuing medical education, and protocols and procedures to ensure proper and safe ultrasound practice. One important component is independent review of submitted images.

To standardize ultrasound education for residents in obstetrics and gynecology and fellows in maternal-fetal medicine, the American College of Obstetricians and Gynecologists, the Society for Maternal-Fetal Medicine, and the AIUM have developed consensus documents (Abuhamad, 2018; Benacerraf, 2018). A focus of training—and of ultrasound practice—is standardization of an ultrasound curriculum and provision of competency assessment tools for image acquisition.

TECHNOLOGY AND SAFETY

The image on the ultrasound screen is produced by sound waves that are reflected back from fluid and tissue interfaces of the fetus, amnionic fluid, and placenta. Ultrasound transducers contain groups of piezoelectric crystals that convert electrical energy into sound waves and convert returning sound waves back into electrical energy. The sound waves are emitted in synchronized pulses. As these pulses pass through tissue layers, dense tissue such as bone produces high-velocity reflected waves. With routine gray-scale imaging, which is also known as brightness-mode (B-mode), these reflected waves are displayed as bright echoes on the screen. Conversely, fluid generates few reflected waves and appears dark. Digital images generated at

50 to more than 100 frames per second undergo postprocessing that yields the appearance of real-time imaging.

Ultrasound refers to sound waves traveling at a frequency above 20,000 hertz (Hz [cycles per second]). Transducers use wide-bandwidth technology to perform within a range of frequencies. Higher-frequency transducers yield better image resolution, whereas lower frequencies penetrate tissue more effectively. In early pregnancy, a 5- to 12-megahertz (MHz) transvaginal transducer usually provides excellent resolution, because the early fetus lies close to the transducer. In the first and second trimesters, a 4- to 6-MHz transabdominal transducer is similarly sufficiently close to the fetus to yield precise images. By the third trimester, however, a lower-frequency 2- to 5-MHz transducer may be needed for tissue penetration—particularly in obese patients—and this can lead to compromised image resolution.

Embryo and Fetal Safety

Sonography should be performed only for a valid medical indication and use the lowest possible exposure setting to gain necessary information. This is the *ALARA* principle—as low as reasonably achievable. Examinations are performed only by those trained to recognize fetal abnormalities and artifacts that may mimic pathology and with techniques to avoid ultrasound exposure beyond what is considered safe for the fetus (American College of Obstetricians and Gynecologists, 2020; American Institute of Ultrasound in Medicine, 2018a). No causal relationship has been demonstrated between diagnostic ultrasound and any recognized adverse effect in human pregnancy. The International Society of Ultrasound in Obstetrics and Gynecology (2016) further concludes that there is no scientifically proven association between ultrasound exposure in the first or second trimesters and autism spectrum disorder or its severity.

All ultrasound machines are required to display two indices: the *thermal index* and the *mechanical index*. The thermal index measures the relative probability that the examination may raise the temperature enough to induce injury. However, fetal damage resulting from commercially available ultrasound equipment in routine practice is extremely unlikely. The potential for temperature elevation is higher with longer examination time and is greater near bone than in soft tissue. Theoretical risks are higher during organogenesis than later in gestation. The thermal index for soft tissue, *Tis*, should be used before 10 weeks' gestation, and that for bone, *Tib*, at or beyond 10 weeks (American Institute of Ultrasound in Medicine, 2018a).

The thermal index is higher with pulsed Doppler applications than with routine B-mode scanning. In the first trimester, if pulsed Doppler is clinically indicated, the thermal index should be ≤ 0.7, and the exposure time should be as brief as possible (American Institute of Ultrasound in Medicine, 2020b). This is an important consideration when pulsed Doppler is applied to assist with identification or characterization of suspected abnormalities at 11 to 14 weeks' gestation. To document the embryonic or fetal heart rate, motion-mode (M-mode) scanning is used instead of pulsed Doppler imaging.

The mechanical index is a measure of the likelihood of adverse effects related to rarefactional pressure, such as cavitation, which is relevant only in tissues that contain air. Microbubble ultrasound contrast agents are not used in pregnancy for this reason. In mammalian tissues that do not contain gas bodies, no adverse effects have been reported over the range of diagnostically relevant exposures. Fetuses cannot contain gas bodies and thus are not considered at risk.

The use of ultrasound for any nonmedical purpose, such as "keepsake fetal imaging," is considered *contrary to responsible medical practice* and is not condoned by the Food and Drug Administration (FDA) (2019), the American Institute of Ultrasound in Medicine (2020b), or the American College of Obstetricians and Gynecologists (2020b). However, images or video clips from medically indicated ultrasound examinations may be shared with patients.

Operator Safety

The reported prevalence of work-related musculoskeletal discomfort or injury among sonographers approximates 70 percent (Janga, 2012; Roll, 2012). The most common injuries are capsulitis and tendonitis of the shoulder, epicondylitis of the elbow, carpal and cubital tunnel syndrome, and neck or back strain (Murphey, 2018). The main risk factors for injury during transabdominal ultrasound examinations are awkward posture, sustained static forces, and various pinch grips used to maneuver the transducer (Centers for Disease Control and Prevention, 2006). Excessive flexion, extension, or abduction while scanning places stress on joints and muscles. Task repetition without adequate recovery time may compound risks. Maternal habitus can be contributory because more force is often needed when imaging obese patients.

The following guidelines may help avert injury:

1. Position the patient close to you on the examination table. As a result, your elbow is close to your body, shoulder abduction is <30 degrees, and your thumb is facing up.
2. Adjust the table or chair height so that your forearm is parallel to the floor.
3. Use a chair with back support, if seated. Avoid leaning toward the patient or monitor. Support your feet, and keep ankles in neutral position.
4. Face the monitor squarely and position it so that it is viewed at a neutral angle from the horizon, such as 15 degrees downward.
5. Avoid reaching, bending, or twisting while scanning.
6. Take frequent breaks to help prevent muscle strain. Stretching and strengthening exercises can be helpful.

GESTATIONAL AGE ASSESSMENT

Gestational age is based on two things: the certainty of the woman's last menstrual period (LMP) date and measurements of the embryo or fetus at the initial ultrasound examination. Gestational sac measurement is not suitable for gestational age assignment. If the LMP is certain, the estimated due date (EDD) is based on LMP unless the date–measurement discrepancy exceeds thresholds listed in Table 14-1 (American College of Obstetricians and Gynecologists, 2019b,c). If the

TABLE 14-1. Assessment of Gestational Age

Gestational Age[a]	Parameter(s)	Threshold Value to Redate[b]
<9 wks	CRL	>5 d
9 to <14 wks	CRL	>7 d
14 to <16 wks	BPD, HC, AC, FL	>7 d
16 to <22 wks	BPD, HC, AC, FL	>10 d
22 to <28 wks	BPD, HC, AC, FL	>14 d
≥28 wks	BPD, HC, AC, FL	>21 d

[a]Based on last menstrual period (LMP).
[b]Ultrasound gestational age should be used if it differs from the LMP-derived gestational age by more than the threshold value.
AC = abdominal circumference; BPD = biparietal diameter; CRL = crown-rump length; FL = femur length; HC = head circumference.

discrepancy exceeds these thresholds, or if the LMP is uncertain or unknown, ultrasound measurements establish the EDD.

Ultrasound measurement of the crown-rump length (CRL) is the most accurate method to establish or confirm gestational age (Appendix, p. 1234). Transvaginal imaging yields higher resolution images. The CRL is measured in the midsagittal plane with the embryo or fetus in a neutral, nonflexed position. This allows its length to be measured in a straight line (Fig. 14-1). The mean of three discrete measurements is used. Before 14 weeks' gestation, the CRL is accurate to within 5 to 7 days (American College of Obstetricians and Gynecologists, 2019c).

Starting at $14^{0/7}$ weeks' gestation, the biparietal diameter, head circumference, abdominal circumference, and femur length should be measured. Equipment software formulas calculate estimated gestational age and fetal weight from these four biometric parameters. The accuracy of the fetal weight estimate is assumed to be within 15 percent of the actual weight (American Institute of Ultrasound in Medicine, 2018a). Measurement criteria are discussed in Chapter 15 (p. 272).

Before 22 weeks, gestational age assessment using these four biometric parameters is accurate to within 7 to 10 days (American College of Obstetricians and Gynecologists, 2019c). Various nomograms are available for other structural measurements, including the transverse cerebellar diameter, orbital distances, thoracic circumference, and length of the ear, kidney, long bones, and feet. These may be used to address specific questions regarding organ system abnormalities or syndromes (Appendix, pp. 1238–1241).

If the initial ultrasound examination is performed at or beyond 22 weeks' gestation, the pregnancy is *suboptimally dated* (American College of Obstetricians and Gynecologists, 2019b). In such cases, subsequent ultrasound evaluation in 3 to 4 weeks may be considered. This is especially true if the ultrasound measurements are smaller than expected for gestational age based on LMP and thus poor fetal growth is a possibility.

Fertilization is presumed to occur 2 weeks after a confident LMP. Therefore, for pregnancies achieved with in vitro fertilization and fresh transfer, 266 days are added to the egg-retrieval/fertilization date to calculate the EDD. Similarly, if using a day-3 frozen embryo, adding 263 days accounts for the days of embryo culture. For pregnancies conceived with intrauterine insemination, LMP is used.

FIRST-TRIMESTER ULTRASOUND

The three types of first-trimester examinations include standard ultrasound; nuchal translucency evaluation—between 11 and 14 weeks' gestation; and detailed first-trimester anatomy evaluation between 12 and 14 weeks' gestation.

Indications for the standard first-trimester examination are listed in Table 14-2 (American College of Obstetricians and Gynecologists, 2020; American Institute of Ultrasound in Medicine, 2018a). Early pregnancy can be evaluated with transabdominal or transvaginal sonography, or both. The components listed in Table 14-3 should be assessed (American

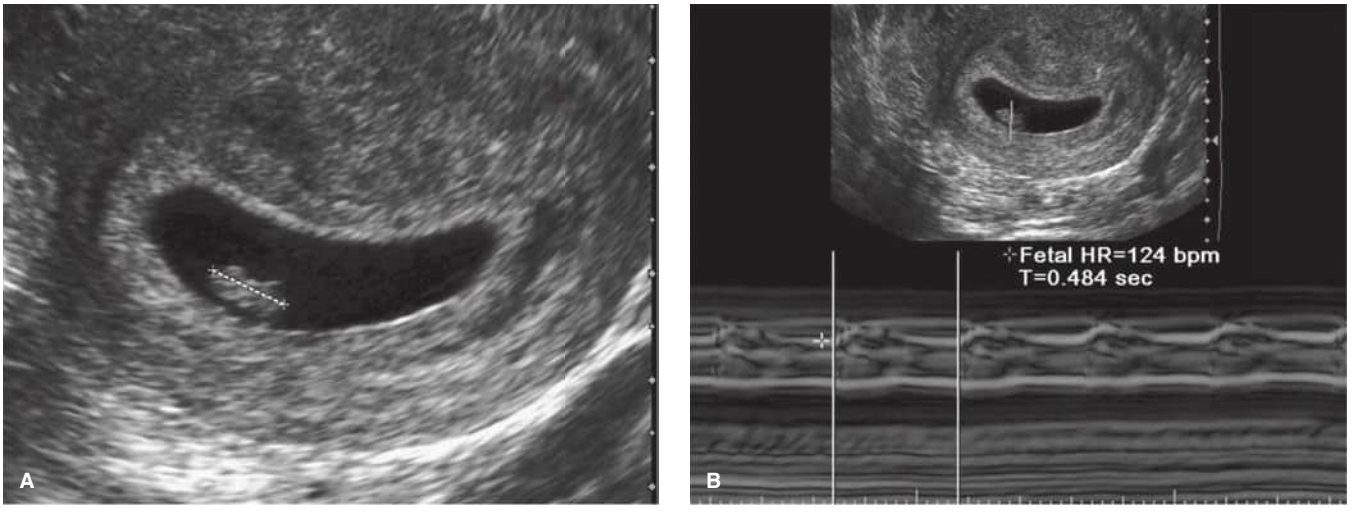


FIGURE 14-1 A. The measured crown-rump length is approximately 7 mm in this 6-week embryo. **B.** M-mode demonstrates embryonic cardiac activity and a heart rate of 124 beats per minute.

TABLE 14-2. Indications for First-Trimester Ultrasound Examination

Confirm an intrauterine pregnancy
Estimate gestational age
Confirm cardiac activity
Diagnose/evaluate a multifetal gestation, including chorionicity and amnionicity
Assess for certain fetal anomalies, such as anencephaly
Measure fetal nuchal translucency, when part of an aneuploidy screening program
Evaluate for uterine abnormalities or pelvic masses
Evaluate for suspected ectopic pregnancy
Evaluate for suspected gestational trophoblastic disease
Evaluate for the cause of vaginal bleeding
Evaluate for the cause of pelvic pain
Serve as adjunct to embryo transfer, chorionic villus sampling, and intrauterine device localization and removal

College of Obstetricians and Gynecologists, 2020; American Institute of Ultrasound in Medicine, 2018a). The first trimester is the ideal time to evaluate the uterus, adnexa, and cul-de-sac. Ultrasound interrogation at this time can reliably diagnose anembryonic gestation, embryonic demise, ectopic pregnancy, and gestational trophoblastic disease. In a multifetal gestation, determination of chorionicity is most accurate in the first trimester (Chap. 48, p. 841). Gestational sac implantation in a prior cesarean scar is increasingly detected in the first trimester as well.

An intrauterine gestational sac may be consistently visualized with transvaginal sonography by 5 weeks' gestation, and an embryo with cardiac activity by 6 weeks. The embryo should be visible transvaginally once the mean sac diameter has reached 25 mm—otherwise the gestation is *anembryonic*. Whenever an embryo or fetus is identified, it should be measured, and cardiac motion should be documented with either video clip or M-mode scanning (see Fig. 14-1B). Cardiac motion may be visible with transvaginal imaging when the length of the embryo is 2 mm and should be visible at 7 mm in a live embryo (American College of Obstetricians and Gynecologists, 2020). If an embryo measures <7 mm and has no visible cardiac activity, subsequent examination is recommended in 1 week (American Institute of Ultrasound in Medicine, 2018a). At Parkland Hospital, first-trimester demise is diagnosed with transvaginal ultrasound if the embryo has reached 10 mm and lacks cardiac motion, taking measurement error into consideration. Criteria to diagnose first-trimester demise are found in Table 11-2 (p. 202).

A recent addition to the standard first-trimester examination is an assessment of selected anatomical components when fetal size permits. These include the calvarium, umbilical cord insertion into the ventral wall, and presence of extremities (American Institute of Ultrasound in Medicine, 2018a).

Nuchal Translucency

This represents the maximum thickness of the subcutaneous translucent area between the skin and soft tissue overlying the fetal spine at the back of the neck. The nuchal translucency (NT) is measured in the sagittal plane between 11 and 14 weeks' gestation using precise criteria (Table 14-4) (American Institute of Ultrasound in Medicine, 2018a; International Society of Ultrasound in Obstetrics and Gynecology, 2016). When the NT measurement is increased, the risk for fetal aneuploidy and various structural anomalies—in particular heart defects—is significantly elevated. It is a component of first-trimester

TABLE 14-3. Components of Standard Ultrasound Examination by Trimester

First Trimester[a]	Second and Third Trimester
Gestational sac size, location, and number	Gestational age assessment
Embryo and/or yolk sac identification	Fetal number, including amnionicity and chorionicity of multifetal gestations
Crown-rump length	Fetal weight estimation
Gestational age assessment	Fetal anatomical survey, including documentation of technical limitations
Fetal number, including amnionicity and chorionicity of multifetal gestations	Fetal cardiac activity, documented with M-mode or 2-dimensional video clip
Embryonic/fetal cardiac activity, documented with M-mode or 2-dimensional video clip	Fetal presentation
Fetal anatomy assessment including calvarium, nuchal region, ventral wall cord insertion, and presence of limbs (depending on gestational age and fetal size)	Amnionic fluid measurement (single deepest pocket, amniotic fluid index, or qualitative assessment)
Fetal nuchal translucency assessment	Placental location, appearance, and relationship to internal cervical os[a]
Maternal uterus, adnexa, and cul-de-sac evaluation	Placental cord insertion site documentation when technically possible
	Evaluation of the maternal uterus, adnexa, and cervix[a]

[a]If a transabdominal examination is not definitive, transvaginal (or transperineal) evaluation is recommended.

TABLE 14-4. Guidelines for Nuchal Translucency (NT) Measurement

Angle of insonation is perpendicular to NT line
Fetus is measured in midsagittal plane, with nasal tip, palate, and diencephalon visible
Margins of NT edges are visible
Majority of image is filled by the fetal head, neck, and upper thorax
Fetal neck lies in a neutral position, not flexed or hyperextended
Amnion line must be separate from the NT line
+ calipers are placed perpendicular to the fetal long axis, on the inner borders of the nuchal membranes, with none of the horizontal crossbar protruding into the space
Measurement should be obtained at the widest NT space
Largest of 3 NT measurements should be used

aneuploidy screening, which is discussed in Chapter 17 (p. 337). The aneuploidy risk calculation depends on the crown-rump length. However, an NT measurement ≥3 mm is associated with increased risk for fetal structural or genetic abnormalities and is an indication for a detailed fetal anatomical survey.

Detailed First-Trimester Ultrasound Examination

Assessment for fetal abnormalities in an at-risk pregnancy may include a detailed survey of fetal anatomy at 12 to 14 weeks' gestation. Such examinations are a recent addition and limited to specialized centers with advanced imaging skills, although use may be expected to expand. *Despite improvements in imaging technology, it is not realistic to expect that all major abnormalities detectable in the second trimester may be visualized in the first trimester.* Abnormalities may change in appearance as the fetus develops, and new findings may become evident. If an abnormality is identified in the first trimester, detailed second-trimester sonography will be important to further characterize the findings or identify associated abnormalities. In an at-risk pregnancy, a normal first-trimester examination does not obviate the recommendation for a detailed second-trimester fetal anatomical survey.

In a systematic review of more than 118,000 pregnancies undergoing fetal NT assessment, 46 percent of major abnormalities were detected in low-risk or unselected pregnancies (Karim, 2017). In high-risk pregnancies, anomaly detection exceeded 60 percent. Detection rates are high for fetal anencephaly, alobar holoprosencephaly, and ventral wall defects. However, in one series of 40,000 pregnancies with fetal anatomical evaluation at the time of NT assessment, only a third of major cardiac anomalies were identified. No cases of microcephaly, agenesis of the corpus callosum, cerebellar abnormalities, congenital pulmonary airway malformations, or bowel obstruction were detected (Syngelaki, 2011). Some of these abnormalities had not yet developed by the end of the first trimester, and this is an important caveat for counseling.

SECOND- AND THIRD-TRIMESTER ULTRASOUND

Ultrasound should be routinely offered to all pregnant women between 18 and 22 weeks' gestation (American College of Obstetricians and Gynecologists, 2020). Recognizing that the gestational age at which an abnormality is identified may affect pregnancy management options, providers often opt to perform the examination before 20 weeks. Indications for second- and third-trimester sonograms are listed in Table 14-5 (American College of Obstetricians and Gynecologists, 2020; American Institute of Ultrasound in Medicine, 2018a). Based on data from large insurance providers, pregnant women typically receive at least 4 to 5 sonograms per pregnancy (O'Keeffe, 2013). Examinations are classified as standard, specialized, or limited. Specialized examination types include the detailed fetal anatomy examination, detailed evaluation for placenta accreta spectrum (p. 253), fetal echocardiography, Doppler velocimetry (p. 262), and the biophysical profile (Chap. 20, p. 389).

Standard Second- and Third-Trimester Ultrasound Examinations

The standard examination includes evaluation of fetal number and presentation, cardiac activity, fetal biometry, amnionic fluid volume, placental location, cervical length, and a survey of fetal anatomy (see Table 14-3). Anatomical components are listed in Table 15-1 (p. 273). With twins or other multiples, documentation should also include the number of chorions

TABLE 14-5. Indications for Standard Second- and Third-trimester Ultrasound Examinations

Routine evaluation of gestational age and fetal anatomy[a]
Fetal growth evaluation or size-date discrepancy
Fetal abnormality (follow-up evaluation)
Amniocentesis or other procedure
Cervical length assessment
Multifetal gestation
Vaginal bleeding
Placenta previa or low-lying placenta[b]
Vasa previa[b]
Placenta accreta spectrum[b]
Placental abruption[b]
Uterine or adnexal abnormality[b]
Gestational trophoblastic disease[b]
Amnionic fluid volume abnormality[b]
Preterm rupture of membranes or preterm labor
Inability to document fetal heart tones
Assessment of fetal well-being
Assessment of fetal presentation
Adjunct to external cephalic version

[a]Standard ultrasound examination should be offered in all pregnancies, ideally at 18–20 weeks' gestation.
[b]Includes evaluation of suspected cases.

and amnions, comparison of fetal sizes, estimation of amnionic fluid volume within each sac, and fetal phenotypic gender.

The American Institute of Ultrasound in Medicine (2018a) revised its prior 2013 standard ultrasound practice parameter to include the following updates:

1. Components added to the standard fetal anatomical survey are presence of the hands and feet, and when feasible, the three-vessel view and three-vessel trachea views of the heart (Fig. 15-37, p. 290).
2. If the relationship between placenta and cervix cannot be assessed transabdominally, transvaginal evaluation should be performed. Transperineal evaluation remains an option but in our experience is rarely used.
3. If the cervix appears abnormal or is not adequately visualized transabdominally, transvaginal (or transperineal) examination is recommended. If cervical length assessment is requested, measurement should be based on a transvaginal image.
4. In the setting of velamentous cord insertion, color and pulsed Doppler ultrasound should be used to evaluate for vasa previa (Figs. 6-6 and 6-7, p. 115).

Detailed Second- and Third-Trimester Ultrasound Examinations

The *detailed fetal anatomy* examination is also known as a targeted or 76811 examination. It is performed when the risk for a fetal structural or genetic abnormality is elevated because of history, screening test result, or abnormal finding during standard examination (Table 14-6) (American Institute of Ultrasound in Medicine, 2019). The detailed ultrasound examination is intended to be indication-driven and is not repeated without an extenuating circumstance, such as a new risk factor (American Institute of Ultrasound in Medicine, 2019). Physicians who perform or interpret these ultrasound examinations should have gained expertise in fetal imaging through both training and ongoing experience (American College of Obstetricians and Gynecologists, 2020).

Components of the detailed examination are intended to be determined on a case-by-case basis. Table 15-1 (p. 273) lists nearly 70 anatomical components that may be included. When practices apply for adjunct accreditation in performance of the detailed fetal anatomic survey, the American Institute of Ultrasound in Medicine specifies 50 components that must be included when submitting normal cases for review. At Parkland Hospital, we attempt to image these components in all detailed anatomic surveys. When performing a given detailed examination, one challenge is determining which components are needed for a given indication, as these have not been codified. The most prevalent risk factors and thus indications for detailed ultrasound examinations are maternal obesity and maternal age ≥35 years. In a systematic review of more than 16,000 pregnancies affected by anomalies, obesity conferred modestly

TABLE 14-6. American Institute for Ultrasound in Medicine Indications for Detailed Second- and Third-trimester Ultrasound Examinations

Prior fetus or infant with a structural or genetic abnormality
Current pregnancy with known or suspected fetal abnormality or growth restriction
Increased risk for fetal structural abnormality in current pregnancy
Teratogen exposure (Chap. 8)
Diabetes diagnosed before 24 weeks' gestation
Nuchal translucency ≥3.0 mm
Abnormal serum analyte levels (e.g., elevated alpha fetoprotein)
Assisted reproductive technology used to achieve conception
Prepregnancy body mass index ≥30 kg/m^2
Multifetal gestation
Increased risk for fetal genetic abnormality in current pregnancy
Woman or her partner carries a genetic abnormality
Maternal age ≥35 years at delivery
Nuchal translucency ≥3.0 mm
Abnormal aneuploidy screening test result (Chap. 17, p. 333)
Minor aneuploidy marker found during standard ultrasound examination
Other condition affecting the fetus
Congenital infection (Chaps. 67, 68)
Substance abuse
Alloimmunization (Chap. 18, p. 352)
Amnionic fluid volume abnormality
Suspected placenta accreta spectrum or associated risk factors

Adapted with permission from American Institute of Ultrasound in Medicine (AIUM): Practice parameter for the performance of detailed second- and third-trimester diagnostic obstetric ultrasound examinations. J Ultrasound Med 38(12):3093, 2019.

increased odds of a neural-tube defect (1.9), ventriculomegaly (1.7), cardiovascular anomaly (1.3), cleft lip/palate (1.2), anorectal atresia (1.5), and limb reduction defect (1.7) (Stothard, 2009). Subsequently, Biggio and colleagues (2010) reported that obesity was associated with a higher anomaly prevalence only in the setting of diabetes. Maternal age ≥35 years is considered another indication for detailed sonographic examination. However, the fetal anomaly risk may be related to the associated increase in aneuploidy. Goetzinger and colleagues (2017) found that the anomaly rate among euploid fetuses born to older mothers was not increased.

Fetal Echocardiography

This specialized examination of fetal cardiac structure and function is designed to identify and characterize abnormalities. Echocardiography indications include suspected fetal cardiac structural or functional abnormality; heart rate abnormality or arrhythmia; extracardiac anomaly or hydrops; chromosomal abnormality; nuchal translucency ≥3.5 mm; in vitro fertilization; monochorionic twin gestation; first-degree relative to the fetus with a congenital cardiac defect; first- or second-degree relative to the fetus with a Mendelian syndrome and childhood cardiac manifestation; prior fetus with heart block in the setting of maternal anti-Ro or La antibodies; retinoid exposure; and metabolic risk factor such as pregestational diabetes or phenylketonuria (American Institute of Ultrasound in Medicine, 2020a). Selected cardiac anomalies are reviewed in Chap. 15 (p. 291).

Limited Ultrasound Examination

A *limited* second- or third-trimester examination is performed to address a specific clinical question. Evaluation of fetal number, presentation, and cardiac activity; amnionic fluid volume; and placental location with respect to the internal os are common indications (American Institute of Ultrasound in Medicine, 2018b). The examination may include fetal biometry but not a complete anatomical survey. In the absence of an emergency, a limited examination is performed only if a standard ultrasound survey has already been completed. Otherwise, provided that the gestational age is at least 18 weeks, a standard ultrasound examination is recommended.

Fetal Anomaly Detection

With current advances in imaging technology, approximately 60 percent of major fetal abnormalities may be detected during standard ultrasound examinations (Byrne, 2020; Rydberg, 2017). For detailed ultrasound surveys performed in pregnancies at increased risk for anomalies, detection rates may exceed 90 percent (Dashe, 2009; Levi, 1998). The sensitivity of the examination varies according to factors such as gestational age, maternal habitus, fetal position, equipment features, examination type, operator skill, and the specific abnormality. For example, maternal obesity lowers the anomaly detection rate by 20 percent (Dashe, 2009).

Detection rates vary considerably according to the abnormality. In the EUROCAT network of 28 population-based registries, 40 percent of major fetal abnormalities are detected prenatally (EUROCAT, 2019). Detection rates of selected abnormalities are as follows: anencephaly, 98 percent; spina bifida, 89 percent; hydrocephaly, 82 percent; cleft lip/palate, 70 percent; hypoplastic left heart, 88 percent; transposition of the great vessels, 69 percent; diaphragmatic hernia, 73 percent; gastroschisis, 92 percent; omphalocele, 90 percent; bilateral renal agenesis, 94 percent; posterior urethral valves, 80 percent; limb reduction defects, 60 percent; and clubfoot, 60 percent. In contrast, anomalies with poor sonographic detection rates in the second trimester include microcephaly, choanal atresia, cleft palate, Hirschsprung disease, anal atresia, and congenital skin disorders. Although clinicians tend to focus on abnormalities amenable to sonographic detection, those that are undetectable can be no less devastating to families. *Every sonographic examination should include a frank discussion of examination limitations.*

Three-Dimensional Ultrasound Examination

Over the past three decades, three-dimensional (3-D) ultrasound has gone from a novelty to a feature of all modern equipment. After a region of interest is identified, a volume is acquired using a 3-D transducer. This volume can be rendered to display axial, sagittal, coronal, or oblique images. Sequential slices may be generated, similar to computed tomographic (CT) images. Unlike two-dimensional (2-D) scanning, which appears to be happening in real time on the screen, 3-D imaging is static and obtained by processing a volume of stored images. With *four-dimensional ultrasound*, rapid reconstruction of the rendered images conveys the impression that the scanning is in real time.

For selected anomalies, such as those of the face and skeleton, for tumors, and for some cases of neural-tube defects, 3-D sonography can add useful information (American College of Obstetricians and Gynecologists, 2020; Goncalves, 2005). That said, comparisons of 3-D and conventional 2-D sonography for the diagnosis of most congenital anomalies have not demonstrated better overall detection rates (Goncalves, 2006; Reddy, 2008). The American College of Obstetricians and Gynecologists (2020b) has concluded that proof of a clinical advantage of 3-D ultrasound for prenatal diagnosis is generally lacking.

PLACENTA AND CERVIX

The standard examination includes evaluation of the anatomical relationship between the placenta and the internal cervical os, the umbilical cord insertion into the placenta, and cervical length assessment. (American Institute of Ultrasound in Medicine, 2018a). Evaluation for placenta accreta spectrum is a detailed examination type (see Table 14-6).

Placenta Previa and Low-lying Placenta

The location of the placenta with respect to the cervix may be accurately assessed by approximately 16 weeks' gestation. If transabdominal visualization is limited, transvaginal ultrasound is recommended. *Placenta previa* is diagnosed if the placenta overlies the internal cervical os to any degree or

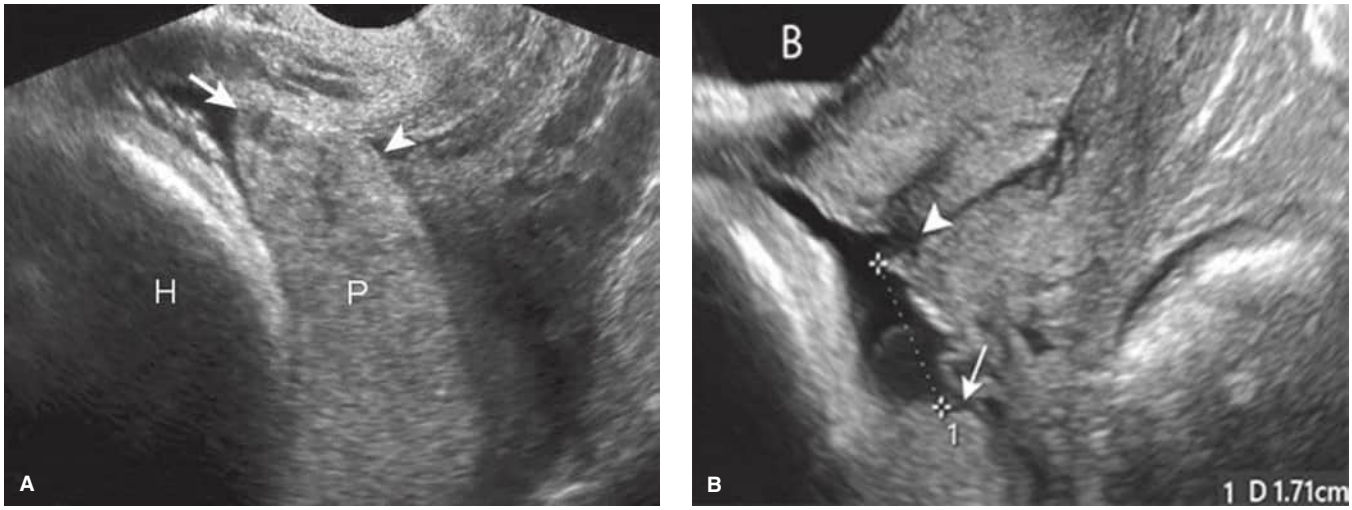

FIGURE 14-2 A. Placenta previa. In this transvaginal image, the inferior edge (*arrow*) of the posterior placenta (*P*) overlies the internal cervical os (*arrowhead*). H = head. **B.** Low-lying placenta. The inferior placental edge (*arrow*) is within 2 cm of the internal cervical os (*arrowhead*) in this transvaginal image. The bladder (B) is seen anterior to the cervix.

reaches its margin (Fig. 14-2A). If the inferior placental edge is within 2 cm of the internal os but does not reach the cervix, the diagnosis is *low-lying placenta* (see Fig. 14-2B). Whenever placenta previa or low-lying placenta are diagnosed, a follow-up ultrasound examination is recommended at approximately 32 weeks' gestation, with transvaginal evaluation if needed to verify the relationship between the placenta and cervix. If findings persist, a 36-week ultrasound examination also is recommended. Management of these placenta types are discussed in Chapter 43 (p. 757).

The umbilical cord insertion into the placenta should be interrogated. Marginal cord insertion, also known as *battledore placenta*, is diagnosed if the umbilical cord inserts into the edge of the placenta or within 2 cm of the placental margin. If the umbilical cord does not insert into the placenta—but rather into the membranes—the diagnosis is *velamentous cord insertion* (Fig. 6-6, p. 115). With the latter, the umbilical arteries and vein traverse the membranes along the uterine wall unprotected by Wharton jelly before entering the placental margin. If umbilical vessels course within the portion of membrane overlying the cervix or within 2 cm of the cervix, the diagnosis is *vasa previa* (Fig. 6-7, p. 116). Vasa previa may also occur if there are two or more placental lobes—as with a succenturiate lobe—and the interconnecting vessels traverse the intervening membranes over or in proximity to the internal cervical os. Transvaginal ultrasound with color Doppler highlights the vessels, and pulsed-wave Doppler of the spanning arterial vessel demonstrates a fetal heart rate, which confirms the diagnosis. A subsequent detailed ultrasound examination is recommended at 32 weeks' gestation (Society for Maternal-Fetal Medicine, 2015b). Chapter 6 (p. 114) contains content on management of these entities.

■ Placenta Accreta Spectrum

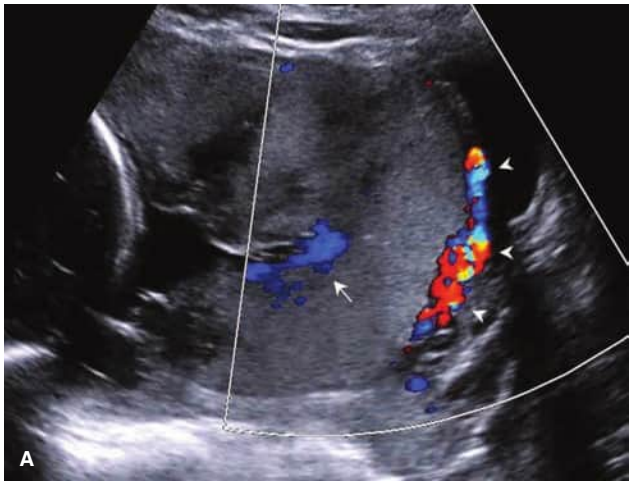
Placenta accreta, increta, and percreta comprise the placenta accreta spectrum (PAS). They are characterized by abnormal placental invasion onto, into, or through the myometrium, respectively (Chap. 43, p. 759). Evaluation includes transabdominal and transvaginal imaging, with and without color or power Doppler and with the patient's bladder partially filled. In one metaanalysis that included more than 3200 pregnancies, the sensitivity of ultrasound to identify placenta accreta, increta, and percreta was 91, 93, and 89 percent, respectively. Corresponding specificities were 97, 98, and 99 percent, respectively (Pagani, 2018). Five ultrasound criteria assist with detection and characterization of PAS (Fig. 14-3):

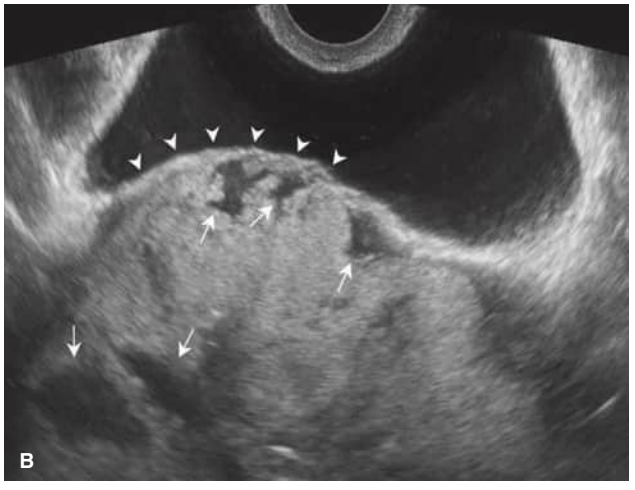
1. Placental *lacunae*, which are vascular spaces that may contain prominent color Doppler flow
2. Attenuation or thinning of the retroplacental myometrium, such that the *smallest myometrial thickness* measurement is <1 mm. This is also referred to as loss of the retroplacental clear space
3. Disruption of the bladder-uterine serosal interface, which appears as an irregular, echogenic boundary between the bladder and uterine serosa with gray-scale imaging
4. Bridging vessels, which are demonstrated with color Doppler to course from the placenta to the bladder-serosal interface
5. A placental "bulge" that pushes outward and distorts the contour of the uterus or other organs. In some cases of placenta percreta, a focal exophytic mass also is seen.

The accuracy of these criteria varies in published series and is affected by the number and predictive value of given findings and by associated risk factors such as placenta previa and number of prior cesarean deliveries (Jauniaux, 2016; Rac, 2015). Serial evaluation may be helpful, particularly in the third trimester. With concurrent placenta previa and history of cesarean delivery, any of these ultrasound findings prompts a detailed ultrasound evaluation. The role of magnetic resonance (MR) imaging as an adjunct in pregnancies with suspected PAS is reviewed later (p. 268).

■ Cesarean Scar Pregnancy

Placental implantation within a prior hysterotomy scar—termed cesarean scar pregnancy (CSP)—is often a precursor





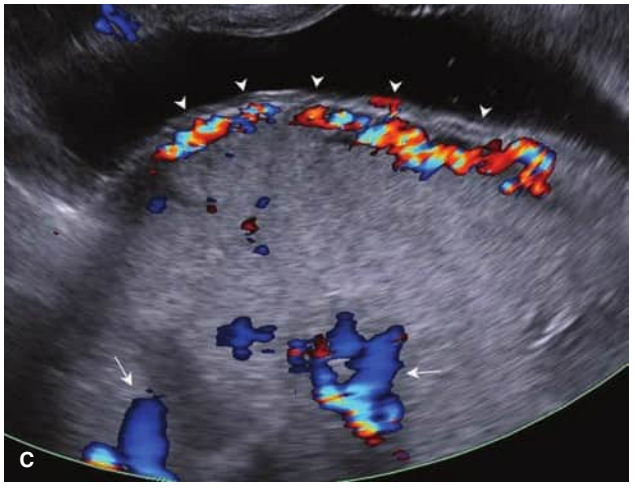


FIGURE 14-3 These third-trimester sonograms demonstrate findings that characterize placenta accreta spectrum. **A.** Transabdominal color mapping depicts bridging vessels between the bladder and the uterine serosa (*arrowheads*) and shows large intraplacental lacunae (*arrow*). **B.** Transvaginal transverse image showing a large bulge (suggesting placenta percreta) along the bladder-uterine serosal interface (*arrowheads*) and multiple large, irregular lacunae (*arrows*). **C.** Disruption of the bladder-serosal interface. The echogenic interface between bladder and serosa appears irregular (*arrowheads*). The smallest myometrial thickness measures <1 mm, and bridging vessels are highlighted by color Doppler. Large lacunae also are shown (*arrows*).

to second- or third-trimester PAS (Happe, 2020; Rac, 2016; Timor-Trisch, 2014). Sonographically, the gestational sac lies low and anteriorly in the uterus. CSPs may appear to rest on the prior scar or may fill the *niche*, which is a myometrial pocket defect in the thinned hysterotomy scar (Kaelin Agten, 2017). Placental sonolucencies, a precursor to PAS lacunae, may be seen. The retroplacental myometrium may be attenuated to a degree that the distance from the anterior trophoblastic border to the uterine serosa measures <3 mm (D'Antonio, 2018; Moschos, 2014; Happe, 2020). Color Doppler may demonstrate prominent vascularity in the region of the prior hysterotomy scar (Fig. 14-4). In some cases, the gestational sac may bulge toward the bladder. CSP evaluation and management are discussed in Chapter 12 (p. 229).

■ Cervical Length

Although the cervix may be imaged transabdominally (Fig. 14-5A), visualization is often limited by maternal habitus, cervical position, or shadowing by the fetal presenting part. In addition, the maternal bladder or pressure from the transducer may artificially elongate the cervix's appearance. As a result, values from transabdominal or transvaginal measurement of the cervix can differ significantly.

If the cervix appears short or is inadequately visualized during transabdominal evaluation, transvaginal assessment should be considered (American Institute of Ultrasound in Medicine, 2018a). Clinical decision-making should use only cervical length measurements obtained transvaginally (Fig. 14-5B). Measurement should be performed at or beyond 16 weeks' gestation. A short cervix is associated with an elevated risk for preterm birth, particularly in those with prior preterm birth. Risk rises proportionally with the degree of cervical shortening (Chap. 45, p. 793).

To measure the cervix transvaginally, the imaging criteria shown in Table 14-7 are followed. The endocervical canal should be visible in its entirety, and images ideally are obtained over several minutes to capture dynamic change. *Funneling* is a protrusion of amnionic membranes into a portion of the endocervical canal that has dilated (Fig. 14-6). Funneling is not an independent predictor of preterm birth but is associated with cervical shortening. Transvaginal assessment is recommended if a funnel is suspected transabdominally. The cervical length is measured distal to the funnel, because the funnel's base becomes the functional internal os. If the cervix is dilated, as with cervical insufficiency, the membranes may prolapse through the endocervical canal and into the vagina to produce an hourglass appearance. *Sludge* represents an aggregate of particulate matter (debris) within the amnionic sac and close to the internal os. In pregnancies at risk for preterm birth, sludge further raises the risk.

AMNIONIC FLUID

■ Physiology

Amnionic fluid serves several roles. Fetal breathing is essential for normal lung growth, and fetal swallowing permits

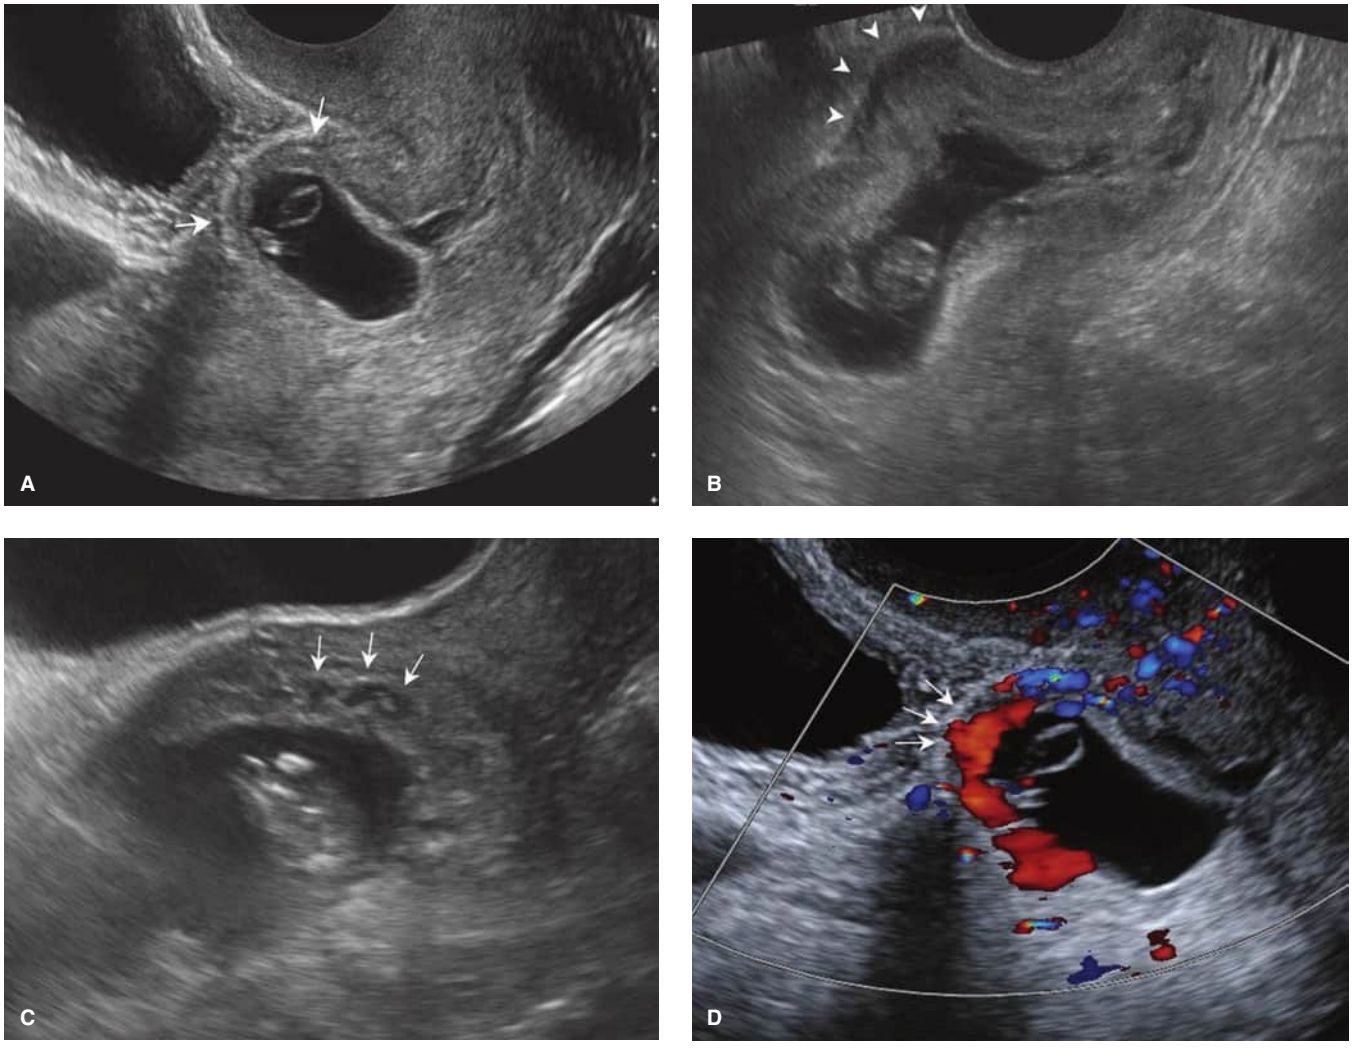

FIGURE 14-4 Cesarean scar pregnancy, transvaginal images. **A.** The trophoblast appears to fill the scar "niche" (*arrows*). **B.** Outward bulging of the gestational sac toward the bladder (*arrowheads*). **C.** Placental sonolucencies (*arrows*). **D.** Attenuation of the retroplacental myometrium. The distance from the anterior trophoblastic border to the uterine serosa is <1 mm (*arrows*). Color Doppler demonstrates vascularity in the region of the prior hysterotomy scar.

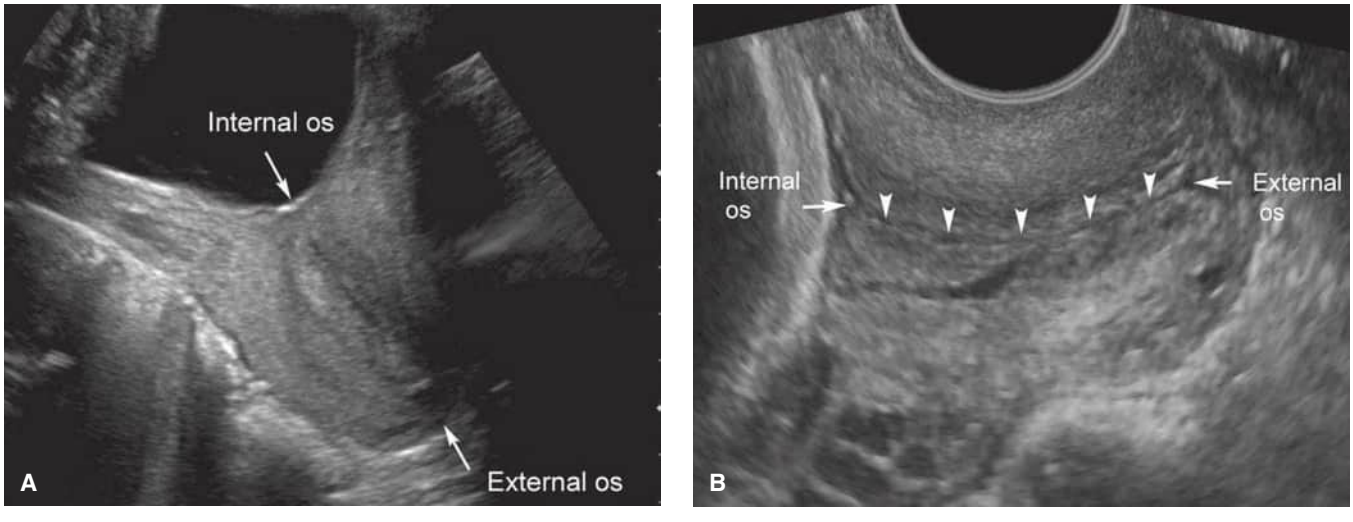

FIGURE 14-5 **A.** Transabdominal image of the cervix depicting the internal os and external os. **B.** Transvaginal imaging provides a more accurate evaluation of the cervix and should be used for medical decision-making. In this image, arrowheads mark the endocervical canal. (Reproduced with permission from Dr. Emily Adhikari.)

TABLE 14-7. Criteria for Transvaginal Evaluation of the Cervix

Imaging the Cervix

- Maternal bladder should be empty.
- Transducer is inserted under real-time observation, identifying midsagittal plane, internal os, and then external os, while keeping the internal os in view.
- Internal os, external os, and entire endocervical canal should be visible. The internal os may appear as a small triangular indentation at the junction of the amnionic cavity and endocervical canal.
- Image is enlarged so that the cervix fills approximately 75% of the screen.
- Anterior and posterior width of the cervix should be approximately equal.
- Transducer is pulled back slightly until the image begins to blur, ensuring that pressure is not placed on the cervix, then inserted only enough to restore a clear image.
- Images should be obtained with and without fundal or suprapubic pressure, to assess for dynamic change or shortening on real-time imaging.

Measuring the Cervix

- Calipers are placed at the point where anterior and posterior walls of cervix meet.
- Endocervical canal appears as a faint, linear echodensity.
- If canal has a curved contour, a straight line between the internal and external os will deviate from the path of the endocervical canal.
- If midpoint of the line between the internal and external canal deviates by ≥3 mm from the endocervical canal, measure the cervical length in two linear segments.
- Funneling, sludge (debris), or dynamic change is noted.
- At least three separate images are measured during a period of at least 3 minutes to allow for dynamic change. Visualization of cervical shortening on real-time imaging, with or without fundal or suprapubic pressure, raises preterm birth risks.
- Shortest cervical length image that meets all criteria should be used.

gastrointestinal (GI) tract development. The fluid also creates a physical space for fetal movement, which is necessary for neuromusculoskeletal maturation. Amnionic fluid further guards against umbilical cord compression and protects the fetus from trauma. It also has bacteriostatic properties.

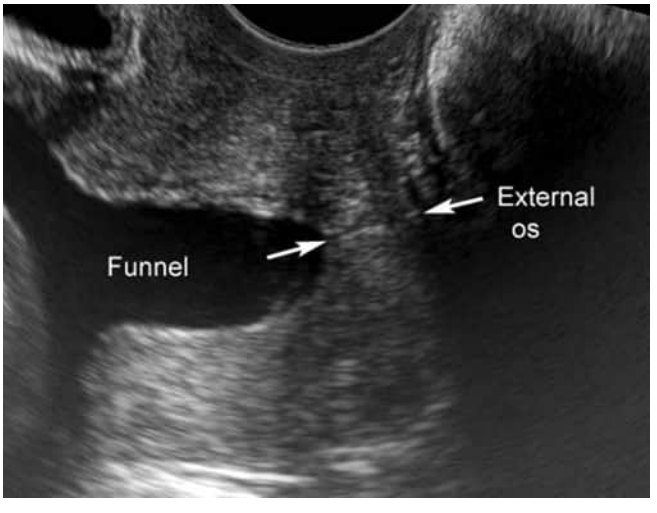

FIGURE 14-6 Transvaginal image depicting a foreshortened cervix with funneling. Funneling is a protrusion of amnionic membranes into a portion of the endocervical canal that has dilated. The distal protruding edge of the funnel becomes the functional internal os (*left arrow*). Thus, the measured cervical length, which lies between the arrows, should not include the funnel. (Reproduced with permission from Dr. Emily Adhikari.)

Early in pregnancy, amnionic fluid is similar in composition to extracellular fluid. Amnionic fluid arises as a transudate of plasma either from the fetus through its nonkeratinized skin or from the mother across the uterine decidua and placenta surface (Beall, 2007). Specifically, early transfer of water and other small molecules occurs via three mechanisms: across the amnion—*transmembranous flow*; across fetal vessels on the placental surface—*intramembranous flow*; and across fetal skin—*transcutaneous flow*. Fetal urine production does not become a major component of amnionic fluid until the second trimester, which explains why fetuses with lethal renal abnormalities may not manifest severe amnionic volume declines until after 18 weeks' gestation. Water transport across the fetal skin continues until keratinization occurs at 22 to 25 weeks. In the second half of pregnancy, fetal urination is the primary source of amnionic fluid. In late gestation, the fetal respiratory tract also produces approximately 350 mL of lung fluid per day. Fetal swallowing is the primary mechanism for amnionic fluid resorption and averages 500 to 1000 mL per day (Mann, 1996). By term, the entire amnionic fluid volume is recirculated on a daily basis (Table 14-8). However, impaired swallowing, secondary to either a central nervous system (CNS) abnormality or GI tract obstruction, can result in impressive amnionic fluid volume expansion.

The osmolality of amnionic fluid is similar to that of fetal urine and *hypotonic* to that of maternal and fetal plasma. Specifically, the osmolality of maternal and fetal plasma approximates 280 mOsm/mL, whereas that of amnionic fluid is about

TABLE 14-8. Amnionic Fluid Volume Regulation in Late Pregnancy

Pathway	Effect on Volume	Approximate Daily Volume (mL)
Fetal urination	Production	1000
Fetal lung fluid secretion	Production	350
Fetal swallowing	Resorption	750
Intramembranous flow across fetal vessels on the placental surface	Resorption	400
Transmembranous flow across amnionic membrane	Resorption	Minimal

Data from Magann, 2011; Modena, 2004; Moore, 2010.

260 mOsm/L. The hypotonicity of amnionic fluid accounts for up to 400 mL per day of intramembranous fluid transfer across and into fetal vessels on the placental surface (Mann, 1996). Maternal dehydration can lead to higher maternal osmolality, which favors fluid transfer from the fetus to mother and then from the amnionic fluid compartment into the fetus (Moore, 2010).

Amnionic fluid volume expands from approximately 30 mL at 10 weeks' gestation to 200 mL by 16 weeks and reaches 800 mL by the mid-third trimester (Brace, 1989; Magann, 1997). Using dye dilution, Magann and associates (1997) reported that the average amnionic fluid volume was approximately 400 mL between 22 and 30 weeks' gestation, then rose to 800 mL until 40 weeks, and subsequently declined by 8 percent per week. There was a wide normal range, particularly in the third trimester. Abnormally decreased fluid volume is termed *oligohydramnios*, whereas abnormally increased fluid volume is termed *hydramnios* or *polyhydramnios*.

■ Semi-quantitative Assessment

Evaluation of amnionic fluid volume is a component of every second- or third-trimester ultrasound examination. Volume is measured semi-quantitatively using the single deepest pocket of fluid or the amnionic fluid index (AFI). Both measurements are reproducible and, in the setting of a fluid abnormality, can be followed serially over time to assess trends and aid communication among providers. For this reason, subjective assessment alone is not recommended.

The single deepest pocket of fluid is measured in a sagittal plane with the ultrasound transducer held perpendicular to the floor and parallel to the long axis of the woman. A pocket should be at least 1 cm wide to be considered adequate, and the measurement should not include fetal parts or loops of umbilical cord. Color Doppler is generally used to verify that umbilical cord is not within the measurement. The measurement is considered normal if it is >2 cm and <8 cm. Values below and above this range indicating oligohydramnios and hydramnios, respectively. These thresholds correspond to the 3rd and 97th percentiles (Chamberlain, 1984). When evaluating twins and other multifetal gestations, a single deepest pocket is assessed in each gestational sac, using the same normal range (Hernandez, 2012; Society for Maternal-Fetal Medicine, 2013). The fetal biophysical profile similarly uses a single deepest vertical pocket threshold of >2 cm to indicate normal amnionic fluid volume (Chap. 20, p. 389).

To measure the AFI, the uterus is divided into four equal quadrants—the right and left upper and lower quadrants, respectively. The AFI is the sum of the single deepest pocket from each quadrant. In a study of 1400 measurements obtained from the INTERGROWTH-21st trial, the mean intra- and interobserver variability of AFI measurements were each below 1 cm (Sande, 2015). Two standard deviations from the mean, however, reached 5 and 7 cm, respectively. As useful rule of thumb, the AFI is generally three times higher than the single deepest pocket of fluid.

The AFI is considered normal if >5 cm and <24 or 25 cm. Using an AFI nomogram based on cross-sectional evaluation of nearly 800 uncomplicated pregnancies, the mean AFI ranged between 12 and 15 cm from 16 weeks until 40 weeks' gestation (Moore, 1990). Other investigators have published nomograms with similar mean values (Fig. 14-7) (Hinh, 2005; Machado, 2007).

■ Hydramnios

Abnormally increased amnionic fluid volume complicates 1 to 2 percent of singleton pregnancies (Dashe, 2002; Khan, 2017; Pri-Paz, 2012). Hydramnios may be categorized as *mild* if the AFI is 25 to 29.9 cm; *moderate*, if 30 to 34.9 cm; and *severe*, if ≥35 cm (Luo, 2017; Odibo, 2016). Using a single deepest pocket of amnionic fluid, as is done in multifetal gestations, mild hydramnios is defined as 8 to 9.9 cm, moderate as 10 to 11.9 cm, and severe hydramnios as ≥12 cm (Fig. 14-8). Mild hydramnios accounts for approximately two thirds of cases and is frequently idiopathic and benign. By comparison, severe hydramnios is far more likely to have an underlying etiology and to have consequences for the pregnancy.

Underlying causes of hydramnios include fetal structural abnormalities or genetic syndromes in approximately 15 percent and diabetes in 15 to 20 percent (Table 14-9). Selected anomalies and the likely mechanism by which they cause hydramnios are shown in Table 14-10. Congenital infection, red blood cell alloimmunization, and placental chorioangioma are less frequent etiologies. Hydramnios may also complicate syphilis and cytomegalovirus, toxoplasmosis, and parvovirus infections (Chaps. 67 and 68, pp. 1183 and 1206). Hydramnios is often seen with *hydrops fetalis* (Chap. 18, p. 360). The

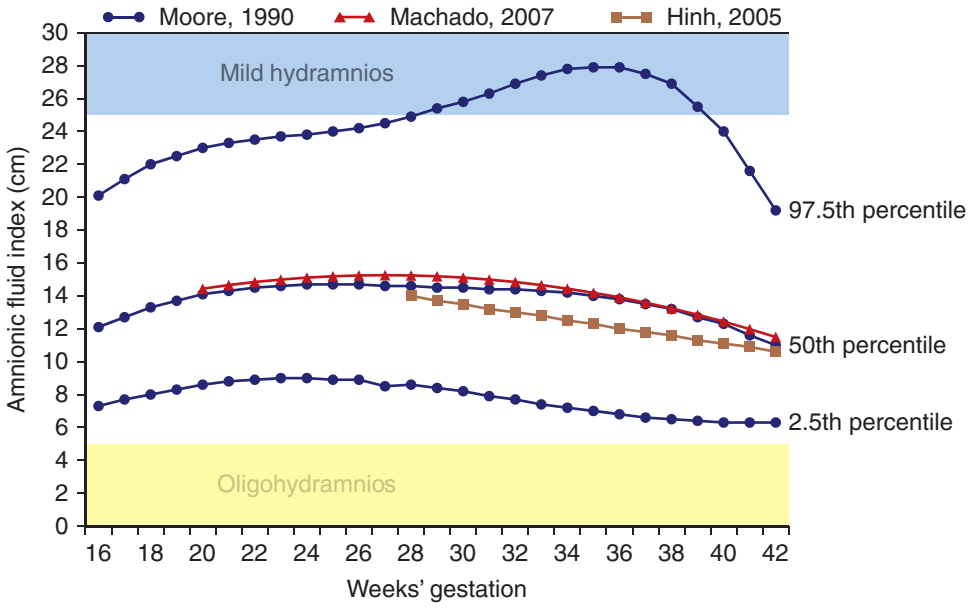

FIGURE 14-7 Amnionic fluid index (AFI) according to gestational age–specific and threshold values. The blue curves represent the 2.5th, 50th, and 97.5th AFI percentile values, based on the nomogram by Moore (1990). Red and tan curves represent 50th percentile values for AFI from Machado (2007) and from Hinh and Ladinsky (2005), respectively. The light blue and yellow shaded bars indicate threshold values used to define hydramnios and oligohydramnios, respectively.

underlying pathophysiology in such cases is frequently related to a high-cardiac-output state, and severe fetal anemia a classic example. A detailed ultrasound examination is indicated whenever hydramnios is identified. If a fetal abnormality is identified at that time, the aneuploidy risk is significantly elevated.

The degree of hydramnios positively correlates with the likelihood of an anomalous fetus. At Parkland Hospital, the prevalence of an anomalous neonate approximated 8 percent with mild hydramnios, 12 percent with moderate hydramnios, and more than 30 percent with severe hydramnios (Dashe, 2002). Even if no abnormality was detected during targeted sonographic evaluation, the likelihood of a major anomaly identified at birth was 1 to 2 percent if hydramnios was mild or moderate and 10 percent if hydramnios was severe. The overall reported risk that an underlying anomaly will be discovered after delivery ranges from 9 percent in the neonatal period to 28 percent among infants followed to 1 year of age (Abele, 2012; Dorleijn, 2009).

The amnionic fluid glucose concentration is higher in diabetic women than in those without diabetes, and the AFI may correlate positively with the amnionic fluid glucose concentration (Dashe, 2000; Spellacy, 1973; Weiss, 1985). Such findings support the hypothesis that maternal hyperglycemia causes fetal hyperglycemia, which leads to fetal osmotic diuresis into the amnionic fluid compartment. Repeat screening for gestational diabetes in pregnancies with hydramnios does not appear to be beneficial if the second-trimester glucose tolerance test result was normal (Frank Wolf, 2017).

Hydramnios is more frequently noted in multifetal gestations than in singleton ones. In a review of nearly 2000 twin gestations, Hernandez and coworkers (2012) identified hydramnios in 18 percent of both monochorionic and dichorionic pregnancies. In monochorionic gestations, hydramnios in one sac and oligohydramnios in the other are diagnostic criteria for twin-twin transfusion syndrome (TTTS) (Chap. 48, p. 848). Isolated hydramnios solely in one sac also may precede this syndrome's development (Chon, 2014). In the absence of a fetal abnormality or TTTS, complication risks are not generally higher (Hernandez, 2012).

Idiopathic hydramnios is a diagnosis of exclusion. It accounts for up to 70 percent of all hydramnios cases, is mild in approximately 80 percent of idiopathic cases, and subsequently resolves in more than one third (Odibo, 2016; Wiegand, 2016).

FIGURE 14-8 Severe hydramnios. This pocket of amnionic fluid measured >15 cm, and the amnionic fluid index measured nearly 50 cm.

Management

Severe hydramnios occasionally results in early preterm labor or maternal respiratory compromise. In such cases, large-volume amniocentesis—termed *amnioreduction*—may be needed. The technique is similar to that for genetic amniocentesis but is generally done with an 18- or 20-gauge needle. Fluid is collected in either a vacuum container bottle or a larger syringe (Chap. 17, p. 344). Approximately 1000 to 2000 mL of fluid is slowly withdrawn over 20 to 30 minutes, depending on the severity of hydramnios and gestational age. The goal is to restore amnionic fluid volume to the upper normal range. Subsequent amnioreduction procedures may be required as often as weekly or semiweekly.

In a review of 138 singleton pregnancies requiring amnioreduction for hydramnios, a fetal GI malformation was identified in 20 percent, a chromosomal abnormality or genetic condition

TABLE 14-9. Hydramnios: Prevalence and Associated Etiologies—Values in Percent

	Golan (1993) n = 149	Many (1995) n = 275	Biggio (1999) n = 370	Dashe (2002) n = 672	Pri-Paz (2012) n = 655

Diabetes	15	18	20	7	18

[a]A significant correlation was identified between severity of hydramnios and likelihood of an anomalous infant.

in almost 30 percent, and a neurological abnormality in 8 percent (Dickinson, 2014). In only 20 percent of cases was the hydramnios idiopathic. The initial amnioreduction procedure was performed at 31 weeks' gestation, and the median gestational age at delivery was 36 weeks.

Outcomes

Hydramnios can be associated with preterm birth, placental abruption, uterine dysfunction during labor, and postpartum hemorrhage. When an underlying cause is identified, the severity of hydramnios positively correlates with risk for preterm delivery, small-for-gestational age newborn, and perinatal mortality (Pri-Paz, 2012). However, *idiopathic* hydramnios is generally not associated with preterm birth (Magann, 2010; Many, 1995; Panting-Kemp, 1999). Placental abruption may result from rapid decompression of an overdistended uterus following rupture of membranes or therapeutic amnioreduction, occasionally days or weeks later. Uterine dysfunction from

TABLE 14-10. Selected Anomalies and Mechanism for Hydramnios

Mechanism	Anomaly Examples
Impaired swallowing (CNS)	Anencephaly Hydranencephaly Holoprosencephaly
Impaired swallowing (craniofacial)	Cleft lip/palate Micrognathia
Tracheal compression or obstruction	Neck venolymphatic abnormality CHAOS[a]
Thoracic etiology (mediastinal shift)	Diaphragmatic hernia[a] Cystic adenomatoid malformation[a] Pulmonary sequestration[a]
High-output cardiac state	Ebstein anomaly[a] Tetralogy of Fallot with absent pulmonary valve[a] Thyrotoxicosis[a]
Functional cardiac etiology	Cardiomyopathy, myocarditis[a]
Cardiac arrhythmia	Tachyarrhythmia[a]: atrial flutter, atrial fibrillation, supraventricular tachycardia Bradyarrhythmia[a]: heart block
GI obstruction	Esophageal atresia Duodenal atresia
Renal-urinary	Ureteropelvic junction obstruction ("paradoxical hydramnios") Bartter syndrome
Neurological or muscular etiology	Arthrogryposis, akinesia sequence Myotonic dystrophy
Neoplastic etiology	Sacrococcygeal teratoma[a] Mesoblastic nephroma[a] Placental chorioangioma[a]

[a]Poses risk for hydrops.
CNS = central nervous system; CHAOS = congenital high-airway obstruction sequence; GI = gastrointestinal.

overdistention may lead to postpartum atony and associated postpartum hemorrhage.

With idiopathic hydramnios, birthweight exceeds 4000 g in nearly 25 percent of cases, and the likelihood is greater if the hydramnios is moderate or severe (Luo, 2017; Odibo, 2016; Wiegand, 2016). A rationale for this association is that larger fetuses have higher urine output, by virtue of their increased volume of distribution, and fetal urine is the largest contributor to amnionic fluid volume. Cesarean delivery rates are also higher in pregnancies with idiopathic hydramnios, and reported rates range from 35 to 55 percent (Dorleijn, 2009; Khan, 2017; Odibo, 2016).

An unresolved question is whether hydramnios alone raises the risk for perinatal mortality (Khan, 2017; Pilliod, 2015; Wiegand, 2016). Using birth certificate data from California, Pilliod and colleagues (2015) reported that at 37 weeks' gestation, the stillbirth risk was sevenfold higher in pregnancies with hydramnios. Risks appear to be compounded when fetal-growth restriction is comorbid with hydramnios (Erez, 2005).

Oligohydramnios

Abnormally decreased amnionic fluid volume complicates 1 to 2 percent of pregnancies (Casey, 2000; Petrozella, 2011). Oligohydramnios is diagnosed if the AFI measures <5 cm or the single deepest pocket is <2 cm (American College of Obstetricians and Gynecologists, 2020). An AFI threshold of 5 cm is below the 2.5th percentile throughout the second and third trimesters (see Fig. 14-7). Importantly, use of AFI rather than single deepest pocket will identify more pregnancies as having oligohydramnios but without evidence of improved pregnancy outcomes (Kehl, 2016; Nabhan, 2010). When evaluating multifetal pregnancies for TTTS, a single deepest pocket <2 cm is used to define oligohydramnios (American College of Obstetricians and Gynecologists, 2021c). When no measurable pocket of amnionic fluid is identified, the term *anhydramnios* is used.

By 18 weeks' gestation, the fetal kidneys are the main contributor to amnionic fluid volume. Selected renal abnormalities that lead to absent fetal urine production include bilateral *renal agenesis*, bilateral *multicystic dysplastic kidney*, unilateral renal agenesis with contralateral multicystic dysplastic kidney, and the infantile form of *autosomal recessive polycystic kidney disease*. Lower urinary abnormalities may also cause oligohydramnios because of fetal *bladder outlet obstruction* (Figs. 15-58 through 15-61, p. 300). Complex fetal genitourinary abnormalities such as *persistent cloaca* and *sirenomelia* similarly may result in a lack of amnionic fluid. With oligohydramnios before the mid-second trimester, particularly before 20 to 22 weeks, pulmonary hypoplasia is a significant concern. The prognosis is extremely poor unless fetal therapy is an option (Chap. 19, p. 377).

Oligohydramnios is also associated with exposure to drugs that block the renin-angiotensin system. These include angiotensin-converting enzyme (ACE) inhibitors, angiotensin-receptor blockers, and nonsteroidal antiinflammatory drugs (NSAIDs). When taken in the second or third trimester, ACE inhibitors and angiotensin-receptor blockers may result in fetal hypotension, renal hypoperfusion, and renal ischemia, leading to subsequent anuric renal failure (Bullo, 2012; Guron, 2000). Fetal skull bone hypoplasia and limb contractures also have been described (Schaefer, 2003). Additionally, NSAIDs can be associated with fetal ductus arteriosus constriction and impaired fetal urine production (Chap. 8, p. 151).

Oligohydramnios in the late second trimester or in the third trimester is often associated with uteroplacental insufficiency. A placental abnormality or a maternal complication such as preeclampsia or vascular disease are examples. Initially, ruptured membranes should be excluded. Then, particularly in the second trimester, a detailed ultrasound examination should be performed to search for fetal and placental abnormalities. If a placental hematoma or chronic abruption is sufficiently severe to result in oligohydramnios—the chronic abruption-oligohydramnios sequence (CAOS)—then it commonly also causes growth restriction (Chap. 43, p. 750).

Management

Oligohydramnios detected before 36 weeks' gestation in the presence of normal fetal anatomy and growth is generally managed expectantly and coupled with fetal surveillance (Chap. 20, p. 392). For late-preterm and early-term pregnancies, risks of fetal compromise outweigh potential complications of preterm delivery. The American College of Obstetricians and Gynecologists (2021b) recommends delivery between $36^{0/7}$ and $37^{6/7}$ weeks. In a review of 16 trials of pregnancies with apparent isolated oligohydramnios, oral or intravenous hydration was associated with a significantly improved AFI. However, it was unclear whether this translated into better pregnancy outcomes (Gizzo, 2015).

Outcomes

In a review of pregnancies with oligohydramnios at Parkland Hospital, Petrozella and associates (2011) found that an AFI <5 cm identified between 24 and 34 weeks' gestation was associated with increased risks for perinatal morbidity and mortality (Table 14-11). Similarly, a metaanalysis comprising more than 10,000 pregnancies found that oligohydramnios conferred a twofold risk for cesarean delivery due to nonreassuring fetal status and a fivefold risk for an Apgar score <7 at 5 minutes compared with pregnancies with a normal AFI (Chauhan, 1999).

As discussed, if oligohydramnios is defined as an AFI <5 cm rather than a single deepest pocket <2 cm, more pregnancies will be classified as such. Kehl and coworkers (2016) performed a prospective trial with more than 1000 term pregnancies in which women with an AFI <5 cm or a single deepest pocket <2 cm were randomly assigned to labor induction or expectant care. Significantly more pregnancies were diagnosed with oligohydramnios using the AFI criterion—10 percent compared with just 2 percent—when single deepest pocket was used. This led to a higher rate of labor induction in the AFI group but not to a difference in neonatal outcomes.

Borderline Oligohydramnios

This diagnosis is somewhat controversial. Also called *borderline AFI.* It usually refers to an AFI between 5 and 8 cm (Magann, 2011; Petrozella, 2011). During the mid-third trimester, an

TABLE 14-11. Pregnancy Outcomes in Women Diagnosed with Oligohydramnios between 24 and 34 Weeks' Gestation at Parkland Hospital

Factor	AFI ≤5 cm (n = 166)	AFI 8 to 24 cm (n = 28,185)	*p* Value
Major malformation	42 (25)	634 (2)	<.001
Stillbirth	8 (5)	133 (<1)	<.001
Gestational age at delivery[a]	35.1 ± 3.3	39.2 ± 2.0	<.001
Preterm birth, spontaneous[a]	49 (42)	1698 (6)	<.001
Preterm birth, indicated[a]	23 (20)	405 (2)	<.001
Cesarean delivery for nonreassuring fetal status[a]	10 (9)	1083 (4)	<.001
Birthweight <10th percentile[a]	61 (53)	3388 (12)	<.001
<3rd percentile[a]	43 (37)	1130 (4)	<.001
Neonatal death[a]	1 (1)	24 (<1)	<.001[b]

Data expressed as No. (%) and mean ± standard deviation.
[a]Anomalous infants excluded.
[b]This difference was no longer significant after adjustment for gestational age at delivery.
Data from Petrozella LN, Dashe JS, McIntire DD, et al: Clinical significance of borderline amniotic fluid index and oligohydramnios in preterm pregnancy. Obstet Gynecol 117(2 pt 1):338, 2011.

AFI value of 8 cm is below the 5th percentile on the Moore nomogram (see Fig. 14-7). Petrozella (2011) found that pregnancies between 24 and 34 weeks' gestation with an AFI between 5 and 8 cm were not more likely than those with an AFI >8 cm to have maternal hypertensive complications or an increased risk for stillbirth and neonatal death. Wood and colleagues (2014) reported a higher rate of fetal-growth restriction in pregnancies with borderline AFI but not an increase in rates of preterm delivery or need for neonatal intensive care. In a study of late-preterm pregnancies that were otherwise uncomplicated, borderline AFI conferred no increased risk for preterm delivery, nonreassuring fetal heart rate tracing, low Apgar score, or neonatal respiratory compromise (Sahin, 2018). Evidence is insufficient to support fetal surveillance or delivery in this setting (Magann, 2011).

DOPPLER

When sound waves strike a moving target, the frequency of the waves reflected back is shifted in proportion to the velocity and direction of that moving target—a phenomenon known as the *Doppler shift*. Because magnitude and direction of the frequency shift depend on the motion of a moving target, Doppler can help evaluate flow within blood vessels.

An important component of the Doppler equation is the angle of insonation, abbreviated as theta (θ) (Fig. 14-9). This is the angle between the sound waves from the transducer and flow within the vessel. Measurement error becomes large when θ is not close to zero, in other words, when blood flow is not coming *directly* toward or away from the transducer. For this reason, ratios are often used to compare different waveform components and allow cosine θ to cancel out of the equation. Figure 14-10 is a schematic of the Doppler waveform and describes the three ratios commonly used. The simplest is the *systolic-diastolic ratio (S/D ratio),* which compares the maximal (or peak) systolic flow with end-diastolic flow to evaluate downstream impedance to flow. Currently, two types of Doppler modalities are available for clinical use.

Continuous-wave Doppler equipment contains two types of crystals, one to transmit high-frequency sound waves and another to continuously capture signals. In M-mode imaging, continuous-wave Doppler is used to evaluate motion through time, however, it cannot image individual vessels.

Pulsed-wave Doppler uses only one crystal, which transmits the signal and then waits until the returning signal is received before transmitting another one. It allows precise visualization and color-flow mapping of the vessel of interest. By convention,

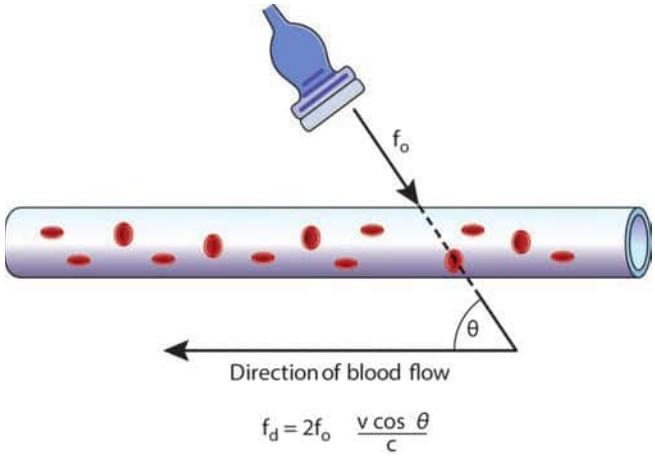

FIGURE 14-9 Doppler equation. Ultrasound emanating from the transducer with initial frequency f_o strikes blood moving at velocity v. Reflected frequency f_d is dependent on angle θ between beam of sound and vessel.

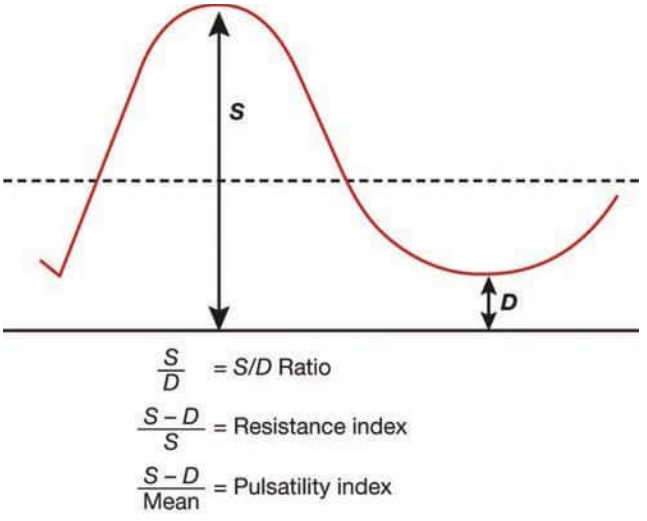

FIGURE 14-10 Doppler systolic–diastolic waveform indices of blood flow velocity. S represents the peak systolic flow or velocity, and D indicates the end-diastolic flow or velocity. The mean, which is the time-average mean velocity, is calculated from computer-digitized waveforms.

blood flowing toward the transducer is displayed in red and that flowing away from the transducer appears in blue.

Umbilical Artery

The umbilical artery differs from other vessels in that it normally has forward flow throughout the entire cardiac cycle. With advancing gestation, the amount of flow during diastole increases because of decreasing placental impedance. The S/D ratio approximates ≤4.0 after 20 weeks' gestation, <3.0 after 30 weeks', and close to 2.0 at term. More end-diastolic flow is observed at the placental cord insertion than at the fetal ventral wall, a reflection of downstream impedance to flow. Thus, abnormalities such as absent or reversed end-diastolic flow will appear first at the cord insertion site into the fetus. The International Society of Ultrasound in Obstetrics and Gynecology recommends that umbilical artery Doppler measurements be made in a free loop of cord (Bhide, 2013). However, assessment close to the ventral wall insertion may optimize measurement reproducibility in cases in which flow is diminished (Berkley, 2012).

The waveform is considered abnormal if the S/D ratio is >95th percentile for gestational age. Threshold values are listed in the Appendix (p. 1242). In extreme cases of growth restriction, end-diastolic flow can become absent or even reversed (Fig. 47, p. 830). Such reversal of end-diastolic flow has been associated with greater than 70-percent obliteration of the small muscular arteries in placental tertiary stem villi (Kingdom, 1997; Morrow, 1989).

Umbilical artery Doppler has been rigorously investigated to test of fetal well-being. As described in Chapter 47 (p. 830), this tool aids management of fetal-growth restriction and is associated with improved outcome in these cases (American College of Obstetricians and Gynecologists, 2019a). It is not recommended for other indications. Similarly, its use as a screening tool for growth-restriction is not advised (Berkley, 2012). Abnormal umbilical artery Doppler findings should prompt a detailed fetal evaluation, if not already done, because abnormal measurements are often associated with major fetal anomalies and aneuploidy (Wenstrom, 1991).

Ductus Arteriosus

Doppler evaluation of the ductus arteriosus is used primarily to monitor fetuses exposed to indomethacin and other NSAIDs. Indomethacin may cause ductal constriction or closure, particularly when used in the third trimester (Huhta, 1987). The resulting increased pulmonary flow can cause reactive hypertrophy of the pulmonary arterioles and eventual development of fetal pulmonary hypertension. In a review of 12 randomized trials involving more than 200 exposed pregnancies, Koren and coworkers (2006) reported that NSAIDs raised the odds of ductal constriction 15-fold. The risk is typically limited to drug use greater than 72 hours' duration. Monitoring for ductal constriction should be considered in such cases, so that the NSAID can be discontinued if ductal constriction is identified. Fortunately, effects are often reversible after NSAID discontinuation.

Uterine Artery

Uterine blood flow is estimated to rise from 50 mL/min early in gestation to 500 to 750 mL/min by term. The uterine artery Doppler waveform is characterized by high diastolic flow velocities and turbulent flow. Greater resistance to flow and development of a *diastolic notch* are associated with later development of gestational hypertension, preeclampsia, and fetal-growth restriction. Zeeman and associates (2003) also found that women with chronic hypertension who had elevated uterine artery impedance at 16 to 20 weeks' gestation were at greater risk to develop superimposed preeclampsia. However, the technique, best testing interval, and defining criteria for this indication have not been standardized. As the predictive value of uterine artery Doppler testing is considered to be low, its use for screening for hypertensive complications of pregnancy or for fetal-growth restriction is not recommended in either high-risk or low-risk pregnancies (American College of Obstetricians and Gynecologists, 2019a, 2020b).

Middle Cerebral Artery

Doppler velocimetry of the middle cerebral artery (MCA) has become the primary method of detecting fetal anemia and is central to surveillance of alloimmunized pregnancies. Anatomically, the path of the MCA is such that flow often approaches the transducer "head-on," which allows accurate determination of flow velocity (Fig. 14-11). The MCA is imaged in an axial view of the head at the base of the skull and ideally within 2 mm of the internal carotid artery origin. Velocity measurement is optimal when the insonating angle θ is close to zero, and no more than 30 degrees of angle correction should be used. In general, other fetal vessels are not suitable for velocity assessment, because a larger insonating angle is needed and confers significant measurement error.

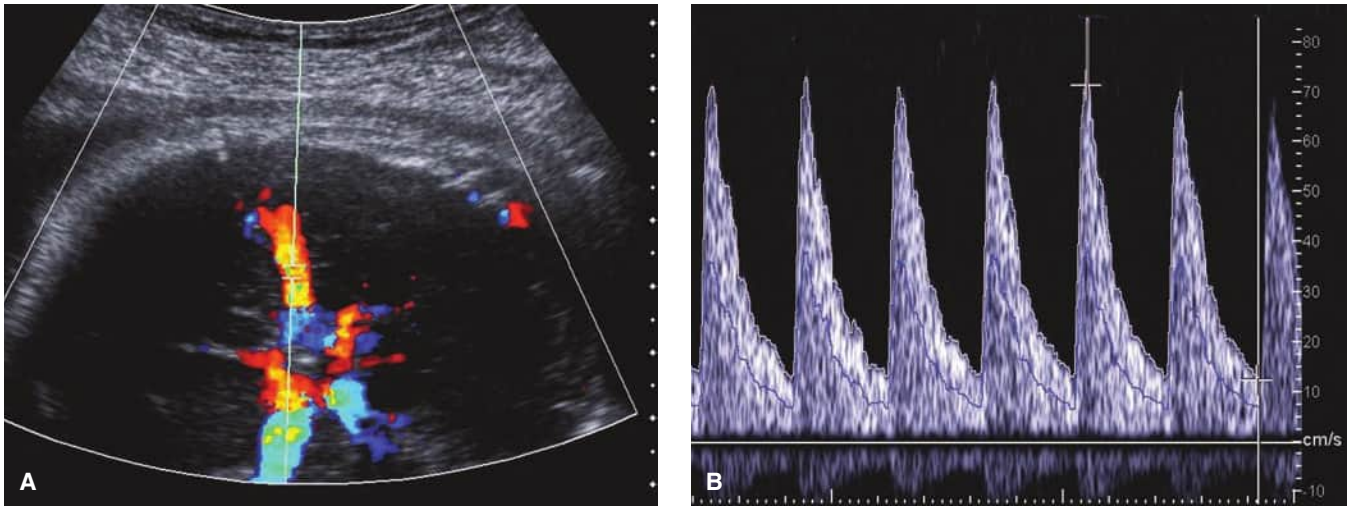

FIGURE 14-11 Middle cerebral artery (MCA) Doppler. **A.** Color Doppler of the circle of Willis demonstrates the correct location to sample the MCA. **B.** The waveform shows a peak systolic velocity exceeding 70 cm/sec in a 32-week fetus with severe fetal anemia secondary to Rh alloimmunization.

With fetal anemia, the *peak systolic velocity* is enhanced due to greater cardiac output and decreased blood viscosity (Segata, 2004). This permits the reliable, noninvasive detection of fetal anemia in cases of blood-group alloimmunization. Mari and colleagues (2000) demonstrated that an MCA peak systolic velocity threshold of 1.50 multiple of the median (MoM) could reliably identify fetuses with moderate or severe anemia. As discussed in Chapter 18 (p. 355), MCA peak systolic velocity has replaced invasive testing with amniocentesis as the preferred test for fetal anemia detection (Society for Maternal-Fetal Medicine, 2015a).

MCA Doppler has also been studied as an adjunct in evaluation of fetal-growth restriction (Chap. 47, p. 830). Fetal hypoxemia is associated with increased blood flow to the brain, heart, and adrenal glands, which leads to greater end-diastolic flow in the MCA. This phenomenon, called "brain-sparing," is actually a misnomer, as it does not protect the fetus but rather is associated with perinatal morbidity and mortality (Bahado-Singh, 1999; Cruz-Martinez, 2011). To evaluate redistribution of blood flow, investigators have studied a ratio of the MCA pulsatility index (PI) to the umbilical artery PI–termed the *cerebroplacental ratio*. Like the S/D ratio, the PI estimates downstream impedance to flow (Fig. 14-10). In the PORTO (Prospective Observational Trial to Optimize Paediatric Health in IUGR) study of ultrasound-dated pregnancies with estimated fetal weights <10th percentile, fetuses with a cerebroplacental PI ratio <1 had an 11-fold greater risk for adverse perinatal outcomes (Flood, 2014). Such findings can further our understanding of fetal pathophysiology. However, the utility of MCA Doppler to aid the timing of delivery is uncertain, and it has not been adopted as standard practice in the management of growth restriction (American College of Obstetricians and Gynecologists, 2021a; Martins, 2020).

■ Ductus Venosus

The fetal ductus venosus shunts oxygenated blood from the intrahepatic portion of the umbilical vein directly to the inferior vena cava, thus bypassing the liver (Fig. 7-9, p. 127). The ductus venosus is imaged as it branches from the umbilical vein at approximately the level of the diaphragm. The waveform is biphasic and normally has forward flow throughout the entire cardiac cycle (Fig. 14-12). The first peak reflects ventricular systole, and the second is ventricular diastolic filling. These are followed by a nadir during atrial contraction—termed the *a-wave*.

It is believed that Doppler findings in preterm fetuses with growth restriction show a progression in which umbilical artery Doppler abnormalities are followed by ones in the MCA and then in the ductus venosus. With severe fetal-growth restriction, cardiac dysfunction may lead to flow in the a-wave that is decreased, absent, and eventually reversed and to pulsatile flow in the umbilical vein (see Fig. 14-12). However, ductus venosus Doppler assessment has not improved perinatal outcomes, and neither the American College of Obstetricians and Gynecologists (2021a) nor the Society for Maternal-Fetal Medicine (Martins, 2020) recommend its use in the routine management of fetal growth-restriction.

MAGNETIC RESONANCE IMAGING

MR imaging is based on the excitation of hydrogen ions in the body by pulsing radiofrequencies with high field-strength magnets (1.5 to 3 Tesla). High-resolution fetal imaging is now possible, in part due to faster acquisition times of less than one second per slice. The relaxing hydrogen ions can be manipulated through various pulse sequences to produce different representations on images. The classic example is simple fluid, such as amnionic fluid or urine in the bladder, which appears bright on T2-weighted and dark on T1-weighted image acquisitions.

Image resolution with MR is often superior to that with sonography because MR is less hindered by bony interfaces, maternal obesity, oligohydramnios, or an engaged fetal head. Thus, it can complement sonography in evaluating suspected fetal abnormalities. Examples include complex abnormalities of the fetal thorax and of the central nervous, GI, genitourinary,

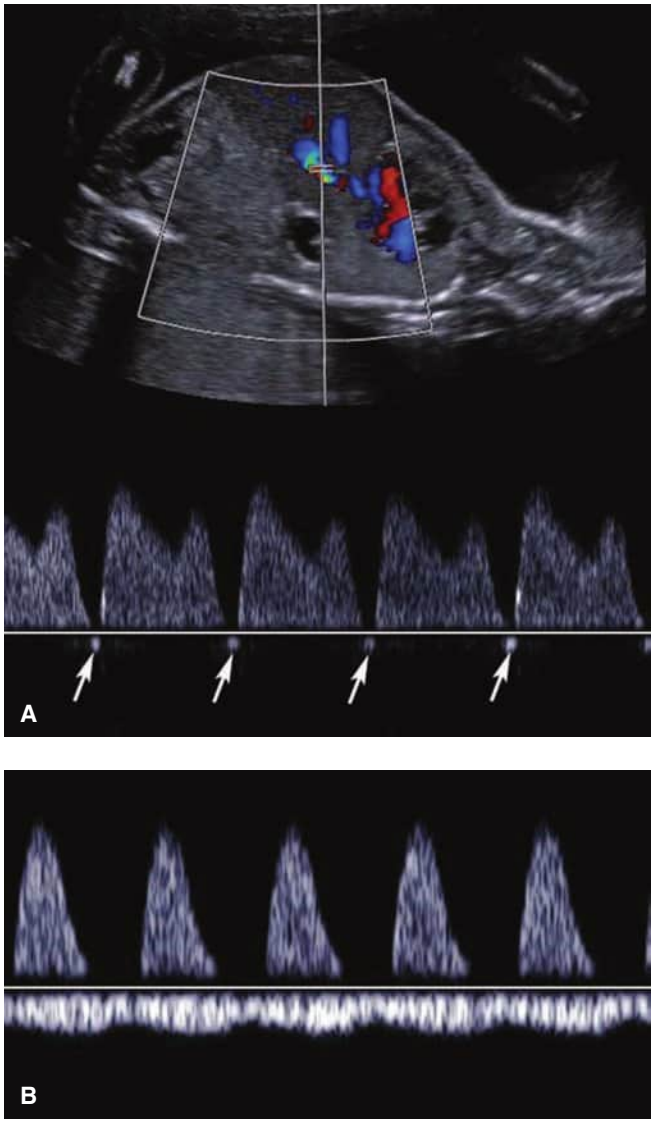

FIGURE 14-12 Venous Doppler abnormalities. **A.** Reversal of a-wave flow in the ductus venosus. Arrows depict a-waves below the baseline. This finding may be identified with cardiac dysfunction in the setting of severe fetal-growth restriction. **B.** Pulsatile flow in the umbilical vein. The undulating umbilical venous waveform below the baseline indicates tricuspid regurgitation. Above the baseline is the umbilical artery waveform, in which there is no visible end-diastolic flow. Because the venous waveform is below the baseline in this image, it is not possible to determine whether the umbilical artery end-diastolic flow is reversed.

and musculoskeletal systems. MR imaging is also used to evaluate maternal pelvic masses and placental invasion. This modality, however, is not portable, is time-consuming, and is generally limited to referral centers with expertise in fetal imaging.

To guide clinical use, the American College of Radiology and Society for Pediatric Radiology (2020b) have developed a practice guideline for fetal MR imaging. This document acknowledges the primacy of sonography as the preferred screening modality. Moreover, it recommends that fetal MR imaging be used for problem solving to contribute to prenatal diagnosis, counseling, treatment, and delivery planning. At Parkland Hospital, MR imaging is performed in 15 percent of pregnancies with major fetal abnormalities (Herrera, 2020). Specific indications are listed in Table 14-12 and are discussed subsequently (American College of Radiology, 2020b).

Safety

MR imaging is not associated with known adverse fetal effects if performed without administration of contrast media (Ray, 2016). It uses no ionizing radiation, and human and tissue studies support its safety (Clements, 2000; Reeves, 2010; Vadeyar, 2000; Wiskirchen, 1999). The strength of the magnetic field is measured in *tesla (T).* Both 1.5T and 3T fetal MR imaging can be done safely and successfully, assuming expertise of the imagers with the physical principles of MR (Prayer, 2017). All clinical examinations must adhere to the specific absorption rate, which is regulated by the FDA, and the ALARA principle should be followed. Specifically, the amount of heat generated in the MR is reflected in the specific absorption rate and must be monitored.

The Society for Pediatric Radiology recommends 3T MR imaging because of its improved signal-to-noise ratio, which results in better resolution (Barth, 2017). We prefer 1.5T for diagnostic imaging given its better field homogeneity. We reserve 3T for functional imaging, which requires higher field strength.

Gadolinium-based MR contrast agents are gadolinium (Gd^{3+}) chelates. These contrast agents enter the fetal circulation and are excreted via fetal urination into amnionic fluid. Here, they may remain for an indeterminate period before being ingested and reabsorbed. The longer time the gadolinium-chelate molecule remains in a protected space such as the amnionic sac, the greater the potential for dissociation of the toxic Gd^{3+} ion. In a population-based review from Ontario, children exposed to gadolinium-enhanced MR imaging in utero were at slightly increased risk for a broad set of rheumatological, inflammatory, or infiltrative skin conditions (Ray, 2016). In adults with renal disease, this contrast agent is associated with development of nephrogenic systemic fibrosis, a potentially severe complication. MR imaging with gadolinium is not recommended in pregnancy without a life-threatening indication.

Technique

Before MR imaging, all women complete a written safety questionnaire that includes information about metallic implants, pacemakers, or other metal- or iron-containing devices. High-level magnetization may cause dangerous movement in these devices, causing adjacent tissue damage and malfunction. (American College of Radiology, 2020a). Iron supplementation may cause image artifact in the colon but does not usually affect the resolution of fetal images. In more than 4500 MR procedures performed at Parkland Hospital in pregnancy during the past 18 years, <1 percent of our patients suffered maternal anxiety secondary to claustrophobia. To reduce anxiety in this small group, a single oral dose of diazepam, 5 to 10 mg, or lorazepam, 1 to 2 mg, may be given.

TABLE 14-12. Fetal Conditions for Which Magnetic Resonance Imaging May Be Indicated[a]

Brain and spine
Agenesis of the corpus callosum
Cavum septum pellucidum abnormalities
Cephalocele
Cerebral cortical malformation or migrational abnormalities
Family history conferring a risk for brain anomaly
Hemorrhage
Holoprosencephaly
Hydranencephaly
Infarctions
Monochorionic twin pregnancy complications
Neural-tube defects
Posterior fossa abnormalities
Sacral agenesis (caudal regression)
Sacrococcygeal teratoma
Sirenomelia
Solid or cystic masses
Vascular malformations
Ventriculomegaly
Vertebral anomalies

Skull, face, and neck
Facial clefts
Goiter
Hemangiomas
Teratomas
Venolymphatic malformations
Other abnormalities with potential airway obstruction

Thorax
Bronchogenic cyst or congenital lobar overinflation
Congenital cystic adenomatoid malformation
Diaphragmatic hernia
Effusions
Extralobar pulmonary sequestration
Esophageal atresia
Mediastinal masses
Evaluation of pulmonary hypoplasia secondary to diaphragmatic hernia, oligohydramnios, chest mass, or skeletal dysplasia

Abdomen, pelvis, and retroperitoneum
Abdominopelvic cystic mass
Bowel anomalies (anorectal malformations, complex obstructions)
Complex genitourinary anomalies (bladder outlet obstruction syndromes, bladder exstrophy, cloacal exstrophy)
Renal anomalies with oligohydramnios
Tumors (sacrococcygeal teratoma, neuroblastoma, hemangioma, suprarenal or renal masses)

Complications of monochorionic twins
Assess morbidity after death of a monochorionic co-twin
Determine vascular anatomy prior to laser treatment
Evaluate conjoined twins

Fetal surgery assessment
Anomalies for which fetal surgery is planned
Fetal brain anatomy before and after surgical intervention

[a]In some cases, magnetic resonance imaging is indicated only if the anomaly is suspected but cannot be adequately characterized sonographically, which is assessed on a case-by-case basis.
Summarized from American College of Radiology, Society for Pediatric Radiology: ACR-SPR practice parameter for the safe and optimal performance of fetal magnetic resonance imaging (MRI). Resolution No. 45, 2020.

To begin an MR examination, women are placed in a supine or left lateral decubitus position. A torso coil is used in most circumstances to send and receive the radiofrequency pulses, but a body coil can be used alone to accommodate large maternal habitus. A series of three-plane localizers, or scout views, are obtained relative to the maternal coronal, sagittal, and axial planes. The gravid uterus is imaged in the maternal axial plane (7-mm slices, 0 gap) with a T2-weighted fast acquisition. Typically, these may be a single-shot fast spin echo sequence (SSFSE), half-Fourier acquisition single-shot turbo spin echo (HASTE), or rapid acquisition with relaxation enhancement (RARE), depending on the machine. Next, a fast T1-weighted acquisition such as spoiled gradient echo (SPGR) is performed (7-mm thickness, 0 gap). These large-field-of-view acquisitions through the maternal abdomen and pelvis are particularly good for identifying fetal and maternal anatomy.

Orthogonal images of targeted fetal or maternal structures are then obtained. In these cases, 3- to 5-mm slice thickness, 0 gap T2-weighted acquisitions are performed in the coronal, sagittal, and axial planes. Depending on the anatomy and underlying suspected abnormality, T1-weighted images can be performed to evaluate for subacute hemorrhage, fat, or location of normal structures that appear bright on these sequences, such as liver and meconium in the colon (Brugger, 2006; Zaretsky, 2003b).

Short T1 inversion recovery (STIR) and frequency-selective fat-saturated T2-weighted images may help differentiation in cases in which the water content of the abnormality is similar to that of the normal structure. An example is a thoracic mass compared with normal lung. Diffusion-weighted imaging may be employed to evaluate for restricted diffusion, which can be seen in ischemia, cellular tumors, or clotted blood (Brugger, 2006; Zaretsky, 2003b).

Fetal Anatomy Evaluation

A fetal anatomical survey is generally completed during the MR examination, regardless of the fetal indication. Nearly 95 percent of anatomical components recommended by the International Society of Ultrasound in Obstetrics and Gynecology were visible at 30 weeks' gestation (Millischer, 2013). The aorta and pulmonary artery were the most difficult to evaluate. Zaretsky and coworkers (2003a) similarly found that with the exclusion of cardiac structures, fetal anatomical evaluation was possible in 99 percent of cases.

Central Nervous System

For intracranial anomalies, fast T2-weighted images produce excellent tissue contrast. Cerebrospinal fluid–containing structures appear bright, which allows exquisite detail of the posterior fossa, midline structures, and cerebral cortex. T1-weighted images are used to identify hemorrhage. CNS biometry obtained with MR imaging is comparable with that obtained using sonography, and nomograms are available for the corpus callosum and cerebellar vermis (Harreld, 2011; Katorza, 2016; Twickler, 2002; Xi, 2016).

MR imaging may provide valuable added information when cerebral abnormalities are identified or suspected sonographically (Benacerraf, 2007; Li, 2012). Additional information is more likely to be gained when the examination is performed beyond 24 weeks' gestation. In studies, MR imaging has identified additional CNS findings or led to a changed diagnosis in nearly 50 percent of cases and affected prognosis or management in 20 percent (Griffiths, 2017, Twickler, 2003).

MR imaging accurately portrays cerebral gyration and sulcation patterns (Fig. 14-13) (Levine, 1999). It may assist with identifying agenesis or dysgenesis of the corpus callosum and characterizing migrational abnormalities (Benacerraf, 2007; Li, 2012; Twickler, 2003). In cases of septo-optic dysplasia, MR imaging may confirm absence of the septum pellucidum and display hypoplastic optic tracts (Fig. 14-14). When fetal intracranial hemorrhage (ICH) is suspected, MR imaging can help to characterize the extent of bleeding and to estimate when bleeding occurred. Risk factors for fetal ICH include atypical-appearing ventriculomegaly, concern for neonatal alloimmune thrombocytopenia, and severe TTTS or demise of one monochorionic twin (Hu, 2006). With congenital fetal infections, MR imaging can delineate the variable degrees of neural parenchymal abnormality and subsequent maldevelopment (Soares de Oliveira-Szejnfeld, 2016).

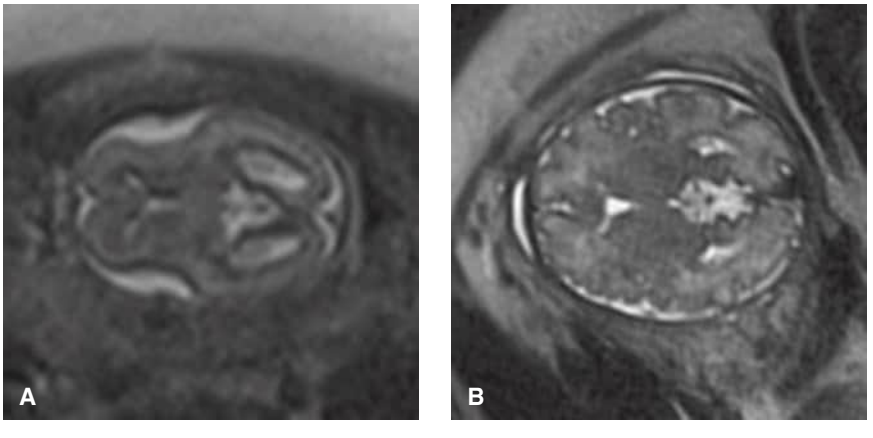

FIGURE 14-13 Axial images of the fetal brain demonstrate the normal gyration and sulcation progression during fetal development. **A.** 23 weeks' gestation. **B.** 33 weeks' gestation. These images were obtained using a Half Fourier Acquisition Single Shot Turbo Spin Echo (HASTE) sequence because it is relatively motion insensitive.

Thorax

MR imaging can delineate the location and size of space-occupying thoracic lesions and quantify the volume of lung tissue. If needed, it can characterize blood flow to a thoracic mass to differentiate cystic adenomatoid malformation from pulmonary sequestration (Chap. 15, p. 287). With congenital diaphragmatic hernia, MR imaging can help verify and quantify the abdominal organs within the thorax (Debus, 2013; Lee, 2011; Mehollin-Ray, 2012). This includes the volume

of herniated liver and of compressed lung tissue (Fig. 14-15). MR imaging can also measure lung volumes in pregnancies with prolonged oligohydramnios secondary to renal abnormalities or ruptured membranes (Messerschmidt, 2011; Zaretsky, 2005).

Abdomen

Meconium accumulation within the GI tract gives a predictable pattern and has high signal intensity on T1-weighted sequences. Thus, MR imaging is a complementary tool in diagnosing GI abnormalities and complex cloacal malformations (Furey, 2016). With cystic abdominal abnormalities, differences in signal characteristics may also help distinguish between meconium in the fetal colon and urine in the bladder (Farhataziz, 2005). Peritoneal calcifications related to meconium peritonitis are more readily apparent sonographically, whereas pseudocysts and resultant abnormalities of meconium migration are better delineated with MR imaging.

Adjunct to Fetal Therapy

Prior to fetal surgery, MR imaging is often used. In cases of myelomeningocele, it precisely displays brain and spine anatomy. For sacrococcygeal teratomas, if fetal surgery is considered, MR imaging may identify tumor extension into the fetal pelvis (Avni, 2002; Neubert, 2004; Perrone, 2018). When a fetal neck mass is identified with ultrasound, MR imaging may help delineate a lesion's extent and its mass effect on the oral cavity and trachea. This can help identify cases that are at risk for adverse outcome and that may benefit from an ex utero intrapartum treatment (EXIT) procedure (Lazar, 2012; Ogamo, 2005; Ng, 2019). MR imaging can also calculate a jaw index when an EXIT procedure may be needed for severe micrognathia (Kooiman, 2018; Morris, 2009). At some centers, before laser ablation of placental anastomoses for TTTS, MR imaging is performed to identify fetal ICH or periventricular leukomalacia (Hu, 2006; Kline-Fath, 2007). Fetal therapy is discussed in Chapter 19 (p. 367).

Placenta

Despite improvements in ultrasound detection of PAS, particularly when the placenta is anterior, characterization of the extent of invasion remains a challenge. MR findings concerning for invasion are depicted in Figure 14-16. They include dark intraplacental bands on T2-weighted images, a focal bulge, placental heterogeneity, involvement of the bladder-uterine

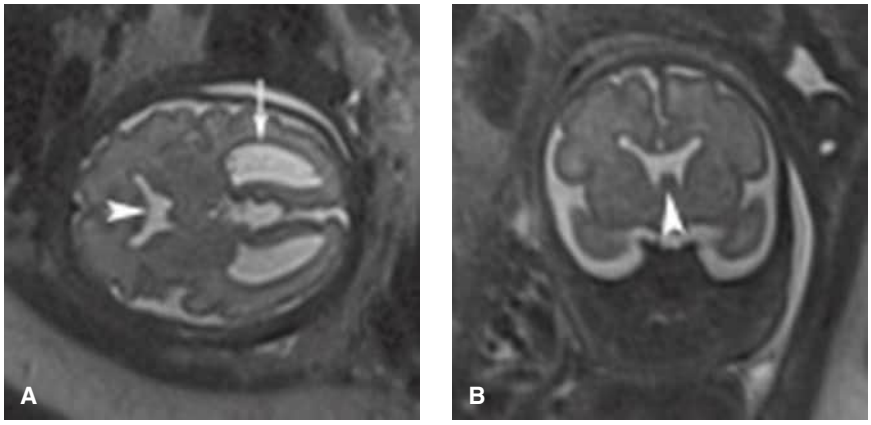

FIGURE 14-14 Septo-optic dysplasia. **A.** Axial. **B.** Coronal. Images at 30 weeks' gestation confirm absence of the cavum septum pellucidum (*arrowheads*) in both. There is also associated mild ventriculomegaly (*arrow*).

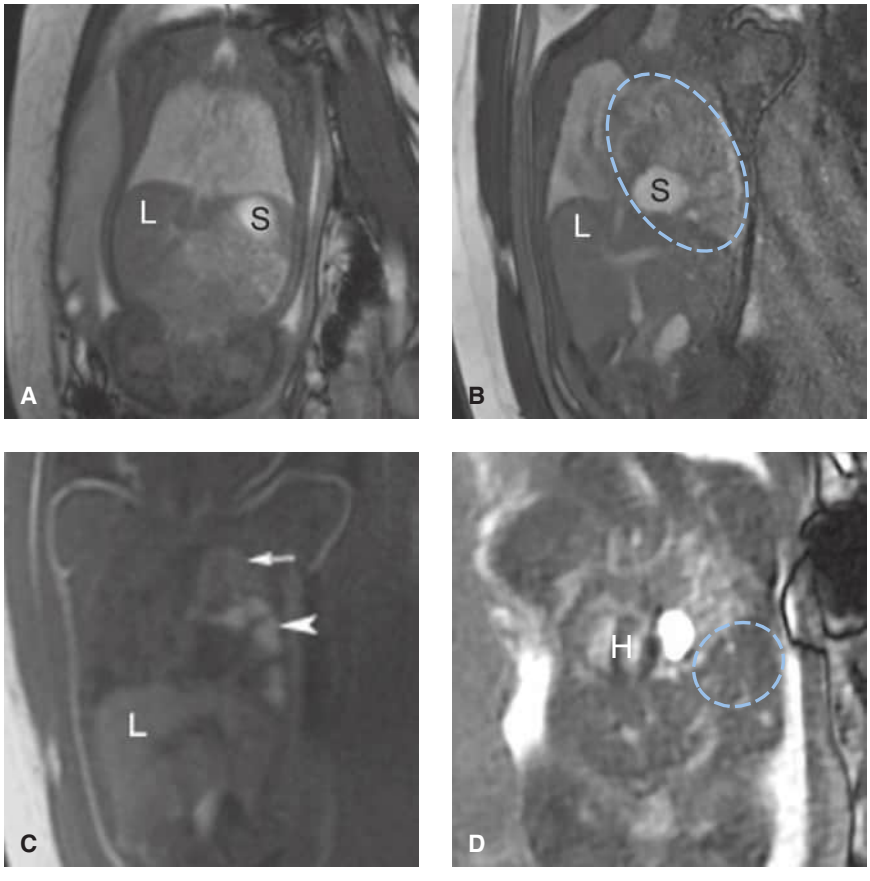

FIGURE 14-15 **A.** Coronal image of normal lungs on a balanced sequence at 29 weeks' gestation. The liver (*L*) and stomach (*S*) lie below the diaphragm. **B.** Left-sided congenital diaphragmatic hernia (CDH) (*dotted ellipse*) seen on balanced sequence at 33 weeks. **C.** The T1-weighted sequence confirms the subdiaphragmatic position of the liver and better delineates the small bowel (*arrow*) and meconium-containing colon (*arrowhead*) that have herniated into the chest. **D.** Another image of a left-sided CDH at 22 weeks demonstrates no normal lung, the heart (*H*) displaced into the right chest, and an elevated liver (*dotted ellipse*).

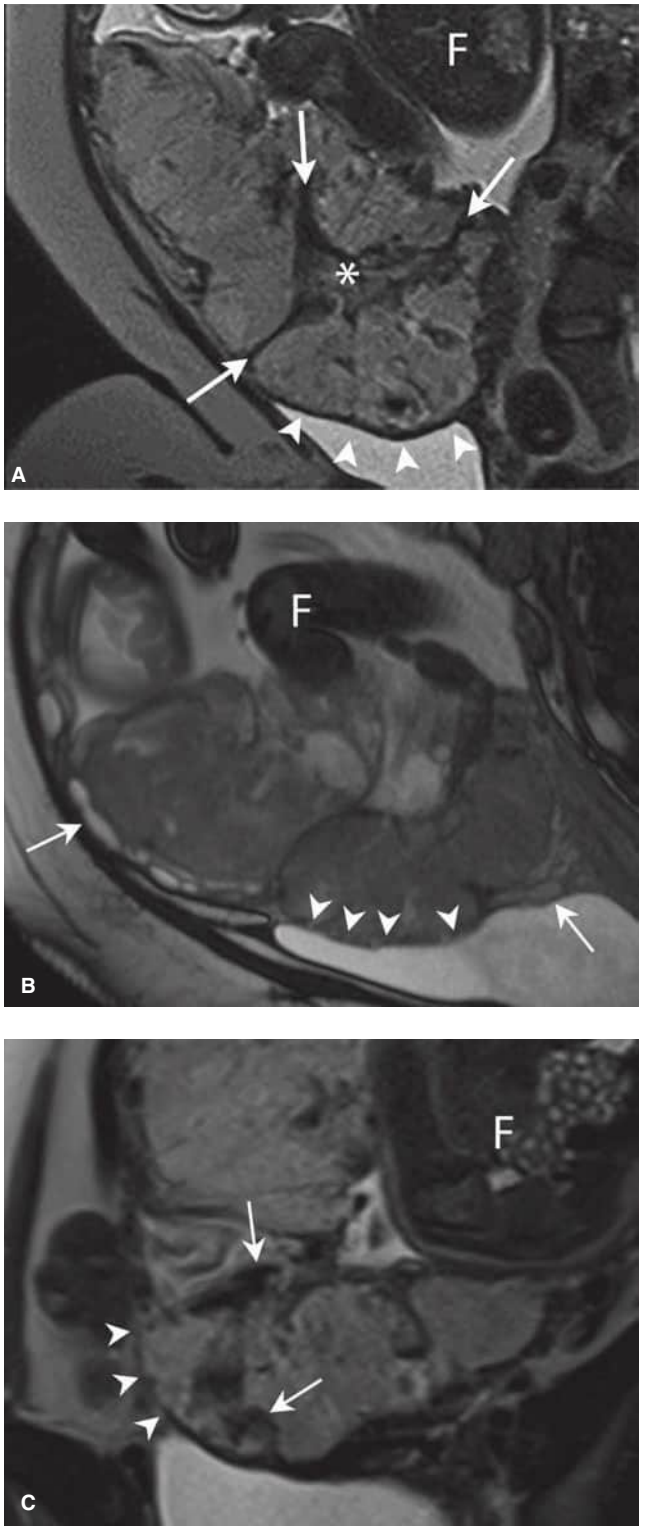

FIGURE 14-16 A. Sagittal T2-weighted image of the placenta demonstrates placenta accreta spectrum (PAS), in this case placenta percreta. There are intraplacental, dark, linear bands (*arrows*), a large bulge along the bladder-serosal interface (*arrowheads*), and a central area of marked inhomogeneity (*asterisk*). **B.** A coronal image from the same study demonstrates the bulge with right lateral extension (*arrowheads*) and multiple, dark, linear bands (*arrows*). **C.** A sagittal, balanced, steady state free precession (SSFE) image shows a bulge, retroplacental vessels, and irregularity of the bladder-serosal interface (*arrowheads*). These contrast with the large maternal varices (*arrows*). F = fetus.

serosal interface, and fibrin deposition (Clark, 2020; Leyendecker, 2012). When used to complement ultrasound, MR imaging's sensitivity to detect invasion is high. Clark and associates (2020) reported that MR imaging findings positively correlated with need for cesarean hysterectomy and with histological and surgical impressions of invasion. Clinical risk factors and ultrasound findings (p. 253) should be incorporated when interpreting MR placental images (Chap. 43, p. 759).

Two emerging technologies also are being employed to investigate placental insufficiency and PAS. Arterial spin labelling is a technique for functional assessment of perfusion and excites maternal red blood cells to serve as endogenous contrast agents (Zun, 2018). Second, radiomics textural analysis characterizes placental morphology in vivo. MR textural features may help select pregnancies requiring cesarean hysterectomy (Do, 2020).

CHAPTER 15

Normal and Abnormal Fetal Anatomy

The ability to detect and characterize abnormalities before birth is one of the marvels of modern obstetrics. Sonography can image the fetus with remarkable precision. Components of the standard anatomic survey are listed in Table 15-1. These have been termed *essential elements* by the American College of Obstetricians and Gynecologists (2020) and *minimal elements* by the American Institute of Ultrasound in Medicine (2018). Ideally, residency training in Obstetrics and Gynecology includes education in acquisition and interpretation of these views. Resources provided by national societies assist with this endeavor (Abuhamad, 2018).

A *detailed fetal anatomic survey* is a specialized examination that may include more than 60 components, each determined on a case-by-case basis. It is the primary method of evaluating at-risk pregnancies and characterizing fetal abnormalities, thereby aiding consultation and delivery planning. Indications are shown in Table 14-6 and discussed further in Chapter 14 (p. 251). At Parkland hospital, the detailed survey includes, at minimum, an attempt to visualize all components required by the American Institute of Ultrasound in Medicine for normal detailed case submission (see Table 15-1).

This chapter presents the standard and detailed anatomic surveys and some of the many fetal abnormalities that may be detected when visualization is optimal. When imaging or measuring any fetal structure, care should be taken to place the focal zone at the appropriate level and to magnify the image appropriately (Abuhamad, 2018). Whenever a fetal abnormality is identified, a detailed anatomic survey is recommended. With rare exception, amniocentesis with chromosomal microarray analysis also is offered. If a cardiac abnormality is identified, fetal echocardiography is indicated. Additional indications for these specialized examinations and for fetal magnetic resonance (MR) imaging are reviewed in Chapter 14.

BIOMETRY

In the first trimester, crown-rump length (CRL) measurement is used to establish or confirm gestational age (Appendix, p. 1234). The earlier that sonography is performed, the more accurate this estimation. Gestational age assessment is reviewed in Chapter 14 (p. 248). The fetus is imaged in the midsagittal plane in a neutral, nonflexed position so that its length can be measured in a straight line (Fig. 15-1). The average of three measurements is used. First-trimester nuchal translucency measurement is reviewed in Chapter 14 (p. 249).

In the second and third trimesters, the biparietal diameter, head circumference, abdominal circumference, and femur length are measured to confirm gestational age, if not already established in the

TABLE 15-1. Components of Standard and Detailed Anatomic Surveys

Standard Ultrasound	Detailed Ultrasound, Additional Components
Head, face, and neck	**Head, face, and neck**
Midline falx	Cranial integrity and shape[a]
Cavum septum pellucidum	Brain parenchyma[a]
Lateral ventricles	Lateral ventricle wall/lining and contour
Choroid plexus	Third ventricle
Cerebellum	Fourth ventricle
Cisterna magna	Corpus callosum
Upper lip	Cerebellar vermis[a] and lobes
Nuchal skinfold measurement, 15–20 weeks	Transverse cerebellar diameter
	Nasal bone measurement, 15–22 weeks[a]
	Profile[a]
	Coronal view of lenses, nose[a], lips
	Orbits with measurement
	Maxilla[a], mandible[a], palate, tongue
	Ear position, size
	Neck[a]
Thorax and heart	**Thorax and heart**
Situs	Interventricular septum
Heart rate (M-mode)	Superior/inferior venae cavae[a]
Four-chamber view of the heart	Aortic arch[a]
Left ventricular outflow tract	Ductal arch
Right ventricular outflow tract	3-vessel view[a]
3-vessel view, if feasible	3-vessel and trachea view[a]
3-vessel trachea view, if feasible	Lungs[a]
	Diaphragm integrity[a]
	Ribs
Abdomen	**Abdomen**
Stomach: presence, size, and situs	Bowel, small and large
Kidneys	Liver
Urinary bladder	Gallbladder
Umbilical cord insertion into fetal abdomen	Spleen
Umbilical cord vessel number	Renal arteries
	Adrenal glands
	Ventral wall integrity
Spine	**Spine**
Cervical, thoracic, lumbar, and sacral spine	Shape[a], curvature[a], conus medullaris
	Integrity of spine and overlying tissue[a]
Extremities (presence only)	**Extremities**
Arms and legs	Architecture, position, number[a]
Hands and feet	Long-bone measurements
	Fingers and toes (number, position)[a]
External genitalia	**External genitalia**
When indicated, e.g., multifetal gestation	

[a]In addition to all standard anatomy components, these detailed ultrasound components are required by the American Institute of Ultrasound in Medicine for normal cases submitted as part of the detailed ultrasound accreditation process. Modified from the American Institute of Ultrasound in Medicine, 2018, 2019, 2020a.

first trimester, and to estimate fetal weight. Ultrasound equipment and report packages calculate these estimates using standardized nomograms (Hadlock, 1991). If an abnormality involving one of the parameters is suspected, consideration is given to excluding it from the gestational age calculation. Fetal weight nomograms are available that do not include the head measurements or the femur measurement (Hadlock, 1984; Shepard, 1982).

The biparietal diameter and head circumference are measured in the *transthalamic view*. This is a transverse image that includes the midline falx cerebri, cavum septum pellucidum,

FIGURE 15-1 The crown-rump length measures 61 mm in this 12-week, 4-day fetus.

thalami, and insula (Fig. 15-2A). The cerebral hemispheres should appear symmetric, and the cerebellum should not be visible. The biparietal diameter is measured perpendicular to the falx cerebri, from the outer edge of the skull in the near field to the inner edge of the skull in the far field. The head circumference is measured by placing an ellipse around the outer edge of the skull. The head circumference may also be calculated by averaging the biparietal diameter and the occipito-frontal diameter and multiplying by π.

The abdominal circumference is measured in a transverse image that includes the stomach and the J-shaped confluence of the umbilical vein with the portal sinus. An ellipse is placed just outside the fetal skin edge (Fig. 15-2B). The image should appear as round as possible and ideally contain no more than 1 rib on either side. The spine should be visible in cross-section at the 3 o'clock or 9 o'clock position, whereas the kidneys should not be visible, as they are lower in the abdomen. Abdominal circumference is the biometric parameter most affected by fetal growth. An abdominal circumference below the 10th percentile may be used to diagnose fetal-growth restriction (Chap. 47, p. 825).

The femur length is measured with the ultrasound beam perpendicular to the long axis of the shaft. Calipers are placed at each end of the calcified diaphysis (Fig. 15-2C). Throughout the second and third trimesters, the femur length to abdominal circumference ratio is normally 20 to 24 percent. If this ratio is below 18 percent, a skeletal dysplasia should be considered, particularly if other long-bone measurements are lagging (p. 302). As discussed in Chapter 17 (p. 340), a mildly foreshortened femur length measurement is also a minor marker for Down syndrome (Herrera, 2020b).

Various nomograms exist for other fetal structures, including the transverse cerebellar diameter, ocular distances, nasal bone, ear length, jaw index, thoracic circumference, and lengths of the liver, kidneys, long bones, and feet. They may be used to address specific questions regarding organ system abnormalities, congenital infection, or genetic syndromes (Appendix, pp. 1238–1241).

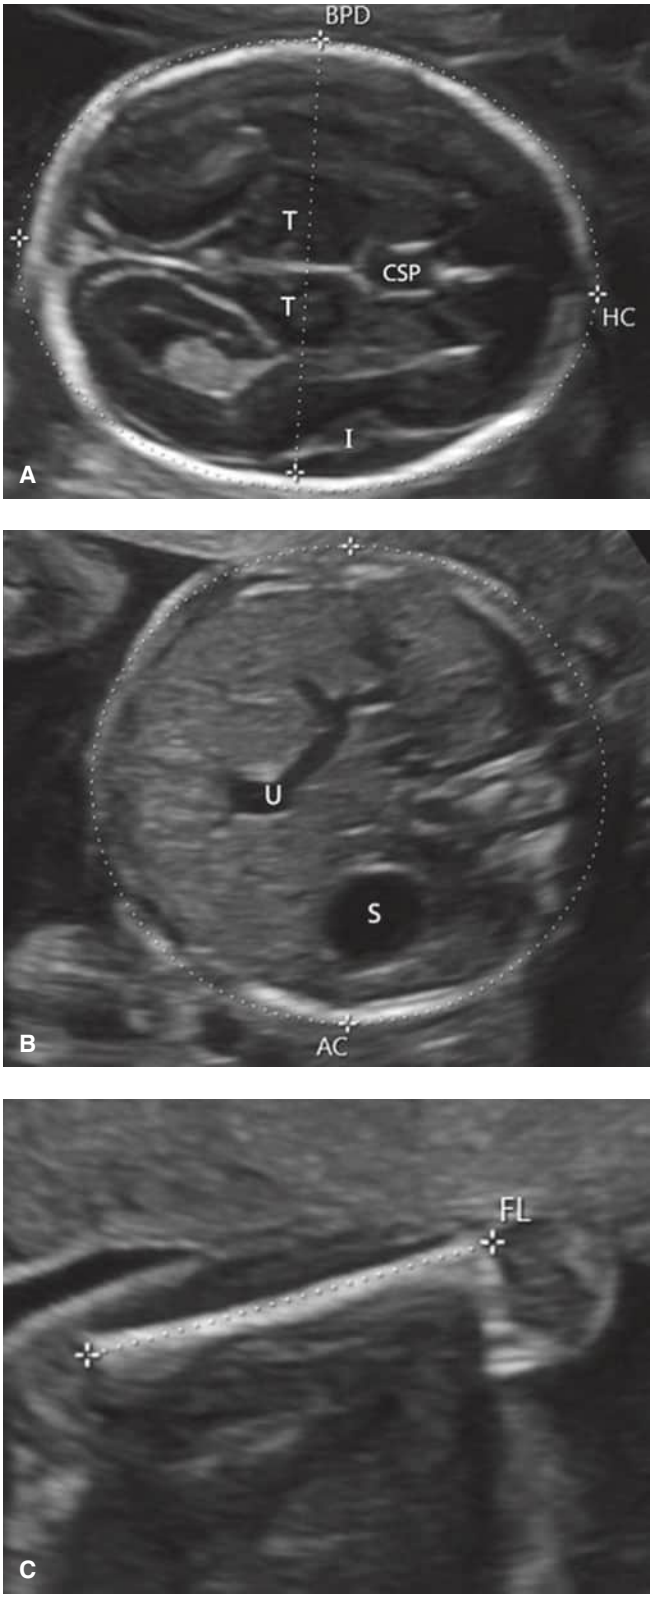

FIGURE 15-2 Normal biometry. **A.** Transthalamic view depicts measurement of the biparietal diameter (*BPD*) and head circumference (*HC*). Landmarks include the cavum septum pellucidum (*CSP*), thalami (*T*), and insula (*I*). **B.** Abdominal circumference view (*AC*) shows measurement and landmarks, which include the stomach (*S*) and the confluence of the umbilical vein (*U*) and the left portal vein. **C.** Femur length measurement (*FL*).

BRAIN AND SPINE

Standard sonographic evaluation of the fetal brain includes three transverse (axial) views. As noted, the *transthalamic view* should contain the midline falx cerebri, cavum septum pellucidum (CSP), thalami, and insula (see Fig. 15-2A). The CSP is the space between the two laminae that separate the frontal horns of the lateral ventricles. It should be visible between approximately 17 and 37 weeks' gestation, but after this, fusion of the septi pellucidi may obliterate the cavum. Inability to visualize a normal CSP may indicate a midline brain abnormality (Fig. 15-3). For example, the frontal horns are widely spaced apart in agenesis of the corpus callosum (ACC), whereas in cases of septo-optic dysplasia (de Morsier syndrome) and lobar holoprosencephaly, the frontal horns communicate. Discussed in Chapter 16 (p. 312), an abnormally wide CSP may also be found with trisomy 18.

The *transventricular view* lies superior to the transthalamic view and, as the name implies, includes the lateral ventricles. The ventricles are measured at their atrium, which is the confluence of the temporal and occipital horns (Fig. 15-4). The measurement is normally 5 to 9 mm throughout the second and third trimesters. Cerebrospinal fluid is produced within the ventricles by the *choroid plexus.* Choroid plexus cysts are present in 0.5 to 2 percent of uncomplicated pregnancies and approximately 30 to 50 percent of pregnancies with trisomy 18 (Fig. 16-5, p. 312) (Reddy, 2014). A detailed ultrasound examination is generally offered when found. In the absence of an associated ultrasound abnormality, or unless an aneuploidy screening test indicates increased risk for trisomy 18, a choroid plexus cyst is considered a normal variant.

For the *transcerebellar view*, the transducer is angled back through the posterior fossa (Fig. 15-5). Structures visible in this image include the

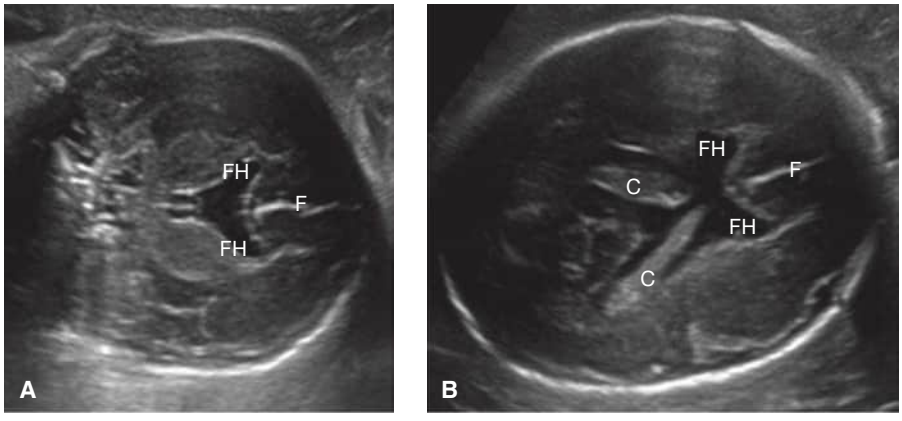

FIGURE 15-3 Absence of the cavum septum pellucidum, with coronal **(A)** and transverse **(B)** images showing communication between the frontal horns (*FH*) of the lateral ventricles. This may be isolated but can occur in the setting of septo-optic dysplasia or lobar holoprosencephaly. C = choroid plexus; F = falx cerebri.

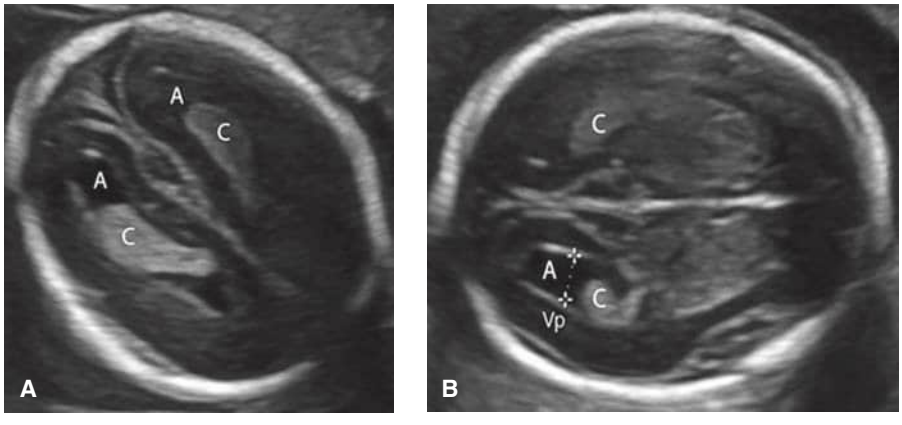

FIGURE 15-4 Transventricular view. **A.** Transverse image of the lateral ventricles, which contain the choroid plexus (*C*). **B.** The ventricles are measured at the atria (*A*), the confluence of the temporal and occipital horns. The measurement is normally 5–9 mm. Vp = lateral ventricle. (Reproduced with permission from Rosa Robles, RDMS.)

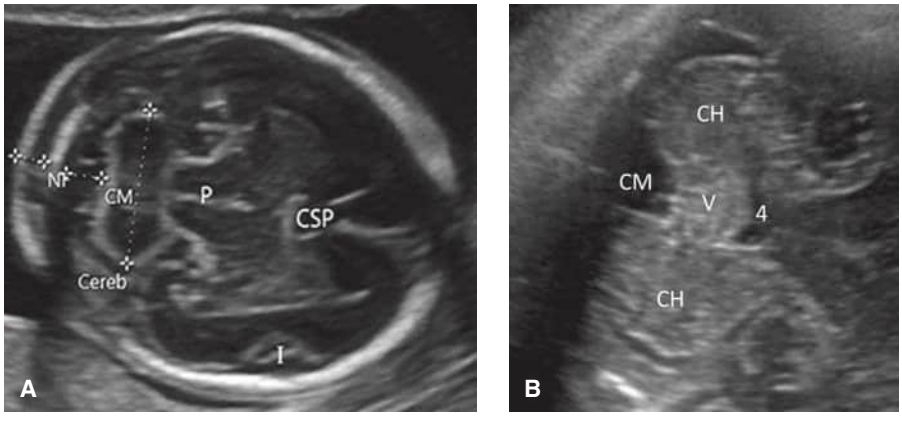

FIGURE 15-5 Transcerebellar view. **A.** Transverse image of the posterior fossa showing measurement of the cerebellum (*Cereb*), cisterna magna (*CM*), and nuchal skinfold thickness (*NF*). **B.** Third-trimester image depicting the cerebellar hemispheres (*CH*) and cerebellar vermis (*V*). The fourth ventricle (4) is anterior to the vermis. CSP = cavum septum pellucidum; I = insula; P = cerebral peduncles.

midline falx cerebri, cavum septum pellucidum, thalami, cerebellum, and cisterna magna. The cerebellum and cisterna magna are measured, and between 15 and 20 weeks' gestation, the nuchal skinfold thickness also is measured. From 15 until 22 weeks, the cerebellar diameter in millimeters is roughly equivalent to the gestational age in weeks (Chavez, 2003). *Cerebellar hypoplasia* has been associated with various central nervous system (CNS) and non-CNS abnormalities (Howley, 2018). The cisterna magna should measure between 2 and 10 mm throughout the second trimester and may reach 12 mm in the latter part of the third trimester. It becomes effaced when the Chiari II malformation is present (p. 277). If the cisterna magna is enlarged, the differential diagnosis includes absence of all or part of the vermis (p. 279), a cyst such as an arachnoid cyst within the posterior fossa, or mega-cisterna magna, which is a diagnosis of exclusion and has an excellent prognosis. An increased nuchal skinfold measurement is associated with increased risk for Down syndrome, other genetic syndromes, and structural abnormalities (Chap. 17, p. 341).

Imaging of the spine includes evaluation of the cervical, thoracic, lumbar, and sacral regions (Fig. 15-6). Representative images are often obtained in the sagittal or coronal plane. However, imaging of each spinal segment in the transverse plane is more sensitive for anomaly detection. Transverse images demonstrate three ossification centers. The anterior ossification center is the vertebral body, and the posterior paired ossification centers represent the junction of vertebral laminae and pedicles. Ossification of the spine proceeds in a cranial-caudal fashion. The ossification of the upper sacrum (S_1-S_2) is not generally visible before 16 weeks' gestation, and ossification of the entire sacrum may not be visible until 21 weeks (De Biasio, 2003). Thus, detection of some spinal abnormalities can be challenging in the early second trimester.

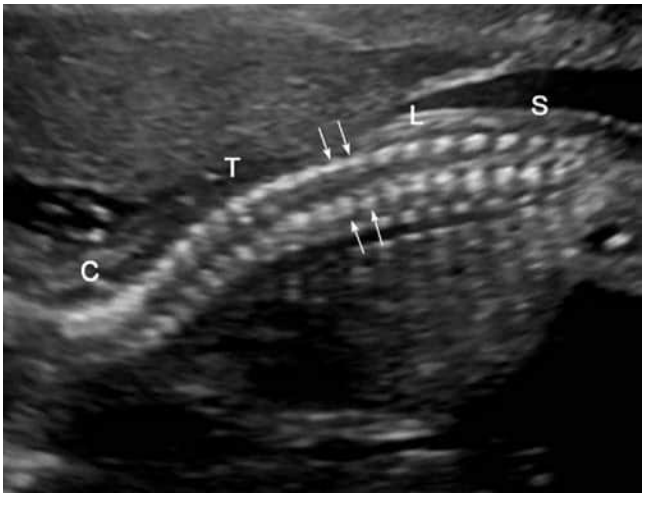

FIGURE 15-6 Normal fetal spine. This sagittal image depicts the cervical (*C*), thoracic (*T*), lumbar (*L*), and sacral spine (*S*). Arrows denote the parallel rows of paired posterior ossification centers, which represent the junction of vertebral lamina and pedicles.

Neural-tube Defects

These defects include anencephaly, myelomeningocele (spina bifida), cephalocele, and rare spinal dysraphisms. Normally, the neural tube closes by the embryonic age of 26 to 28 days (Chap. 7, p. 124). The birth prevalence of neural-tube defects approximates 0.9 in 1000 in the United States and most of Europe and 1.3 in 1000 in the United Kingdom (Cragan, 2009; Dolk, 2010). Many neural-tube defects can be prevented with folic acid supplementation. When isolated, neural-tube defect inheritance is multifactorial, and the recurrence risk without periconceptional folic acid supplementation is 3 to 5 percent (Chap. 16, p. 324).

Screening for neural-tube defects may be performed with either ultrasound alone or ultrasound in addition to maternal serum alpha-fetoprotein (MSAFP) level measurement (American College of Obstetricians and Gynecologists, 2019a). Between 15 and 20 weeks' gestation, an upper MSAFP threshold of 2.5 multiples of the median (MoM) is anticipated to detect 95 percent with fetal anencephaly and 80 percent with myelomeningocele. However, detection with standard sonography is at least comparable to that with MSAFP (Dashe, 2006; Norem 2005). A detailed ultrasound examination is the preferred diagnostic test and may identify other abnormalities or conditions that also elevate MSAFP levels (Table 17-5, p. 338).

Anencephaly is an absence of the cranium and telencephalon above the level of the skull base and orbits (Fig. 15-7). *Acrania* is absence of the cranium with protrusion of disorganized brain tissue, and herniation of the latter tissue is *exencephaly*. Importantly, brain tissue visible in the late first trimester is often not seen when ultrasound is performed in the second or third trimester. Thus, anencephaly is the final stage of exencephaly. It is often diagnosed in the late first trimester, and with adequate visualization, virtually all cases may be diagnosed in the second trimester.

Sonographically, the cranial contour may appear abnormal in the first trimester and may resemble a "shower cap" in the late first or early second trimester. The face often appears triangular, and sagittal images demonstrate lack of an ossified cranium. Hydramnios from impaired fetal swallowing is common in the third trimester. Anencephaly is uniformly lethal. If the pregnancy is continued, perinatal palliative care consultation should be considered (American College of Obstetricians and Gynecologists, 2019b).

Cephalocele is the herniation of meninges through a cranial defect, typically located in the midline occipital region (Fig. 15-8). When brain tissue herniates through the skull defect, the anomaly is termed an *encephalocele.* Herniation of the cerebellum and other posterior fossa structures constitutes a *Chiari III malformation*. Microcephaly is common by the third trimester. Associated intracranial abnormalities are frequently visible, and survivors have a high incidence of neurological deficits and intellectual disability. Cephalocele is an important feature of the autosomal recessive *Meckel-Gruber syndrome*, which includes cystic renal dysplasia and polydactyly. A cephalocele not located in the occipital midline raises suspicion for *amnionic-band sequence* (Chap. 6, p. 113).

FIGURE 15-7 Anencephaly/acrania. **A.** This transabdominal image at 11 weeks' gestation depicts relatively subtle absence of the cranium. **B.** A transvaginal image at 11 weeks demonstrates more clearly the protrusion of a disorganized mass of brain tissue. **C.** By 14 weeks, this tissue resembles a "shower cap." CRL = crown–rump length.

FIGURE 15-8 Encephalocele. This transverse image depicts a large defect in the occipital region of the cranium (*arrows*) through which meninges and brain tissue have herniated.

Spina bifida is characterized by defects in the vertebrae, typically the dorsal arches, and subsequent exposure of the meninges and nerve roots. The prevalence approximates 1 in 2000 births (Cragan, 2009; Dolk, 2010). Herniation of a meningeal sac and neural elements is a *myelomeningocele* (Fig. 15-9A). Less commonly, only an empty meningeal sac herniates, which is a *meningocele.* Transverse images are helpful to demonstrate separation or splaying of the lateral processes and characterize the level of the defect. Most cases are *open spina bifida*, which means that the defect includes skin and soft tissues. Closed defects are skin-covered and more challenging to detect prenatally.

Detection of spina bifida is aided by two characteristic cranial findings (Nicolaides, 1986). Flatting or scalloping of the frontal bones is termed the "*lemon sign,*" and anterior curvature of the cerebellum with effacement of the cisterna magna is the "*banana sign*" (Fig. 15-9B,C). These findings are manifestations of the Arnold-Chiari or Chiari II malformation. This develops when downward displacement of the spinal cord pulls a portion of the cerebellum through the foramen magnum and into the upper cervical canal. The biparietal diameter measurement often lags behind the other biometric parameters. *Ventriculomegaly* is common after mid-gestation, and 80 to 90 percent of infants with myelomeningocele require ventriculoperitoneal

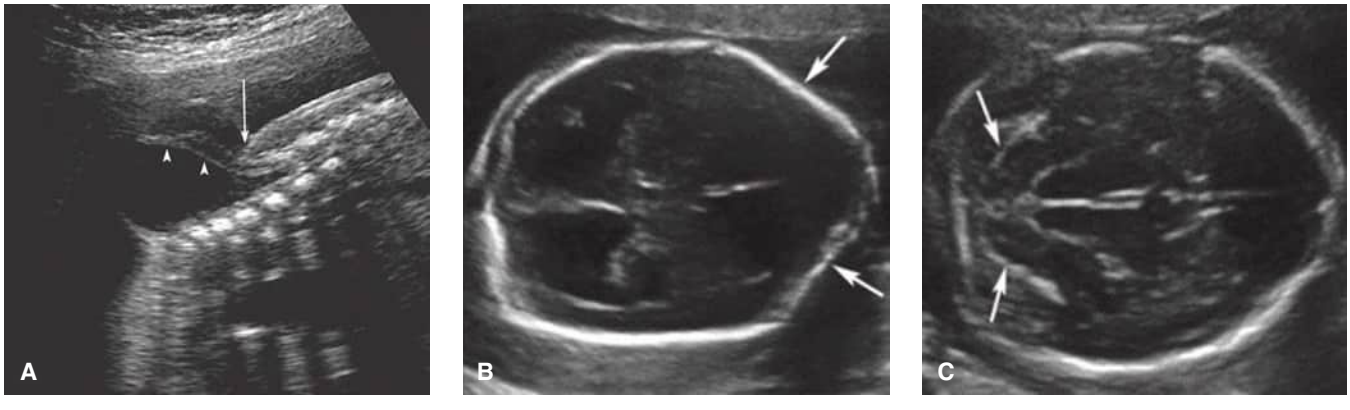

FIGURE 15-9 Myelomeningocele. **A.** Sagittal image of a lumbosacral myelomeningocele. Arrowheads indicate nerve roots within the anechoic herniated sac. The overlying skin abruptly stops at the defect (*arrow*). **B.** Transthalamic image demonstrating flattening of the frontal bones (*arrows*)—the *lemon sign*. **C.** Transcerebellar image depicting the *banana sign*, an anterior curvature of the cerebellum (*arrows*) and effacement of the cisterna magna.

shunt placement (Adzick 2011, Chao, 2010). Affected children require multidisciplinary care to address problems related to the defect such as deficits in swallowing, bladder and bowel function, and ambulation. Fetal myelomeningocele surgery is discussed in Chapter 19 (p. 372).

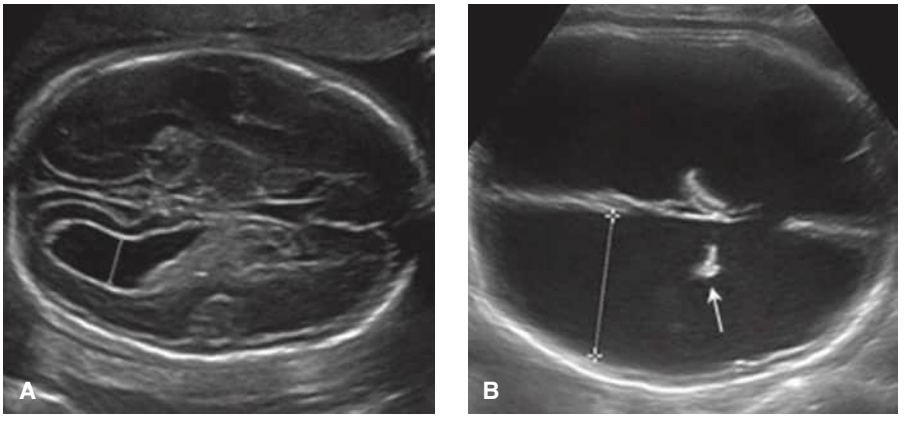

FIGURE 15-10 Ventriculomegaly. **A.** Mild ventriculomegaly. The atria measured 11 mm. No associated abnormality or underlying etiology was identified. **B.** Severe ventriculomegaly. In this fetus with aqueductal stenosis, the atria measured 45 mm. Arrow denotes the dangling choroid plexus.

Ventriculomegaly

Distention of the lateral ventricles is considered a nonspecific marker of abnormal brain development (Pilu, 2018). *Mild ventriculomegaly* is diagnosed when the atrial width measures 10 to 12 mm; *moderate ventriculomegaly*, when the measurement is 13 to 15 mm; and *severe ventriculomegaly* when >15 mm (Society for Maternal-Fetal Medicine, 2018). Representative images are depicted in Figure 15-10. The choroid plexus may appear *dangling* in severe cases.

Ventriculomegaly may occur secondary to a variety of central nervous system abnormalities and is associated with numerous genetic and infectious etiologies. Initial evaluation includes a detailed examination of fetal anatomy, amniocentesis for chromosomal microarray analysis, and testing for congenital infections such as cytomegalovirus and toxoplasmosis (Chap. 16, p. 326). Genetic syndromes resulting in ventriculomegaly include L1 X-linked aqueductal stenosis, Joubert syndrome, Walker Warburg syndrome, hydrolethalus syndrome, and lissencephaly syndromes (Kousi, 2016). Ventriculomegaly does not typically result in significant skull enlargement. Two exceptions—when macrocrania often occurs—are aqueductal stenosis and the asymmetric ventriculomegaly interhemispheric cyst callosal dysgenesis (AVID) syndrome (Oh, 2019). Fetal MR imaging should be considered to assess for associated abnormalities that may not be detectable sonographically (Herrera, 2020a; Katz, 2018) (Chap. 14, p. 263).

Prognosis is determined by etiology, severity, and progression. In a systematic review of nearly 1500 mild to moderate cases, 1 to 2 percent were associated with congenital infection; 5 percent, with aneuploidy; and 12 percent, with neurological abnormality (Devaseelan, 2010). With chromosomal microarray analysis, genetic abnormalities may be identified in 10 to 15 percent (Society for Maternal-Fetal Medicine, 2018). The larger the atria, the greater the likelihood of an underlying CNS abnormality and subsequent abnormal outcome (Gaglioti, 2009; Joó, 2008). If ventriculomegaly is isolated and remains mild, development is normal in at least 90 percent, and if moderate, development is normal in at least 75 percent (Society for Maternal-Fetal Medicine, 2018). Progression significantly raises the likelihood of abnormal neurological development.

Agenesis of the Corpus Callosum

The corpus callosum is a major fiber bundle that connects reciprocal regions of the cerebral hemispheres. It is best viewed in the midsagittal plane, and color Doppler may demonstrate the pericallosal artery (Fig. 15-11). Agenesis of the corpus callosum has characteristic sonographic findings. The frontal horns are widely separated, and the occipital horns are rounded—which is called colpocephaly. Together these findings give the lateral ventricles a teardrop shape (Fig. 15-12). A normal cavum septum pellucidum is not visible because of frontal horn displacement. In the midline, *bundles of Probst* represent fiber tracts that no longer cross in the midline. Ventriculomegaly is not uncommon, and without the corpus callosum bordering the third ventricle superiorly, the third ventricle may be elevated and mildly enlarged.

In population-based series, agenesis of the corpus callosum occurs in 1 in 4000 to 5000 pregnancies (Ballardini, 2018; Stoll, 2019; Szabo, 2011). It is associated with other anomalies, aneuploidy, and more than 200 genetic syndromes. Thus, chromosomal microarray analysis should be offered, and genetic counseling can be challenging. In a review of apparently isolated cases, fetal MR imaging identified additional brain abnormalities in more than 20 percent of cases (Sotiriadis, 2012). If MR imaging does not identify associated abnormalities, normal developmental outcome in 67 to 75 percent of cases and severe disability in about 10 percent has been reported (des Portes, 2018; Sotiriadis, 2012).

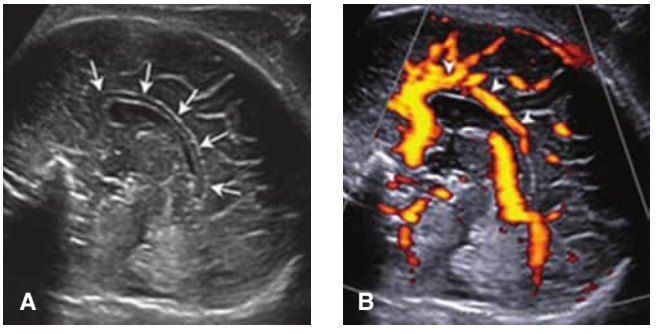

FIGURE 15-11 Normal corpus callosum. **A.** Arrows point to the corpus callosum in this midsagittal image. **B.** Power Doppler image of the pericallosal artery (*arrowheads*).

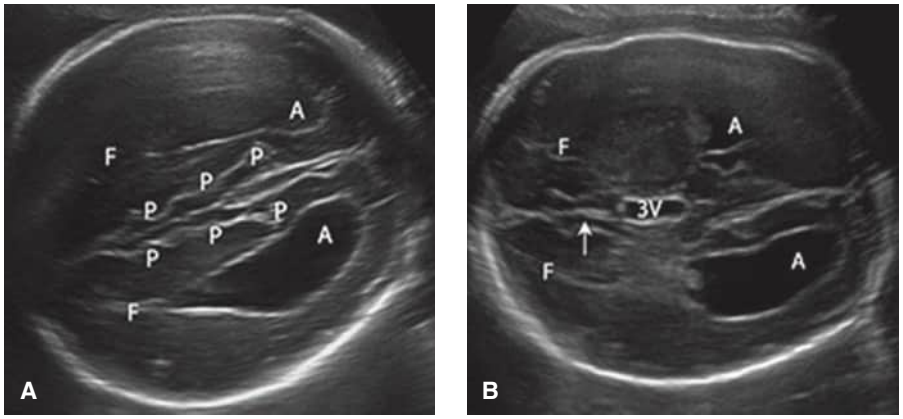

FIGURE 15-12 Agenesis of the corpus callosum. **A.** This transverse image demonstrates a teardrop-shaped ventricle. The frontal horns (*F*) are widely separated, no cavum septum pellucidum is visible, and bundles of Probst (*P*) line the midline. **B.** There is mild ventriculomegaly, no cavum septum pellucidum is visible (*arrow*), and the third ventricle (*3V*) is elevated and enlarged. A = atria.

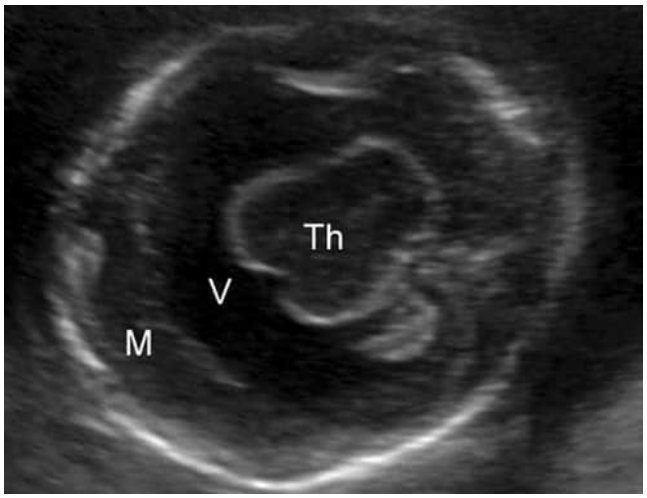

FIGURE 15-13 Alobar holoprosencephaly. The thalami (*Th*) are fused and encircled by a monoventricle (*V*) with a covering mantle (*M*) of cortex. The midline falx is absent. (Reproduced with permission from Rafael Levy, RDMS.)

Holoprosencephaly

During early normal brain development, the prosencephalon or forebrain divides as it becomes the telencephalon and diencephalon. With holoprosencephaly, the prosencephalon fails to divide completely into two separate cerebral hemispheres and underlying paired diencephalic structures. The most severe form, *alobar holoprosencephaly,* is characterized by a single monoventricle that surrounds fused thalami (Fig. 15-13). In *semilobar holoprosencephaly*, hemispheres partially separate. *Lobar holoprosencephaly* refers to a variable degree of fusion of frontal structures and is more challenging to detect with prenatal ultrasound. The lobar form is among possible diagnoses when a normal cavum septum pellucidum cannot be visualized. Last, the *middle interhemispheric variant of holoprosencephaly* is characterized by communication between the midportion of the bodies of the lateral ventricles with separation of the frontal horns, such that the choroid plexus may prolapse from one lateral ventricle into the other. Differentiation into two cerebral hemispheres is induced by prechordal mesenchyme, which is also responsible for differentiation of the midline face. Craniofacial anomalies associated with holoprosencephaly are reviewed later (p. 283).

The birth prevalence of holoprosencephaly is only 1 in 10,000. However, the abnormality has been identified in nearly 1 in 250 early abortuses, which attests to extremely high in-utero lethality (Orioli, 2010; Yamada, 2004). The alobar form accounts for 40 to 75 percent of cases, and 30 to 40 percent have a numerical chromosomal abnormality, particularly trisomy 13 (Orioli, 2010; Solomon, 2010). Conversely, of trisomy 13 cases, two thirds are found to have holoprosencephaly.

Dandy-Walker Malformation

This posterior fossa abnormality is characterized by agenesis of the cerebellar vermis, posterior fossa enlargement, and elevation of the tentorium cerebelli. The cerebellar hemispheres are visibly separated, and fluid in the cisterna magna communicates with the fourth ventricle through the cerebellar vermis defect (Fig. 15-14). The birth prevalence approximates 1 in 12,000 (Long, 2006). Associated anomalies and aneuploidy are common. These include ventriculomegaly in 30 to 40 percent, other anomalies in approximately 50 percent, and aneuploidy in 40 percent (Ecker, 2000; Long, 2006). Dandy-Walker malformation is also associated with numerous genetic and sporadic syndromes, congenital viral infections, and teratogen exposure, all of which greatly affect the prognosis. Thus, the initial evaluation mirrors that for ventriculomegaly (p. 278).

Inferior vermian agenesis is a term used when only the inferior portion of the vermis is absent. Even with partial and relatively subtle vermian agenesis, the prevalence of associated anomalies and aneuploidy is still high, and the prognosis is often poor (Ecker, 2000; Long, 2006).

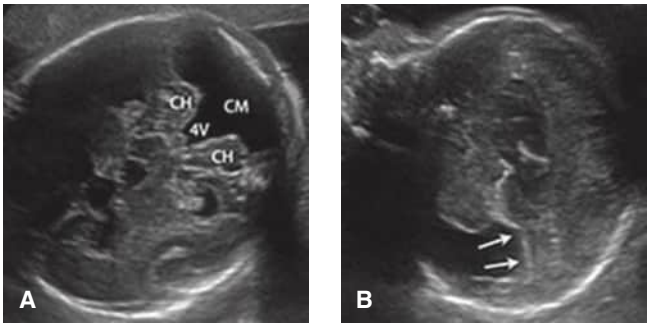

FIGURE 15-14 Dandy-Walker malformation. **A.** The cerebellar hemispheres (*CH*) are widely separated by a fluid collection that connects the 4th ventricle (*4V*) to the enlarged cisterna magna (*CM*). **B.** Sagittal image depicts elevation of the tentorium (*arrows*).

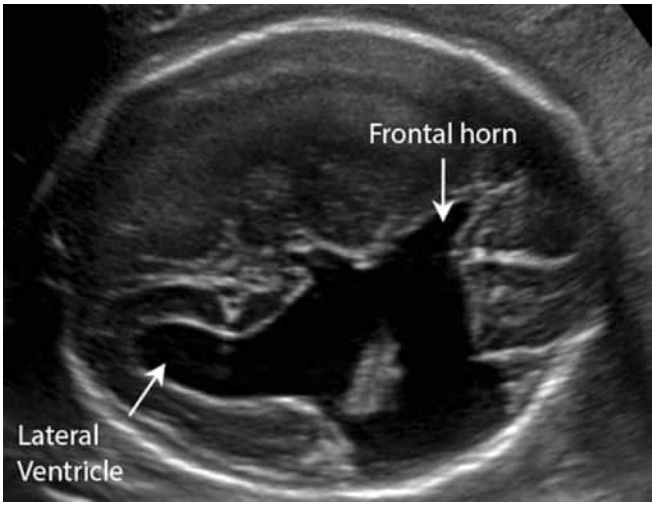

FIGURE 15-15 Schizencephaly. This transverse image shows a large cleft extending from the right lateral ventricle through the cortex. Because the borders of the cleft are separate, the defect is termed *open-lipped*. (Reproduced with permission from Michael Davidson, RDMS.)

Schizencephaly and Porencephaly

Schizencephaly is a rare brain abnormality characterized by clefts in one or both cerebral hemispheres, typically involving the perisylvian fissure. The cleft is lined by heterotopic gray matter and communicates with the ventricle, extending through the cortex to the pial surface (Fig. 15-15). Schizencephaly is believed to be an abnormality of neuronal migration, which explains its typically delayed recognition until after midpregnancy (Howe, 2012). It is associated with absence of the cavum septum pellucidum, resulting in frontal horn communication. Ventriculomegaly is a common finding.

In contrast, porencephaly is a cystic space within the brain that is lined by white matter and may or may not communicate with the ventricular system. It is generally considered to be a destructive lesion. Porencephaly may develop following intracranial hemorrhage in the setting of neonatal alloimmune thrombocytopenia or in an individual with a COL4A-1 mutation—a genetic condition which causes *familial porencephaly*. In a monochorionic twin gestation, acute hypotension following death of a co-twin also may create porencephaly. Fetal MR imaging should be considered when either of these CNS anomalies is identified.

Microcephaly

This condition indicates that the size of the head is profoundly smaller than expected. The Society for Maternal-Fetal Medicine (2016) recommends that fetal microcephaly be defined as a head circumference at least 3 standard deviations (SD) below the mean for gestational age (Appendix, p. 1237). However, many fetuses with measurements in this range have normal head size at birth, and therefore the diagnosis of pathologic microcephaly is not considered *certain* until the head circumference reaches 5 SD below the mean (Society for Maternal-Fetal Medicine, 2016). The forehead is often upsloping. Microcephaly is associated with a wide range of underlying abnormalities, genetic syndromes, and congenital infections such as toxoplasmosis, rubella, and cytomegalovirus, herpes, or Zika infection (Chap. 67, p. 1183). Findings that suggest infection include parenchymal and periventricular echogenic foci, ventriculomegaly, and cerebellar hypoplasia. Amniocentesis should be offered, and fetal MR imaging should be considered. The Society for Maternal-Fetal Medicine (2016) recommends performing a detailed ultrasound examination of the fetal brain if the head circumference measures more than 2 SD below the mean. Another ultrasound evaluation follows in 3 or 4 weeks, with the understanding that it may be difficult to distinguish constitutionally small head size from pathologic findings.

Sacrococcygeal Teratoma

This germ cell tumor is one of the most common tumors in neonates, with a birth prevalence of approximately 1 in 28,000 (Derikx, 2006; Swamy, 2008). It is thought to arise from the totipotent cells along the Hensen node, anterior to the coccyx. Sacrococcygeal teratoma (SCT) classification includes four types (Altman, 1974). Type 1 is predominantly external with a minimal presacral component; type 2 is predominantly external but with a significant intrapelvic component; type 3 is predominantly internal and has abdominal extension; and type 4 is entirely internal with no external component. The tumor histological type may be mature, immature, or malignant.

Sonographically, SCT is a solid and/or cystic mass that arises from the anterior sacrum and usually extends inferiorly and externally as it grows (Fig. 15-16). Solid components often vary in echogenicity, appear disorganized, and may enlarge rapidly with advancing gestation. Fetal MR imaging should be considered because internal pelvic components may be challenging to visualize. Large, solid tumors frequently result in hydrops due to high-output cardiac failure, either as a consequence of tumor vascularity or secondary to bleeding within the tumor and resultant anemia. Hydramnios is common. Fetuses with tumors >5 cm often require cesarean delivery, and classical hysterotomy may be needed (Gucciardo, 2011). Fetal therapy for SCT is discussed in Chapter 19 (p. 373).

Caudal Regression Sequence

This rare anomaly is characterized by absence of the sacral spine and often portions of the lumbar spine. It is approximately 25 times more prevalent in pregnancies complicated by diabetes (Garne, 2012). Caudal regression is associated with genitourinary malformations and syndromes such as the VACTERL association (vertebral defects, anal atresia, cardiac defects, tracheo-esophageal fistula, renal anomalies, and limb abnormalities) (Vilanova-Sanchez, 2018). Sonographic findings include a spine that appears abnormally short, lacks normal lumbosacral curvature, and terminates abruptly above the level of the iliac wings (Fig. 15-17). Because the sacrum does not lie between the iliac wings, they are abnormally close together and may appear shield-like. The lower extremities lack normal soft tissue development and may be abnormally positioned.

Sirenomelia

This rare anomaly may be confused with caudal regression sequence but is quite different. Formerly termed mermaid

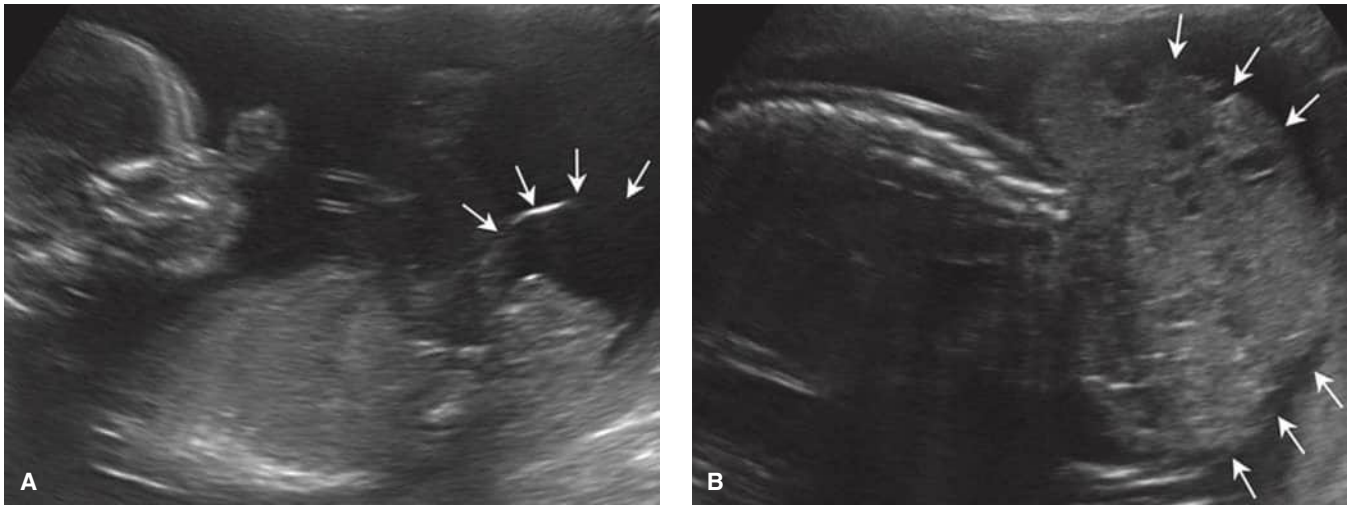

FIGURE 15-16 Sacrococcygeal teratoma. This tumor enlarged from 3 cm in diameter at 19 weeks' gestation **(A)** to 9 cm in diameter during a 5-week period **(B)**. Arrows depict the external borders of the mass.

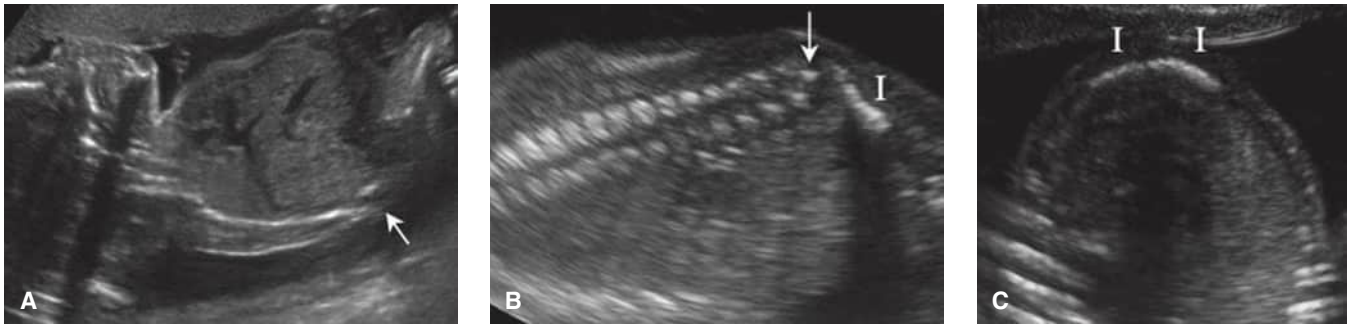

FIGURE 15-17 Caudal regression sequence. **A.** The spine is markedly foreshortened. The arrow shows where it terminates. **B.** The spine ends abruptly above the level of the iliac wings (*I*). **C.** Without a vertebral body between the iliac wings (*I*), they assume a shield shape.

syndrome, it is characterized by a single lower extremity in the midline and bilateral renal agenesis. The extremity may contain one or two sets of bones and feet (Fig. 15-18). The bladder, anus, and genitalia are absent. What may appear to be a single umbilical artery in these cases is instead a remnant of the vitelline artery. After 18 weeks' gestation, when the kidneys become the primary source of amniotic fluid production, resultant anhydramnios may complicate the diagnosis. Cases of surviving infants have a variant of sirenomelia in which there is some functioning renal tissue and urinary output (Pinette, 2005).

■ Hemivertebrae

These spinal *segmentation-fusion defects* are characterized by abnormal development of half of the vertebral

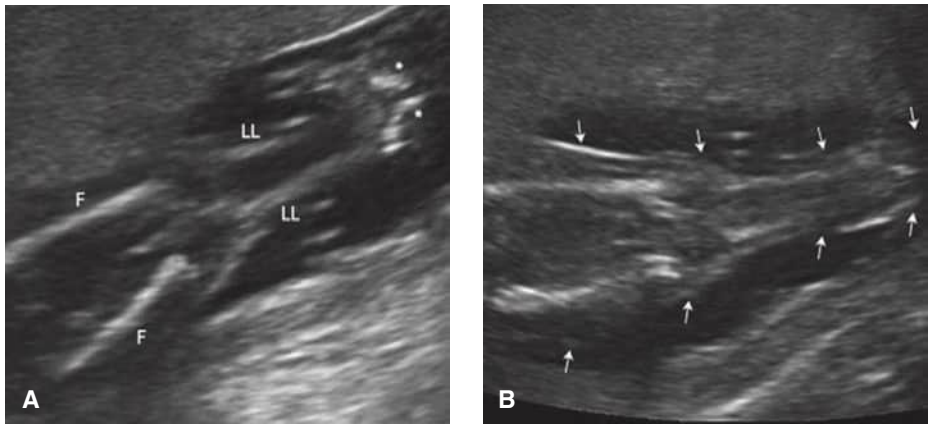

FIGURE 15-18 Sirenomelia. **A.** This single lower extremity contained two femur bones (*F*), two lower leg bones (*LL*), and a fused foot with toes pointing outward (*). **B.** Arrows show the soft tissue outline of the lower extremity. Amnionic fluid is visible only because the gestational age is 17 weeks' gestation. By 18 weeks, absence of kidneys and bladder resulted in anhydramnios. (Reproduced with permission from Melissa Salvie, RDMS.)

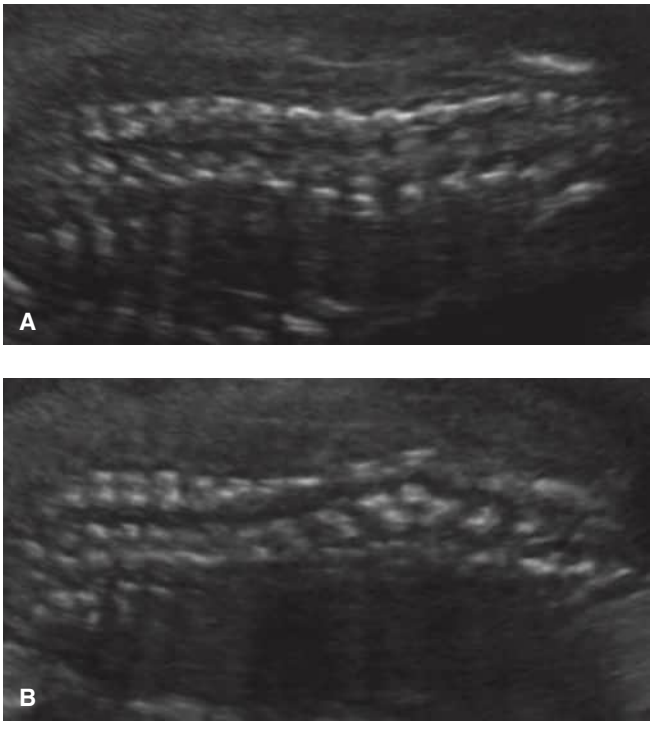

FIGURE 15-19 Hemivertebrae result in abnormal spinal curvature in these coronal images. (Reproduced with permission from Rose Muli, RDMS.)

body. Affected vertebrae are triangular and may be separate or fused to adjacent vertebral bodies. This leads to abnormal curvature of the spine such as scoliosis (Fig. 15-19). Prenatally diagnosed cases typically involve the thoraco–lumbar spine. Associated abnormalities are common, particularly skeletal, renal, and cardiac defects (Basude, 2015; Yulia, 2020). Hemivertebrae are also a component of several syndromes, including the VACTERL association.

HEAD, FACE, AND NECK

Craniofacial anatomy on the detailed anatomic survey may include cranial integrity and shape of the skull (Fig. 15-2A); images of the orbits, nose, and lips; views of the maxilla, mandible, hard palate, and tongue; images of the ears; and evaluation of the neck (Fig. 15-20). Of these structures, only the upper lip is a component of the standard examination. At Parkland Hospital, we include an image of the sagittal profile as part of our standard examination to help detect micrognathia prenatally.

When imaging the neck, particularly in the third trimester, identifying a nuchal cord is not uncommon (Fig. 15-21). This finding is not associated with adverse outcome, and we do not alter fetal surveillance if a nuchal cord is detected.

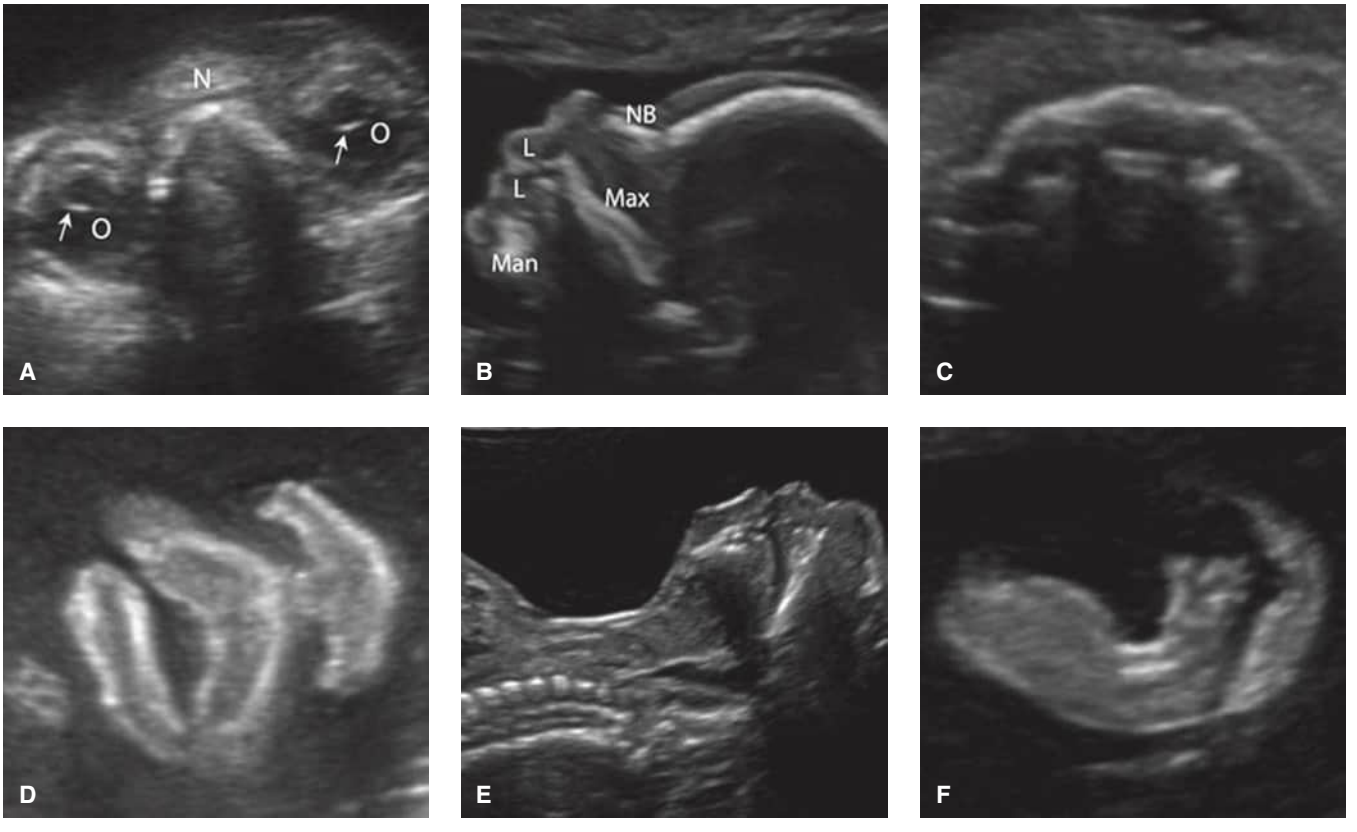

FIGURE 15-20 Normal craniofacial and neck anatomy. **A.** Transverse images of orbits (*O*) and nose (*N*). The small circle within each orbit is the lens. The distance between the orbits roughly approximates the width of each orbit. **B.** Sagittal view of the face, depicting the nasal bone (*NB*), lips (*L*), maxilla (*Max*), and mandible (*Man*). **C.** Transverse image of the alveolar ridge. **D.** Coronal view of the nose, upper lip, and lower lip. **E.** Sagittal image of the neck. **F.** Image of the ear. FIGURE 15-21 Nuchal cord incidentally noted with color Doppler in a transverse image of the fetal neck at 34 weeks' gestation.

■ Dolichocephaly and Brachycephaly

The *cephalic index* reflects the skull shape. It is measured by dividing the biparietal diameter by the occipitofrontal diameter. The cephalic index is normally 70 to 86 percent. It is smaller if the head shape is flattened—*dolichocephaly,* and larger if the shape is rounded—*brachycephaly.* In such cases, the head circumference measurement more reliably estimates gestational age than does the biparietal diameter (Fig. 15-22). These head shape variants may be normal or can be secondary to fetal position or oligohydramnios. Dolichocephaly can occur with neural-tube defects, and brachycephaly may be seen in fetuses with Down syndrome. A strawberry-shaped skull describes a pattern of angulation typical of trisomy 18 (Fig. 16-5, p. 312). With any abnormal skull shape, *craniosynostosis* is a consideration.

■ Abnormalities of Orbits and Nose

Subjectively, the distance in between the orbits is similar to the diameter of each orbit (see Fig. 15-20). The lens is often visible. Nomograms are available for the ocular diameter and for the interorbital and binocular distances (Appendix, p. 1240).

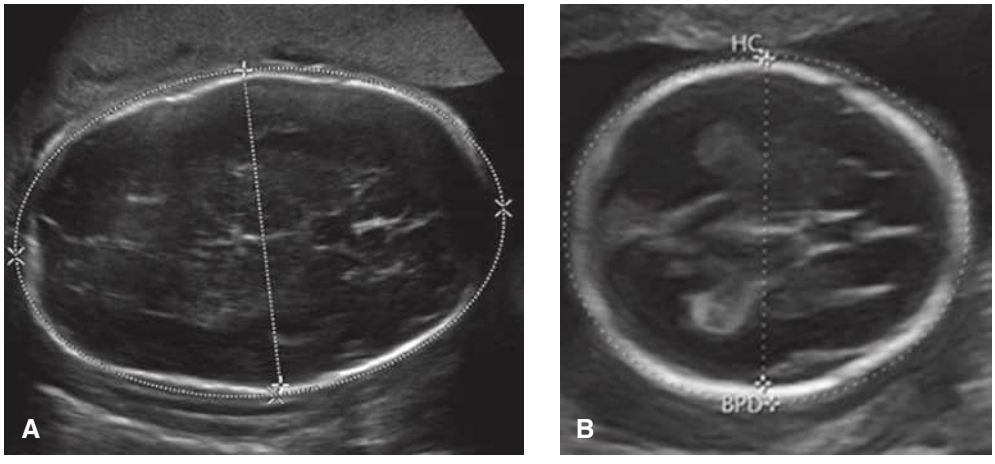

FIGURE 15-22 Transthalamic images demonstrating dolichocephaly **(A)** and brachycephaly **(B)**. The biparietal diameter (*BPD*) and head circumference (*HC*) are measured in each image.

Hypertelorism (Fig. 15-23) is a common finding in trisomy 18. Hypotelorism, with or without microphthalmia, may be found in the setting of holoprosencephaly. In its extreme form only a single orbit is visible—cyclopia. Other comorbid anomalies with holoprosencephaly include a single nostril—cebocephaly, or absence of the entire nose (arhinia) with proboscis (Fig. 15-24).

Nasal bone hypoplasia or sonographic absence is an aneuploidy marker that confers increased risk for fetal Down syndrome (Fig. 15-25). It is not a structural abnormality. Nasal bone measurement is part of the detailed ultrasound examination and is measured only between 15 and 22 weeks' gestation. The measurement is considered foreshortened if less than 2.5 mm or if more than 2 SD below the mean for gestational age (Chap. 17, p. 341). Hypoplasia of the nose is a different condition that can occur following warfarin exposure (Fig. 8-4, p. 156).

■ Facial Clefts

These are grouped into three main types. The first type, *cleft lip and palate*, always involves the lip, may also involve the hard palate, can be unilateral or bilateral, and has a birth prevalence that approximates 1 in 1000 (Cragan, 2009; Dolk, 2010). If isolated, the inheritance is multifactorial—with a recurrence risk of 3 to 5 percent for one prior affected child. If a cleft is visible in the upper lip, a transverse image at the level of the alveolar ridge may demonstrate that the defect also involves the primary palate (Fig. 15-26).

In one review of low-risk pregnancies, cleft lip was identified sonographically in only about half of cases (Maarse, 2010). Approximately 40 percent of those detected prenatally are associated with other anomalies or syndromes, and aneuploidy is common (Maarse, 2011; Offerdal, 2008). The rate of associated anomalies is highest for bilateral defects that involve the palate. In the Utah Birth Defect Network, aneuploidy was identified in 1 percent with cleft lip alone, 5 percent with unilateral cleft lip and palate, and 13 percent with bilateral cleft lip and palate (Walker, 2001).

The second type of cleft is *isolated cleft palate.* It begins at the uvula, may involve the soft palate, and occasionally involves the hard palate—but does not involve the lip. The birth prevalence approximates 1 in 2000 (Dolk, 2010). Identification of an isolated cleft palate has been described using detailed sonography, and particularly with three-dimensional imaging, but detection is not feasible in all cases (Ramos, 2010; Wilhelm, 2010). Isolated cleft palate is not expected to be visualized during a standard ultrasound examination (Maarse, 2011; Offerdal, 2008).

A third type of cleft is *median cleft lip,* which may

be found in fetuses with holoprosencephaly, typically when hypotelorism is also present. Additionally, a median cleft may be associated with hypertelorism and frontonasal dysplasia, formerly called the *median cleft face syndrome*.

Micrognathia

The fetal profile can help identify cases of *micrognathia*—hypoplasia of the mandible, and *retrognathia*, which is recession of the mandible in relation to the maxilla (Fig. 15-27). To quantify micrognathia risk, a transverse image of the mandible can be used to calculate the jaw index, which is the anterior-posterior diameter of the mandible expressed as a percentage of the biparietal diameter (Paladini, 1999). Fetuses with micrognathia and retrognathia frequently have a posterior cleft palate and glossoptosis (recessed tongue)—a constellation of findings known as the Pierre Robin sequence. Micrognathia is also a feature of Treacher Collins syndrome, oral-facial-digital syndromes, trisomies 18 and 13, triploidy, and the 22 q11.2 deletion. Micrognathia may result in hydramnios and can cause airway obstruction at birth. Use of the *ex-utero intrapartum treatment (EXIT)* procedure for severe micrognathia is discussed in Chapter 19 (p. 379).

Micrognathia should not be confused with agnathia–otocephaly, a rare anomaly in which no mandible develops and the ears may fuse in the midline (Fig. 15-28). The latter confers an extremely poor prognosis and has been diagnosed as early as the late first trimester (Rodriguez, 2019).

Epignathus

This rare teratoma arises from the oral cavity or pharynx. It may grow outward or both outward and into the brain, the latter conferring an extremely poor prognosis (Fig. 15-29). If brain involvement is absent, an EXIT procedure, reviewed in Chapter 19 (p. 379), can help secure the airway at delivery (Chung, 2012).

Cystic Hygroma

This venolymphatic malformation is characterized by fluid-filled sacs that extend from the posterior neck (Fig. 15-30). Cystic hygromas may be diagnosed in the first trimester and vary widely in size. Impaired lymphatic drainage from the head into the jugular vein leads to an accumulation of fluid in jugular lymphatic sacs. The birth prevalence of cystic hygromas approximates 1 in 5000. However, reflecting the high in-utero lethality of the condition, the first-trimester incidence exceeds 1 in 300 (Malone, 2005).

Up to 70 percent of cystic hygromas are associated with aneuploidy. When cystic hygromas are diagnosed in the first trimester, trisomy 21 is the most common aneuploidy, followed by 45,X and trisomy 18 (Kharrat, 2006; Malone, 2005). First-trimester fetuses with cystic hygromas are five times more likely to be aneuploid than fetuses with a thickened nuchal translucency. When cystic hygromas are diagnosed in the second trimester, approximately 75 percent of aneuploid cases are 45,X—Turner syndrome (Johnson, 1993; Shulman, 1992).

Even in the absence of aneuploidy, cystic hygromas confer a significantly greater risk for other abnormalities, particularly flow-related cardiac defects. These include hypoplastic left heart and coarctation of the aorta (p. 292). Cystic hygromas may

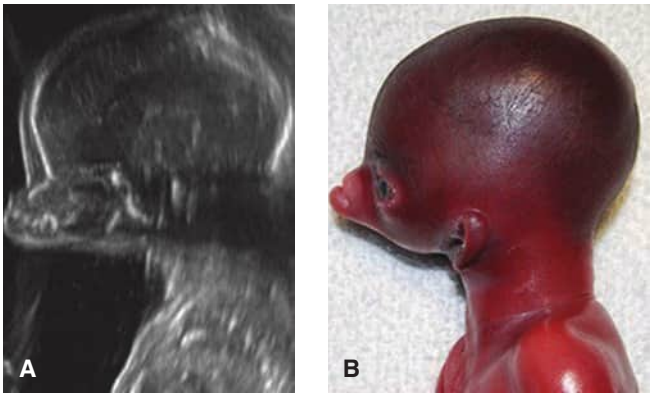

FIGURE 15-28 Agnathia-otocephaly, ultrasound **(A)** and postdelivery **(B)** images. With this rare, lethal anomaly the mandible fails to develop, and the ears are inferiorly displaced and may be fused in the midline.

also be part of a genetic syndrome such as *Noonan syndrome*, an autosomal dominant disorder that shares several features with 45,X. Noonan syndrome is characterized by short stature, lymphedema, high-arched palate, and often pulmonary valve stenosis.

Large cystic hygromas are usually associated with hydrops fetalis, rarely resolve, and carry a poor prognosis. Small hygromas may undergo spontaneous resolution, and provided that fetal karyotype and echocardiography results are normal, the prognosis *may* be good. The likelihood of a nonanomalous liveborn neonate with normal karyotype following identification of first-trimester hygroma approximates 1 in 6 (Kharrat, 2006; Malone, 2005).

THORAX

Thoracic anatomy imaged in the detailed anatomic survey may include the lungs, ribs, and diaphragm. The lungs should appear homogeneous and symmetric, each occupying approximately one third of the area in the four-chamber view of the heart (Fig. 15-31). The thoracic circumference is measured at the skin line in a transverse plane at the level of the four-chamber view. If pulmonary hypoplasia is suspected secondary to a small thorax, such as with a severe skeletal dysplasia, comparison with a reference table may be helpful (Appendix, p. 1238). Representative images of the diaphragm are usually obtained in the parasagittal or coronal plane. The diaphragm appears as a hypoechoic line between the lungs and liver. Thoracic abnormalities may appear sonographically as cystic or solid space-occupying lesions or as an effusion outlining the

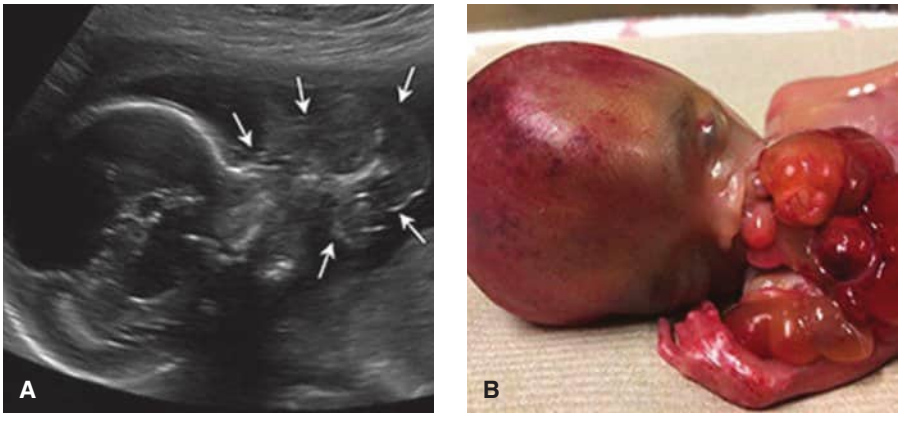

FIGURE 15-29 Epignathus, ultrasound **(A)** and postdelivery **(B)** images. heart or lung(s). Fetal therapy for thoracic abnormalities is discussed in Chapter 19 (p. 376).

■ Diaphragmatic Hernia

This is a defect in the diaphragm through which abdominal organs herniate into the thorax. It is left-sided in approximately 75 percent of cases, right-sided in 20 percent, and bilateral in 5 percent (Gallot, 2007). The prevalence of congenital diaphragmatic hernia (CDH) is 1 in 3000 to 5000 births (Cragan, 2009; Dolk, 2010). Associated anomalies and aneuploidy are found in 40 percent of cases (Gallot, 2007; Stege, 2003). In population-based series, an associated abnormality reduces the overall survival rate of neonates with CDH from approximately 50 percent to about 20 percent (Colvin, 2005; Gallot, 2007). Without other abnormalities, the major causes of neonatal mortality are pulmonary hypoplasia and pulmonary hypertension.

Left-sided CDH typically causes dextroposition of the heart to the right side of the thorax, such that the cardiac axis points toward the midline (Fig. 15-32). Accompanying findings include the stomach bubble or bowel peristalsis in the chest and a wedge-shaped mass—the liver—located anteriorly in the left hemithorax. Liver herniation complicates at least 50 percent of cases and is associated with a 30-percent reduction in the survival rate (Mullassery, 2010). With large lesions, impaired swallowing and mediastinal shift may result in hydramnios and hydrops, respectively.

An effort to reduce neonatal mortality rates and need for extracorporeal membrane oxygenation (ECMO) has focused on prognostic indicators such as the sonographic lung-to-head ratio, described in Chapter 19 (p. 375). MR imaging parameters include measurements of lung volume and degree of liver herniation (Dutemeyer, 2020; Oluyomi-Obi, 2017; Worley, 2009).

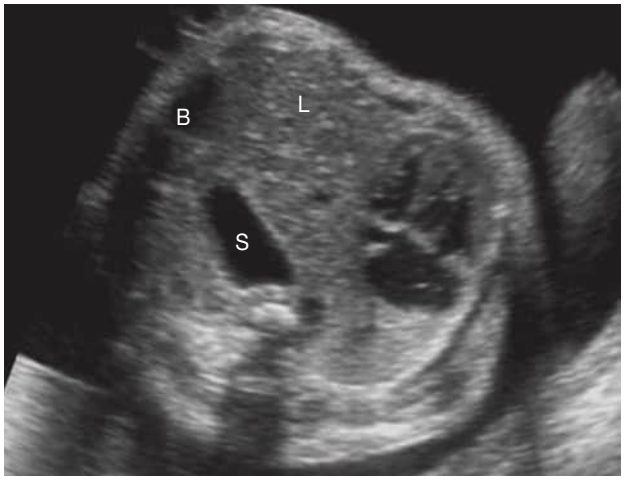

FIGURE 15-32 Congenital diaphragmatic hernia. In this transverse view of the thorax, the heart is shifted to the right side of the chest by a left-sided diaphragmatic hernia containing stomach (*S*), liver (*L*), and bowel (*B*).

■ Congenital Cystic Adenomatoid Malformation

This abnormality represents a hamartomatous overgrowth of terminal bronchioles that communicates with the tracheobronchial tree. It is also called *congenital pulmonary airway malformation (CPAM),* based on an understanding that not all histopathological types are *cystic* or *adenomatoid* (Azizkhan, 2008; Stocker, 1977 2002). The estimated prevalence is 1 in 6000 to 8000 births, and this rate is rising because of improved sonographic detection of milder cases (Burge, 2010; Duncombe, 2002; Lau, 2017).

With ultrasound, a congenital cystic adenomatoid malformation (CCAM) is as a well-circumscribed mass that may appear solid and echogenic or may have one or multiple variably sized cysts (Fig. 15-33). It usually involves one lobe, receives its blood supply from the pulmonary artery, and has pulmonary venous drainage. Lesions with cysts ≥5 mm are generally termed *macrocystic*, and lesions that appear solid or have cysts <5 mm are *microcystic* (Adzick, 1985).

In a review of 645 CCAM cases, the neonatal survival rate exceeded 95 percent, and 30 percent of cases demonstrated apparent prenatal resolution. The other 5 percent of cases—typically very large lesions with associated mediastinal shift—were complicated by hydrops and had poor prognosis (Cavoretto, 2008). Microcystic CCAMs usually become less conspicuous with advancing gestation, because in addition to occupying less of the thorax, their echogenicity more closely resembles surrounding lung tissue. However, a subset of CCAMs may demonstrate rapid growth between 18 and 26 weeks' gestation. Corticosteroid therapy has been used for large microcystic lesions to forestall growth and potentially ameliorate hydrops (Curran, 2010; Peranteau, 2016). If a large dominant cyst is present, thoracoamnionic shunt placement may lead to hydrops resolution. Fetal therapy for CCAM is discussed in Chapter 19 (p. 370).

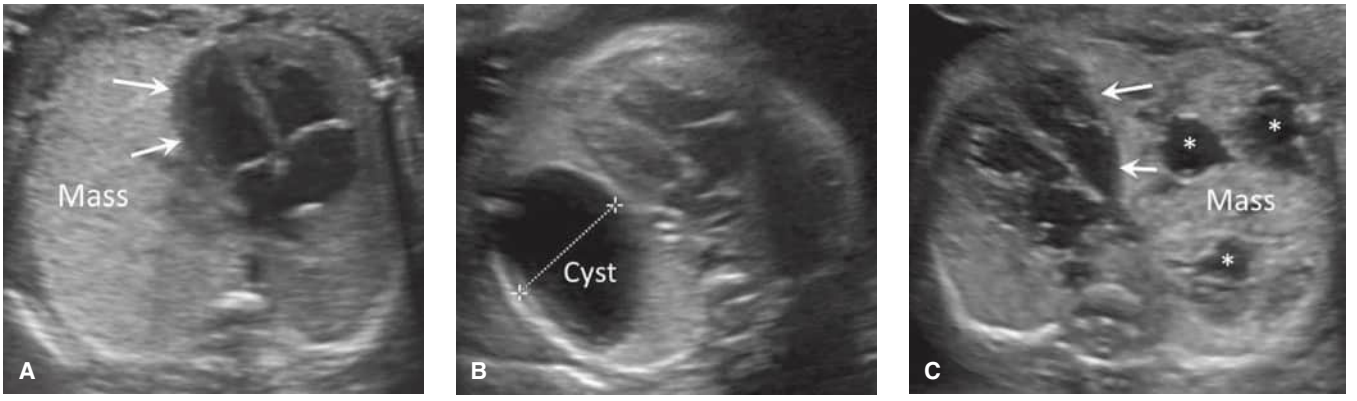

FIGURE 15-33 Congenital cystic adenomatoid malformation (CCAM). **A.** This left-sided microcystic CCAM is an echogenic mass that fills the left hemithorax and causes mediastinal shift, which displaces the heart (*arrows*) to the right side of the chest. **B.** This left-sided macrocystic CCAM contains a cyst as large as the heart and also displaces the heart to the right. **C.** This right-sided CCAM contains multiple cysts of varying size (*) and displaces the heart farther to the left side of the chest (*arrows*).

Pulmonary Sequestration

Also called a *bronchopulmonary sequestration*, this abnormality is an accessory lung bud "sequestered" from the tracheobronchial tree. It is nonfunctioning lung tissue. Most cases diagnosed prenatally are *extralobar,* which means they are enveloped in their own pleura. Overall, however, most sequestrations present in adulthood and are *intralobar*—within the pleura of another lobe. Extralobar pulmonary sequestration is considered significantly less common than CCAM, and no precise prevalence has been reported. Lesions have a left-sided predominance and most often involve the left lower lobe. Associated anomalies have been reported in approximately 10 percent of cases (Yildirim, 2008).

Sonographically, pulmonary sequestration presents as a homogeneous, echogenic thoracic mass (Fig. 15-34A). Thus, it may resemble a microcystic CCAM. However, the blood supply is from the systemic circulation—from the aorta—rather than the pulmonary artery (Fig. 15-34B). Approximately 10 to 20 percent are located below the diaphragm. A small percentage of fetuses with pulmonary sequestration develop a large ipsilateral pleural effusion, and without treatment, this may result in pulmonary hypoplasia or hydrops (Fig. 15-34C). Treatment with thoracoamnionic shunting is discussed in Chapter 19 (p. 376). Hydrops may also result from mediastinal shift or high-output cardiac failure due to the left-to-right shunt imposed by the mass. In the absence of a pleural effusion, the reported survival rate exceeds 95 percent, and 40 percent of cases demonstrate apparent prenatal resolution (Cavoretto, 2008).

Congenital High Airway Obstruction Sequence

This rare anomaly usually results from laryngeal or tracheal atresia. The normal egress of lung fluid is obstructed, and the tracheobronchial tree and lungs become massively distended. Sonographically, the lungs are brightly echogenic, the bronchi are dilated, the diaphragm is flattened or everted, and the heart is compressed (Fig. 15-35). Impaired venous return leads to development of ascites, typically followed by hydrops. In one review of 118 cases, associated anomalies were identified in more than 50 percent (Sanford, 2012). Congenital high airway obstruction sequence (CHAOS) is a feature of the autosomal recessive *Fraser syndrome* and has been associated with the 22q11.2 deletion syndrome. In some cases, the obstructed airway spontaneously perforates, which potentially confers a better prognosis. The EXIT procedure has significantly improved outcome in selected cases.

HEART

Cardiac malformations are the most common class of congenital anomalies. Their overall prevalence is 8 cases in 1000 births (Cragan, 2009). Almost 90 percent of cardiac defects are multifactorial or polygenic in origin, another 1 to 2 percent result from a single-gene disorder or gene-deletion syndrome, and 1 to 2 percent may occur from exposure to a teratogen such as maternal diabetes or isotretinoin. Based on data from population-based registries, approximately 1 in 8 liveborn and stillborn neonates with a congenital heart defect has a chromosomal abnormality (Dolk, 2010; Hartman, 2011). Trisomy 21 accounts for most of these cases, followed by trisomy 18, 22q11.2 deletion, trisomy 13, and monosomy X (Hartman, 2011). Approximately 50 to 70 percent of aneuploid fetuses with cardiac anomalies are also found to have noncardiac abnormalities.

Traditionally, congenital cardiac anomalies have been more challenging to detect than anomalies of other organ systems. Recent series suggest that standard ultrasound may identify 50 to 60 percent of those with major cardiac anomalies before 22 weeks' gestation (Byrne, 2020; Sun, 2018). Prenatal detection may improve neonatal survival, particularly for *ductal-dependent* lesions, that is, those requiring prostaglandin infusion after birth to keep the ductus arteriosus open (Franklin, 2002; Mahle, 2001; Tworetzky, 2001).

Standard Cardiac Examination

Standard cardiac assessment includes a four-chamber view, evaluation of rate and rhythm, evaluation of the left and right ventricular outflow tracts, and when feasible, documentation of the 3-vessel view and 3-vessel trachea view (Figs. 15-36 and

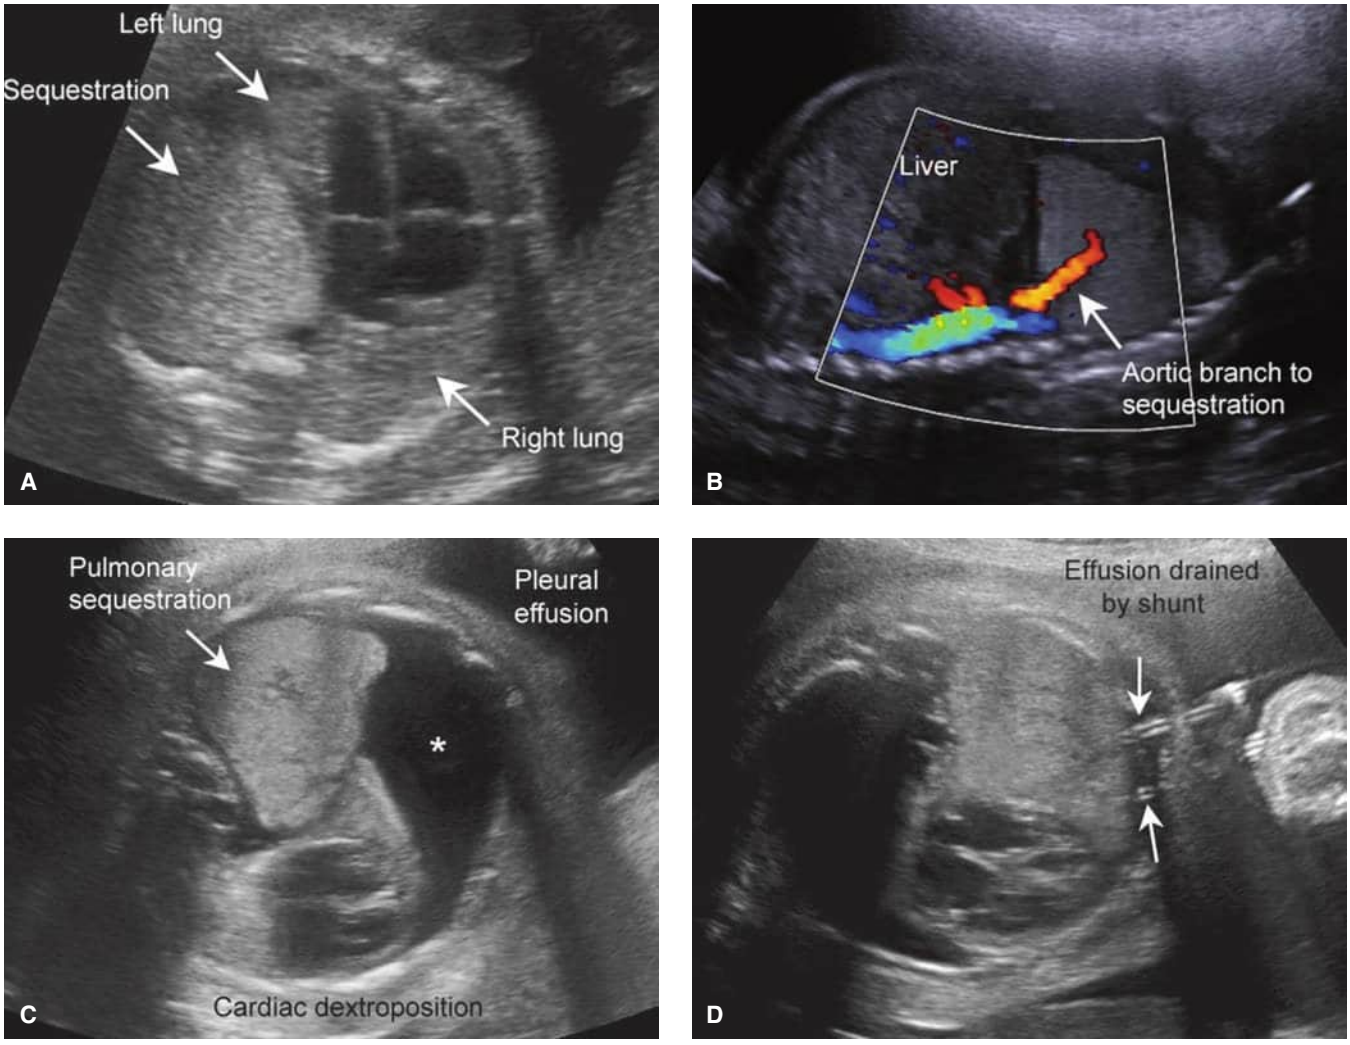

FIGURE 15-34 Pulmonary sequestration. **A.** Transverse image of the thorax depicts a left lower lobe pulmonary sequestration (*PS*) in this 25-week fetus. **B.** Sagittal image showing that blood supply to the mass is from a branch of the abdominal aorta, which confirms the diagnosis. **C.** Over the next 3 weeks, a large ipsilateral pleural effusion develops (*asterisk*), resulting in mediastinal shift and dextroposition of the heart to the far-right thorax. **D.** After placement of a double-pigtail shunt through the chest wall, which drains the effusion into the amniotic fluid, the lung significantly reexpanded. Arrows point to coils of the pigtail shunt. (Reproduced with permission from Dr. Elaine Duryea.)

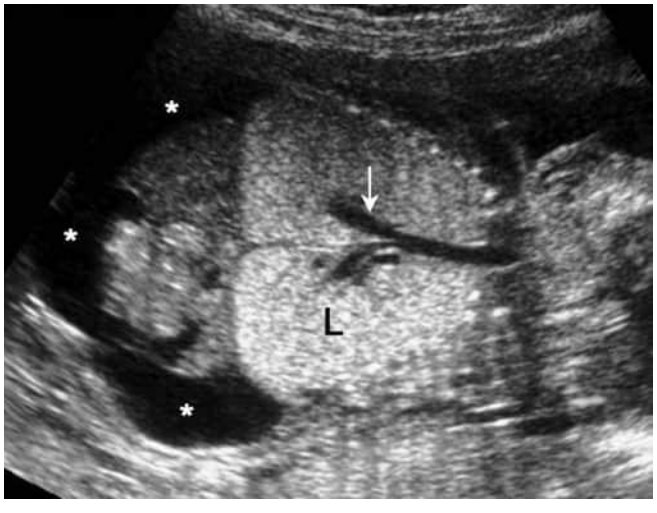

FIGURE 15-35 Congenital high airway obstruction sequence (CHAOS). The lungs (*L*) appear brightly echogenic, and the bronchi (*arrow*) are dilated with fluid. Flattening and eversion of the diaphragm is common, as is ascites (*asterisks*).

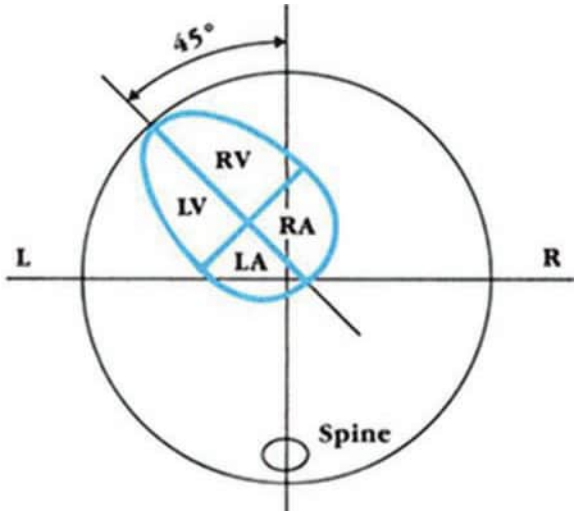

FIGURE 15-36 Diagram showing measurement of cardiac axis from the four-chamber view. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

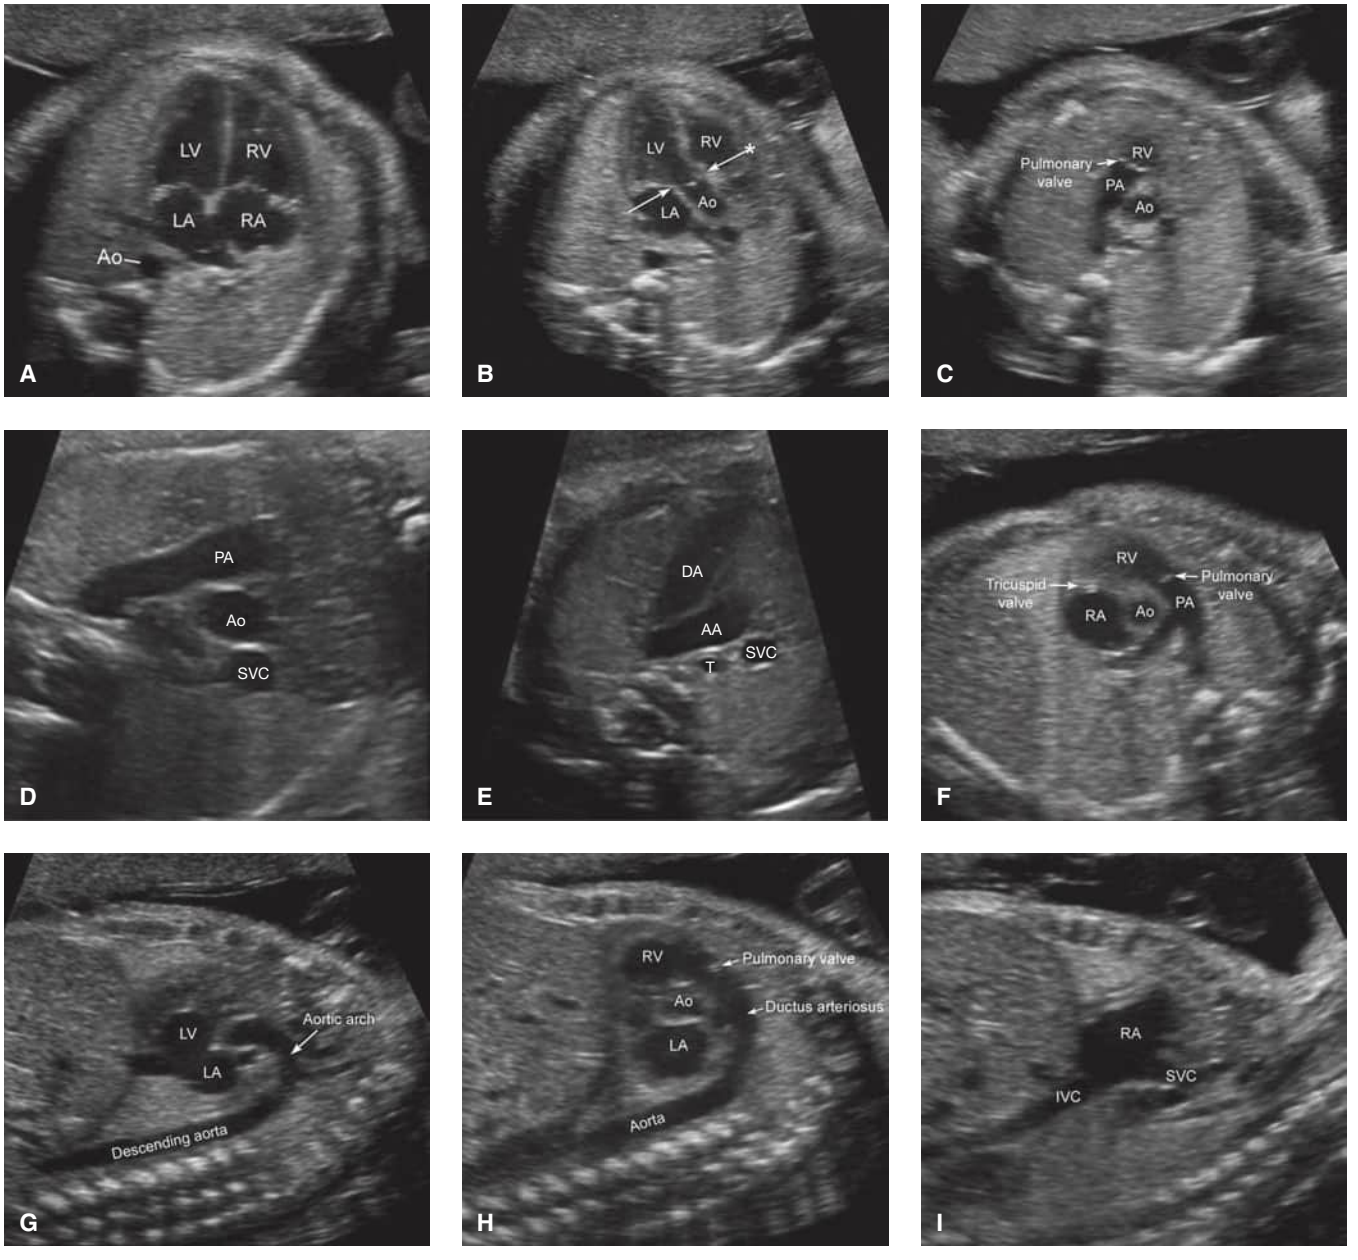

FIGURE 15-37 Standard and detailed examination cardiac views. **A.** Four-chamber view. **B.** Left ventricular outflow tract view. Arrow depicts mitral valve becoming the posterior wall of the aorta. The arrow with asterisk marks the interventricular septum becoming the anterior aortic wall. **C.** Right ventricular outflow tract view. **D.** Three-vessel view. **E.** Three-vessel trachea view **F.** High short-axis view (outflow tracts). **G.** Aortic arch view. **H.** Ductal arch view. **I.** Superior and inferior vena cavae views. AA = aortic arch; Ao = aorta; DA = ductal arch; IVC = inferior vena cava; LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle; SVC = superior vena cava; T = trachea.

15-37). It is hoped that examination of the cardiac outflow tracts and 3-vessel views will improve detection of outflow tract abnormalities that may have a normal-appearing four-chamber view, such as tetralogy of Fallot and transposition of the great arteries. Centers with expertise have reported at least 90 percent detection of such anomalies with incorporation of these views (Brandt, 2015; Palatnik, 2016).

The *four-chamber view* is a transverse image of the fetal thorax at a level immediately above the diaphragm. It allows evaluation of cardiac size, position in the thorax, cardiac axis, atria and ventricles, foramen ovale, atrial septum primum, interventricular septum, and atrioventricular valves (Fig. 15-37A). The left ventricle is apex-forming, and two pulmonary veins are often visible entering the left atrium. The atria and ventricles should be similar in size, and the apex of the heart should form a 45-degree angle with the left anterior chest wall (see Fig. 15-36). Abnormalities of cardiac axis are encountered in more than one third of fetuses with structural cardiac anomalies (Shipp, 1995; Crane, 1997; Sinkovskaya, 2015).

The *left ventricular outflow tract view* demonstrates that the ascending aorta arises entirely from the left ventricle. The interventricular septum is shown to be in continuity with the anterior wall of the aorta, and the mitral valve in continuity with the posterior wall of the aorta (Fig. 15-37B). Ventricular septal

defects and outflow tract abnormalities are often visible in this view.

The *right ventricular outflow tract view* shows the right ventricle giving rise to the main pulmonary artery, which subsequently branches into the right and left pulmonary arteries. (Fig. 15-37C,F). Together, the left and right outflow tract views demonstrate the normal perpendicular orientation of the aorta and pulmonary artery and the comparable size of these great arteries.

The *3-vessel view* (3VV) is a transverse image obtained just above the base of the heart. The three vessels line up in a row: an oblique view of the pulmonary artery, which should appear long and cylindrical; a cross-sectional image of the ascending aorta; and a cross-sectional image of the superior vena cava (SVC) (Fig. 15-37D). The pulmonary artery and aorta should be similar in diameter. The 3-vessel trachea view (3VTV) also is a transverse image but is obtained further cephalad. It includes the pulmonary artery giving rise to the ductus arteriosus as it makes a V-shape with the aortic arch, along with the SVC and the trachea (Fig. 15-37E). The 3VTV can be helpful for identifying aortic arch abnormalities, particularly ductal-dependent lesions.

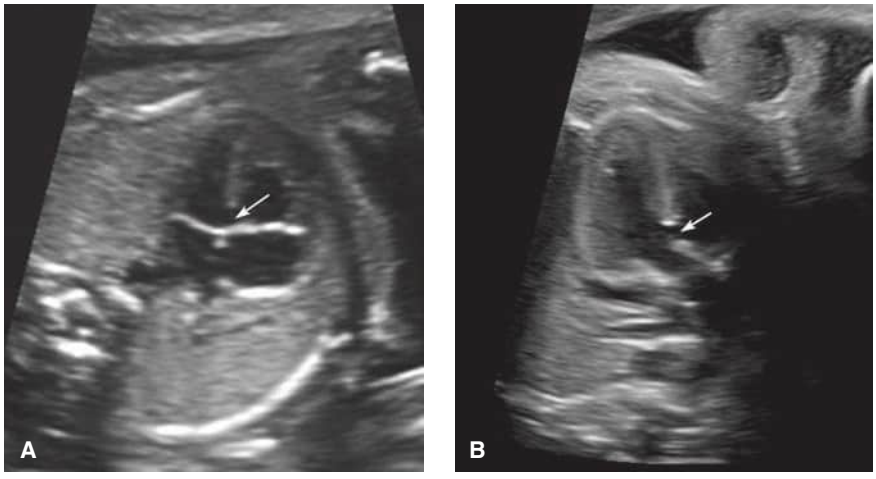

FIGURE 15-38 Ventricular septal defect. **A.** In this four-chamber view, a defect (*arrow*) is noted in the perimembranous portion of the interventricular septum. **B.** The left ventricular outflow tract view demonstrates a break in continuity (*arrow*) between the interventricular septum and the anterior wall of the aorta.

■ Specialized Cardiac Examination

The detailed ultrasound examination includes the five cardiac components of the standard examination plus the superior and inferior vena cavae and the aortic and ductal arch views (Fig. 15-37G–I). The examination also involves evaluation of the interventricular septum and cardiac situs, documentation of which may be facilitated with video clips.

Fetal echocardiography is a more extensive examination of cardiac structure and function designed to characterize abnormalities. In addition to grayscale imaging views, echocardiography includes evaluation of cardiac rate and rhythm, color Doppler ultrasound, pulsed-wave Doppler ultrasound, cardiac biometry, and if clinically relevant, cardiac function assessment (American Institute of Ultrasound in Medicine, 2020b). These components are beyond the scope of this text. Echocardiography indications are discussed in Chapter 14 (p. 252). Selected cardiac anomalies are reviewed next.

Ventricular Septal Defect

This is the most common congenital cardiac anomaly. It is found in approximately 1 in 300 births (Bjornard, 2013; Cragan, 2009; Dolk, 2010). A defect may be appreciated in the perimembranous or muscular portion of the interventricular septum in the four-chamber view, and imaging of the left ventricular outflow tract may show discontinuity of the interventricular septum as it becomes the wall of the aorta (Fig. 15-38). Color Doppler may demonstrate flow across the defect. Genetic abnormalities are diagnosed with chromosomal microarray analysis in approximately 1 percent of isolated cases but found in at least 15 percent if other structural abnormalities also are present (Maya, 2020). More than a third of prenatally diagnosed ventricular septal defects close in utero, and another third close in the first year of life (Cho, 2017; Paladini, 2002; Svirsky, 2019).

Endocardial Cushion Defect

This is also called an *atrioventricular (AV) septal defect* or *AV canal defect*. It has a birth prevalence of approximately 1 in 2500 and is associated with trisomy 21 in more than half of cases (Christensen, 2013; Cragan, 2009; Dolk, 2010). The endocardial cushions are the crux of the heart, and defects jointly involve the atrial septum primum, interventricular septum, and medial leaflets of the mitral and tricuspid valves (Fig. 15-39).

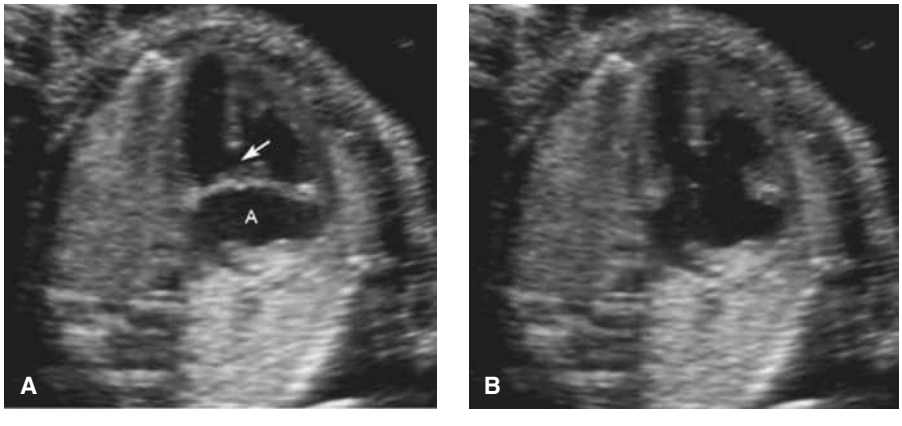

FIGURE 15-39 Endocardial cushion defect. **A.** During ventricular systole, the lateral leaflets of the mitral and tricuspid valves come together in the midline. But the atrioventricular valve plane is abnormal, a common atrium (*A*) is observed, and there is a visible defect (*arrow*) in the interventricular septum. **B.** During diastolic filling, opening of the atrioventricular valves more clearly demonstrates the absence of their medial leaflets.

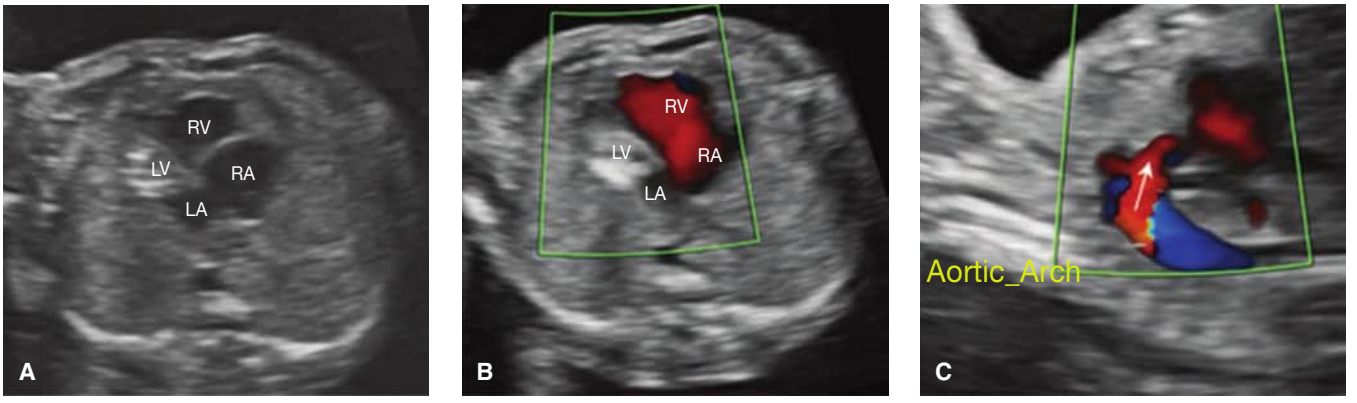

FIGURE 15-40 Hypoplastic left heart syndrome. **A.** In this four-chamber view, the left ventricle appears "filled in" and echogenic, due to endocardial fibroelastosis. **B.** Color Doppler depicts only flow from the right atrium into the right ventricle, and no left ventricular filling is visible. **C.** Color Doppler shows reversal of flow in the aortic arch (*arrow*), which is perfused retrograde via the ductus arteriosus. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

The majority of defects are balanced–with ventricles comparable in size. Some are *unbalanced* however, with one side of the heart significantly smaller than the other. The endocardial cushion defect is considered *partial* if there is absence of the atrial septum primum and a more subtle AV valve plane abnormality, with no ventricular septal defect.

Endocardial cushion defects are a common finding in *heterotaxy*, also known as *cardiosplenic* or *isomerism syndromes*. Heterotaxy implies that thoraco-abdominal organs normally on one side of the body are on an incorrect side, on both sides, or absent, as in polysplenia or asplenia. Complex cardiac abnormalities are a common feature, particularly endocardial cushion defects. In a review of 632 pregnancies with fetal heterotaxy, an endocardial cushion defect was present in 60 percent (Buca, 2018). These endocardial cushion defects are a particularly at-risk group because of their association with third-degree heart block, which confers a poor prognosis.

Hypoplastic Left Heart Syndrome

This anomaly is found in approximately 1 in 4000 births (Bjornard, 2013; Cragan, 2009; Dolk, 2010;). During second-trimester ultrasound examination, the left ventricle may be so small that a chamber is difficult to appreciate (Fig. 15-40). Alternately, the left ventricle may be normal in size or dilated but have severely decreased contractility and an echogenic inner wall due to *endocardial fibroelastosis*. There may be no visible left ventricular inflow or outflow, and reversal of flow may be documented in the aortic arch in the 3-vessel trachea view. As gestation advances, the left ventricle and aorta become progressively smaller. Prenatal detection is nearly 90 percent in population-based registries.

Hypoplastic left heart syndrome is a ductal-dependent lesion for which neonatal administration of prostaglandin therapy is essential. Postnatal treatment consists of a three-staged palliative repair—*single ventricle palliation,* or cardiac transplantation. Rates of survival to adulthood may reach 70 percent (Feinstein, 2012). However, morbidity is high, and developmental delays are common (Lloyd, 2017; Paladini, 2017; Wilson, 2018). Fetal therapy for this condition is discussed in Chapter 19 (p. 378).

Coarctation of the Aorta

Coarctation refers to narrowing of the aortic arch. The birth prevalence approximates 1 in 2500 (Bjornard, 2013). Usually, the narrowing is focal and found just distal to the origin of the left subclavian artery at the aortic isthmus. Alternatively, a long segment of the aorta may be affected. Coarctation may be isolated or associated with other cardiac anomalies, such as hypoplastic left heart syndrome, unbalanced endocardial cushion defect, or double-outlet right ventricle. The most common sonographic finding is disproportion in ventricular size, with the left ventricle smaller than the right. However, only one third with this finding have coarctation (Ghi, 2018; van Nisselrooij, 2018). Other findings include narrowing of the aortic arch in the 3-vessel trachea view or narrowing of the isthmus in the aortic arch view–which may be challenging to image. Coarctation is associated with Turner syndrome (45,X), with the 22q11.2 deletion, and with autosomal trisomies.

Ebstein Anomaly

This rare anomaly is characterized by apical displacement of the tricuspid valve, such that the septal and posterior valve leaflets of the tricuspid valve attach closer to the cardiac apex (Fig. 15-41). The birth prevalence is approximately 1 in 20,000 (Boyle, 2017). Fetuses with Ebstein anomaly develop varying degrees of tricuspid regurgitation. In severe cases, right atrium becomes markedly dilated, and the fetus may develop cardiomegaly and hydrops. For many years, there was concern that lithium exposure predisposed to Ebstein anomaly. However, as discussed in Chapter 8 (p. 154), the absolute attributable risk is likely well below 1 percent.

Tetralogy of Fallot

This anomaly occurs in approximately 1 in 3000 births (Cragan, 2009; Dolk, 2010; Nelson, 2016). It includes a ventricular septal defect; an overriding aorta; a pulmonary valve or pulmonary artery abnormality, and right ventricular hypertrophy (Fig. 15-42). The last does not usually manifest before birth. Due to the location of the ventricular septal defect, the four-chamber view may appear normal.

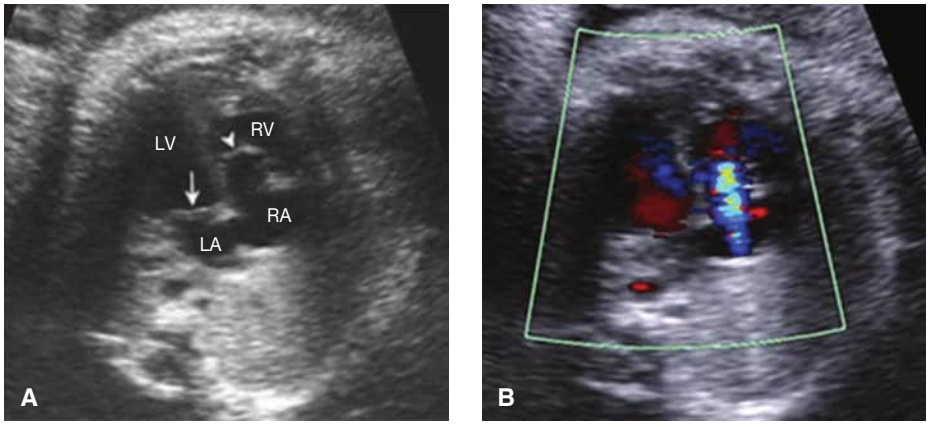

FIGURE 15-41 Ebstein anomaly. **A.** In this four-chamber view, the tricuspid valve's septal leaflet attaches closer to the cardiac apex (*arrowhead*) than the corresponding mitral valve leaflet (*arrow*). **B.** The color Doppler blue jet reflects tricuspid regurgitation. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

The pulmonary artery abnormality is pulmonary stenosis in 60 percent of cases, pulmonary atresia in slightly more than 25 percent, and absent pulmonary valve in 10 to 15 percent (Zhao, 2016). Absence of the pulmonary valve leads to marked enlargement of the pulmonary artery and poses a risk for hydrops. The enlarged pulmonary artery can also compress the trachea and cause tracheomalacia.

Chromosomal abnormalities are identified in approximately one third of fetuses with tetralogy of Fallot. Of these, 22q11.2 deletions compose 15 to 20 percent, and autosomal trisomies constitute 10 percent (Zhao, 2016).

D-Transposition of the Great Arteries

This anomaly is characterized by outflow tracts that arise in parallel from the ventricles. The right ventricle gives rise to the aorta, and the left ventricle to the pulmonary artery (Fig. 15-43). Thus, there is *ventriculo-arterial discordance*. The birth prevalence approximates 1 in 4000 (Bjornard, 2013). The four-chamber view is often normal. Prenatal detection approximates 40 percent but is thought to improve with visualization of the outflow tracts (Ravi, 2018). Additionally, the 3-vessel views may demonstrate only two vessels, because the pulmonary artery is underneath the aorta.

D-transposition contrasts with *L-* or *corrected* transposition of the great arteries, in which there is atrioventricular discordance in addition to ventricular-arterial discordance. L-transposition is strongly associated with other cardiac anomalies and is much less likely to be diagnosed prenatally as an isolated finding.

Double-outlet Right Ventricle

With this anomaly, the majority of blood flow to both the pulmonary artery and the aorta comes from the right ventricle. Double-outlet right ventricle (DORV) is always associated with a ventricular septal defect. DORV has a spectrum of presentation. It is categorized according to the location of the ventricular septal defect and the relative proportion of blood flow from the right ventricle to the outflow tracts. The outflow tracts are often malposed, arising in parallel. The birth prevalence approximates 1 in 20,000 (Bjornard, 2013).

Truncus Arteriosus

This rare anomaly is characterized by a single, large outflow tract exiting the heart—a common arterial trunk—rather than a separate aorta and pulmonary artery. A prominent ventricular septal defect is usually identified, with an enlarged overriding outflow tract that gives rise to pulmonary arteries as well as head and neck vessels (Fig. 15-44). The differential diagnosis includes tetralogy of Fallot with pulmonary atresia. The birth prevalence of truncus arteriosus approximates 1 in 16,000 (Bjornard, 2013). In 1949, Collett and Edwards categorized four types of truncus arteriosus according to the origin of the

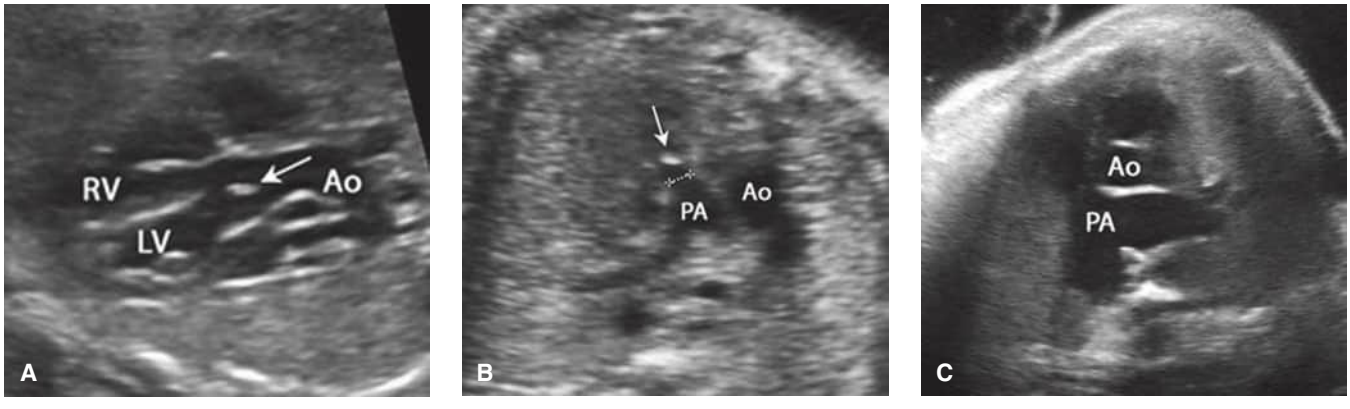

FIGURE 15-42 Tetralogy of Fallot. **A.** Left ventricular outflow tract view shows a ventricular septal defect with an overriding aorta. The arrow points to the aortic valve. **B.** Right ventricular outflow tract view demonstrating severe pulmonary artery stenosis. The arrow points to the pulmonary valve. **C.** In this fetus with tetralogy of Fallot with *absent pulmonary valve*, the pulmonary artery shows marked enlargement. Ao = aorta; LV = left ventricle; PA = pulmonary artery; RV = right ventricle.

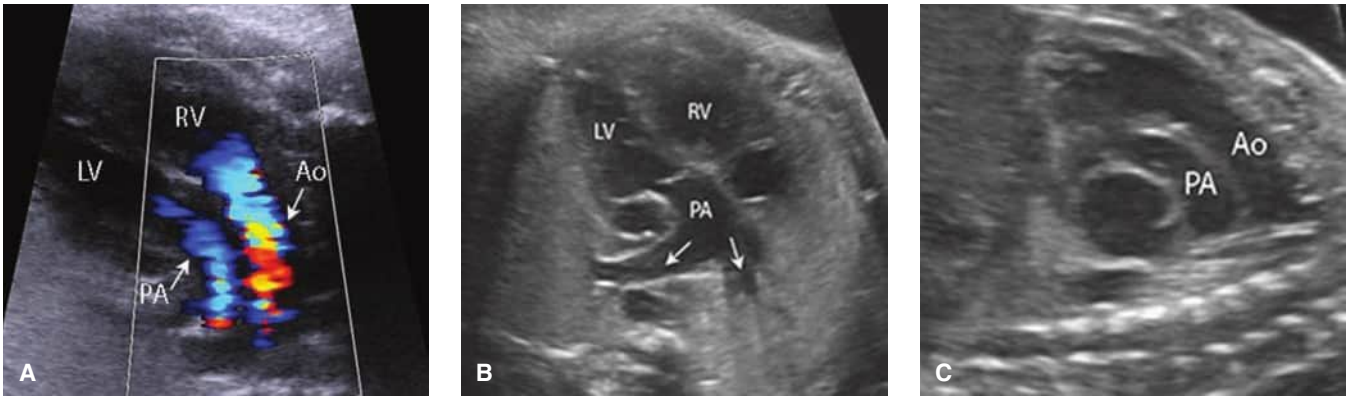

FIGURE 15-43 D-transposition of the great arteries. **A.** Transverse image with color Doppler depicting the outflow tracts arising in parallel. **B.** View of the left ventricle giving rise to the pulmonary artery, which subsequently branches (*arrows*). **C.** Sagittal image of the aorta arising anteriorly from the right ventricle and parallel to the pulmonary artery, which arises posteriorly. Ao = aorta; LV = left ventricle; PA = pulmonary artery; RV = right ventricle.

pulmonary arteries. Characterization of anatomic variants can often only be made postnatally.

Cardiac Rhabdomyoma

This is the most common cardiac tumor. Approximately 50 percent of cases are associated with tuberous sclerosis, an autosomal dominant disease with multiorgan system manifestations. Tuberous sclerosis is caused by mutations in the hamartin (*TSC1*) and tuberin (*TSC2*) genes.

Sonographically, cardiac rhabdomyomas are well-circumscribed echogenic masses, usually within the ventricles or outflow tracts (Fig. 15-45). They may be single or multiple, may grow in size during gestation, and may occasionally lead to inflow or outflow obstruction. In cases without obstruction or large tumor size, the prognosis is relatively good from a cardiac standpoint, because the tumors tend to regress after the neonatal period. Because extracardiac findings of tuberous sclerosis may not be apparent with prenatal sonography, MR imaging may be considered to evaluate fetal CNS anatomy (p. 266).

M-Mode

Motion-mode or M-mode imaging is a linear display of cardiac cycle events, with time on the x-axis and motion on the y-axis. It is often used to measure embryonic or fetal heart rate (Fig. 14-1, p. 248). If an abnormality of heart rate or rhythm is identified, M-mode imaging permits separate evaluation of atrial and ventricular waveforms. Thus, it is particularly useful for characterizing arrhythmias and their response to treatment (Chap. 19, p. 367). M-mode can also be used to assess ventricular function and atrial and ventricular outputs.

Premature Atrial Contractions

Also called atrial extrasystoles, these are the most common fetal arrhythmia and a frequent finding. They represent cardiac conduction system immaturity and often resolve with advancing gestation or in the neonatal period. Premature atrial contractions (PACs) may be conducted and thus sound like extra beats. However, they are more commonly blocked, and with handheld Doppler they sound like dropped beats. As shown

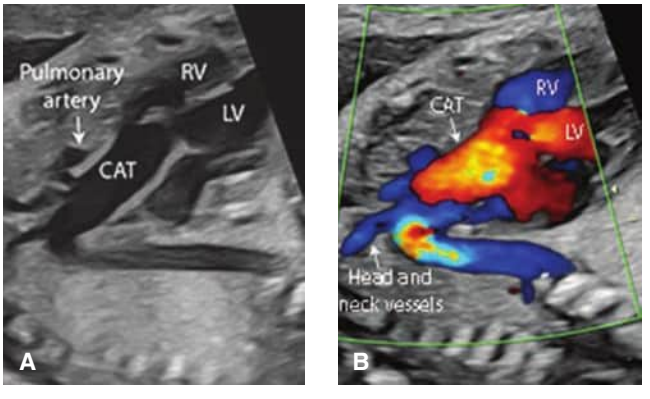

FIGURE 15-44 Truncus arteriosus. Grayscale **(A)** and color Doppler **(B)** images depict a single, large outflow tract. The common arterial trunk (*CAT*) overlies a ventricular septal defect (*arrowhead*) and gives rise to the head and neck vessels and pulmonary arteries. LV = left ventricle; RV = right ventricle. (Reproduced with permission from Paul Mallamaci, RDMS.)

FIGURE 15-45 Rhabdomyoma. In this four-chamber view of the heart, a large, echogenic, well-circumscribed mass (*R*) fills the right ventricle and abuts the tricuspid valve (*arrow*). Despite its size, the mass did not obstruct flow, and the neonate did well.

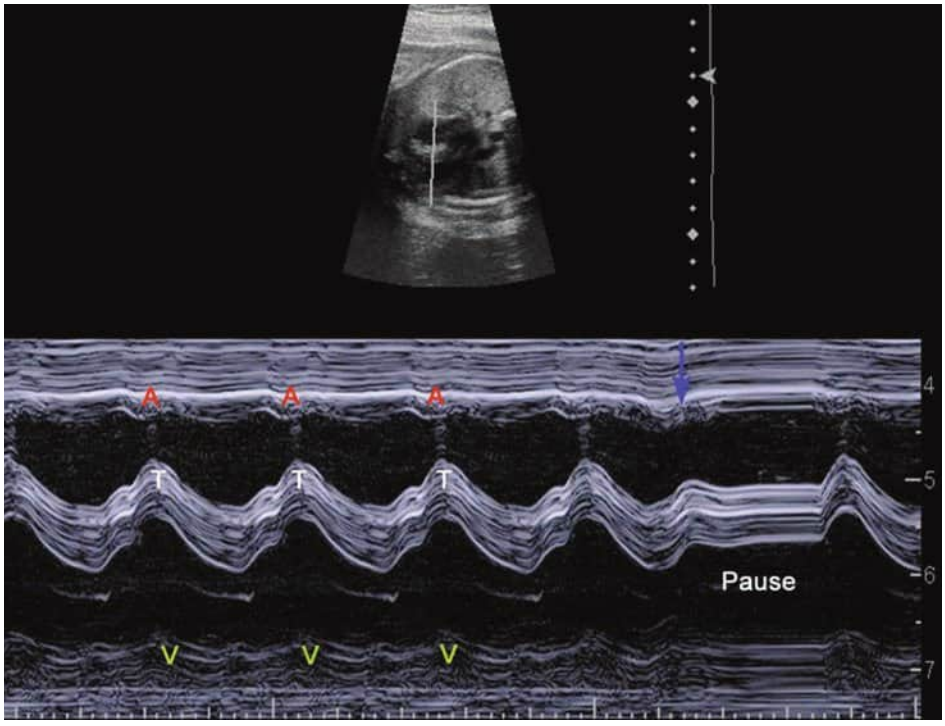

FIGURE 15-46 M-mode. This image demonstrates normal concordance between atrial (*A*) and ventricular (*V*) contractions. Movement of the tricuspid valve (*T*) is also shown. The blue arrow denotes a premature atrial contraction followed by a compensatory pause.

in Figure 15-46, the dropped beat may be demonstrated with M-mode evaluation as a compensatory pause that follows the premature contraction.

PACs are not associated with major structural cardiac abnormalities. Older case reports describe an association with maternal caffeine consumption and with hydralazine (Lodeiro, 1989; Oei, 1989). In approximately 2 percent of cases, affected fetuses are later identified to have *supraventricular tachycardia (SVT)*, which is an arrhythmia that requires urgent treatment (Copel, 2000). Accordingly, pregnancies with fetal PACs are often followed with fetal heart rate assessment as often as every 1 to 2 weeks until the ectopy resolves. Treatment of fetal SVT and other arrhythmias is discussed in Chapter 19 (p. 368).

ABDOMEN

Abdominal anatomy visible in the second and third trimester includes the stomach, liver, gallbladder, spleen, adrenal glands, kidneys, renal arteries, small and large bowel, and ventral wall. The stomach is nearly always identified after 14 weeks' gestation. Nonvisualization of the stomach may be secondary to impaired swallowing in the setting of oligohydramnios or to underlying causes such as esophageal atresia, a craniofacial anomaly, or a CNS or musculoskeletal abnormality. Fetuses with hydrops can also have impaired swallowing.

Both the liver and spleen may be viewed in a transverse image obtained at the level of the stomach and intrahepatic portion of the umbilical vein—the plane at which the abdominal circumference is measured (see Fig. 15-2B). Hepatosplenomegaly may occur with congenital infection or with hydrops. By convention, the liver is measured in the sagittal or coronal plane, from the top of the right hemidiaphragm to the inferior tip of the right lobe (Fig. 15-47). The spleen is posterior to the stomach in the transverse plane. The gallbladder may be imaged just inferior to the level at which the abdominal circumference is measured. It lies to the right of the intrahepatic portion of the umbilical vein and has a conical or teardrop shape (see Fig. 15-47B).

The appearance of fetal bowel changes with maturation. Increased bowel echogenicity may indicate a small amount of swallowed intraamnionic blood, especially if the maternal serum alpha-fetoprotein level is elevated. The bowel appears as bright as bone in approximately 0.5 percent of second-trimester fetuses. In such cases, the risk for fetal trisomy 21 is increased (Fig. 17-3, p. 340). Echogenic bowel is also associated with fetal cytomegalovirus infection and with cystic fibrosis, in which echogenicity represents inspissated meconium.

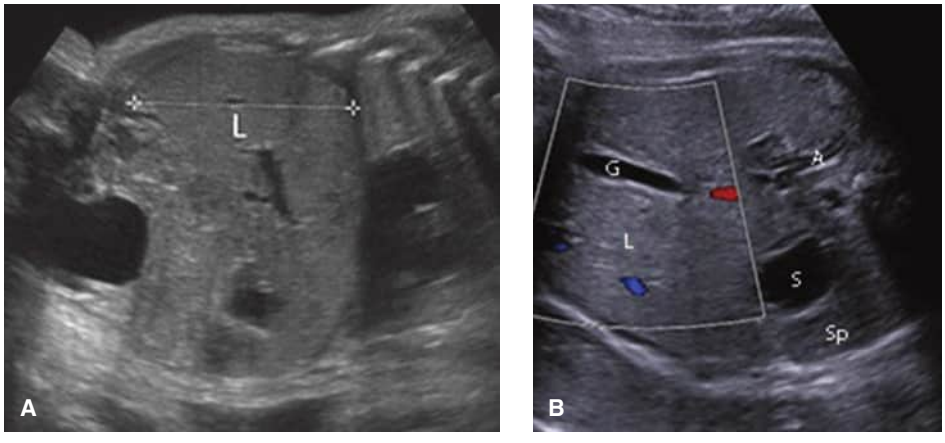

FIGURE 15-47 Abdominal organs. **A.** The liver is measured from the top of the right hemidiaphragm to the inferior tip of the right lobe in this coronal image. **B.** Transverse image of the abdomen just inferior to the level at which the abdominal circumference is measured, depicting the gallbladder (*G*), stomach (*S*), spleen (*Sp*), liver (*L*), and right adrenal gland (*A*).

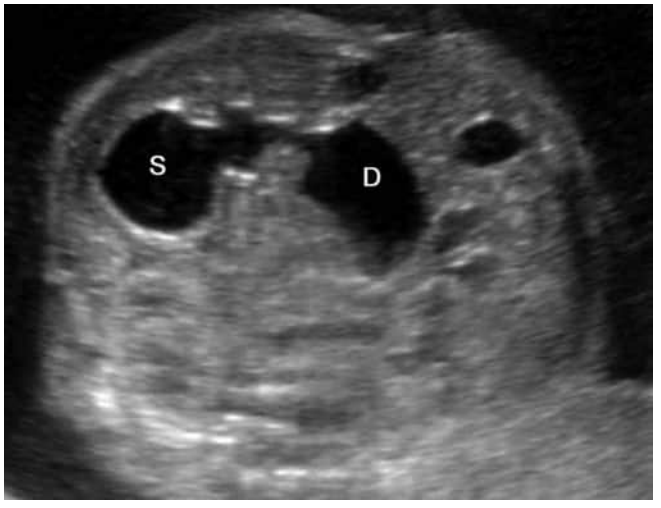

FIGURE 15-48 Duodenal atresia. Transverse image of the *double-bubble sign*, which represents distension of the stomach (*S*) and the first part of the duodenum (*D*). Continuity between these structures confirms that the second cystic structure is the duodenum.

Gastrointestinal Obstruction

Bowel atresia is characterized by obstruction and proximal bowel dilation. In general, the more proximal the obstruction, the more likely it is to lead to hydramnios. The degree of hydramnios from proximal small-bowel obstruction can be sufficiently severe to result in maternal respiratory compromise or preterm labor and may necessitate amnioreduction (Chap. 14, p. 258).

Esophageal Atresia

The birth prevalence of this anomaly approximates 1 in 4000 (Cragan, 2009; Pedersen, 2012). It may be suspected when there is no visible stomach bubble or when the stomach is contracted. However, because esophageal atresia is associated with a *tracheoesophageal fistula* in up to 90 percent of cases, fluid is often able to enter the stomach. More than 50 percent of those with esophageal atresia have other abnormalities or underlying genetic syndromes. Multiple malformations are present in 30 percent of cases, and aneuploidy such as trisomy 18 or 21, in 10 percent. Approximately 10 percent of cases of esophageal atresia is found as part of the VACTERL association (Pedersen, 2012).

Duodenal Atresia

This anomaly occurs in approximately 1 in 10,000 births (Best, 2012; Dolk, 2010). It is characterized by the sonographic *double-bubble sign,* which develops from distention of the stomach and the first part of the duodenum (Fig. 15-48). This finding may not be obvious before 24 weeks' gestation. Demonstrating continuity between the stomach and proximal duodenum confirms that the second "bubble" is the proximal duodenum. Approximately 30 percent of affected fetuses have an associated chromosomal abnormality or genetic syndrome, particularly trisomy 21. Of cases without a genetic abnormality, a third have associated anomalies, most commonly cardiac defects and other gastrointestinal abnormalities (Best, 2012).

Jejunoileal Atresia

This condition may present with dilated small-bowel loops that fill the abdomen or with *meconium peritonitis* from bowel perforation (Fig. 15-49). Associated gastrointestinal abnormalities are identified postnatally in 25 percent of cases, with malrotation in 10 to 15 percent (Stollman, 2009). Cystic fibrosis also is identified in approximately 10 percent.

In general, jejunal atresia is more strongly associated with bowel dilation and hyperperistalsis, and ileal atresia, with perforation. Bowel dilatation in jejunal atresia typically does not present until after 24 weeks' gestation and may be accompanied by hydramnios. Perforation is frequently associated with ascites, and bright echoes may be visible outside the bowel lumen, outlining the peritoneal cavity. Over time, the ascites resolves, and the extravasated meconium may form a pseudocyst. Fetal MR imaging can assist with identifying the level of the defect (Chap. 14, p. 267).

Anal Atresia

Also known as imperforate anus, this condition is less readily diagnosed by sonography. Hydramnios is not a typical feature, and the bowel may not be significantly dilated. A transverse view through the pelvis may show an enlarged rectum as an anechoic structure between the bladder and the sacrum. Anal atresia is a feature of the VACTERL association.

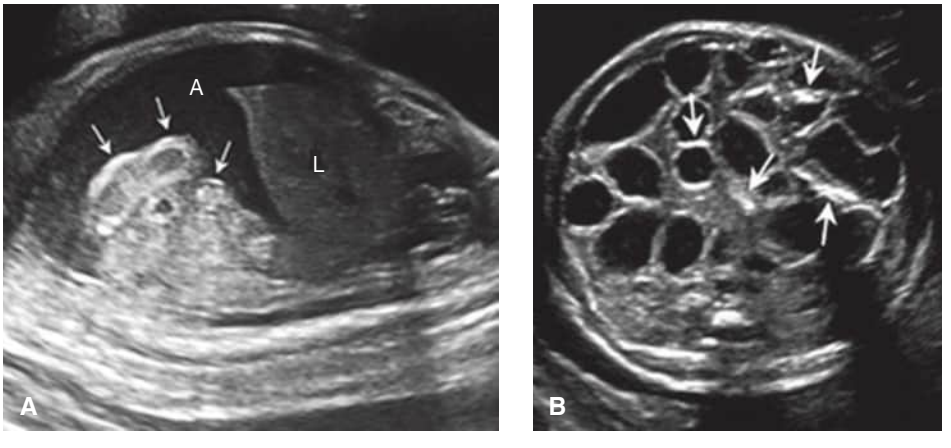

FIGURE 15-49 Jejunoileal atresia with meconium peritonitis. **A.** Sagittal image of the fetal abdomen at 26 weeks' gestation with severe ascites following bowel perforation. Arrows point to the bowel, which is considerably more echogenic than the liver. **B.** Transverse image at 30 weeks demonstrates resolution of ascites. The abdomen is now filled with dilated loops of small bowel. Focal bright echoes (*arrows*) represent extraluminal meconium. A = ascites; L = liver.

FIGURE 15-50 Normal ventral wall. Transverse view of the abdomen demonstrating normal umbilical cord insertion and integrity of the anterior abdominal wall.

Ventral Wall Defects

The integrity of the abdominal wall is assessed at the level of the cord insertion during the standard examination (Fig. 15-50). Ventral wall defects include gastroschisis, omphalocele, and body stalk anomaly.

Gastroschisis

This is a full-thickness abdominal wall defect located to the right of the umbilical cord insertion. Bowel herniates through the defect into the amnionic cavity. Gastroschisis may be diagnosed as early as the late first trimester (Fig. 15-51). The prevalence is approximately 1 in 2000 births (Jones, 2016; Nelson, 2015). Gastroschisis is the one major anomaly more common in fetuses of younger mothers, and the average maternal age is 20 years (Santiago-Muñoz, 2007). Coexisting bowel abnormalities such as *jejunal atresia* are found in approximately 15 percent of cases (Overcash, 2014). Gastroschisis is not associated with aneuploidy, and the survival rate is 90 to 95 percent (Nelson, 2015; Raitio, 2020).

Fetal-growth restriction complicates gastroschisis in 15 to 40 percent of cases (Overcash, 2014; Santiago-Muñoz, 2007). Growth restriction does not appear to confer increased mortality (Nelson, 2015; Overcash, 2014). However, earlier gestational age at delivery does pose a risk for adverse outcome, and planned delivery at 36 to 37 weeks' gestation has not been found to benefit the neonate (Al-Kaff, 2016; South, 2013).

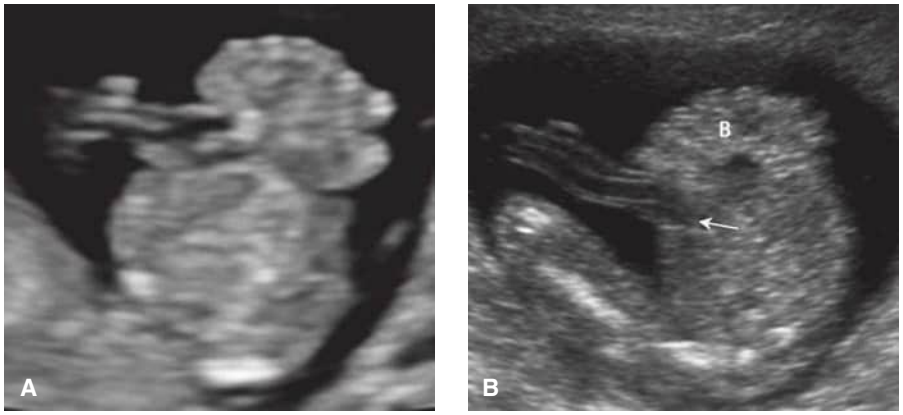

FIGURE 15-51 Gastroschisis. Transverse views of the lower abdomen at 13 weeks' gestation **(A)** and 18 weeks **(B)** depict multiple small bowel loops (*B*) that have herniated into the amnionic cavity through a defect to the right of the cord insertion (*arrow*).

Omphalocele

The birth prevalence of this anomaly approximates 1 in 3000 to 5000 (Canfield, 2006; Dolk, 2010). It develops when the lateral ectomesodermal folds fail to meet in the midline. Abdominal organs herniate into the base of the umbilical cord, covered only by a two-layered sac of amnion and peritoneum (Fig. 15-52). More than half of cases are associated with other major anomalies or aneuploidy. Aneuploidy is particularly common with smaller defects (De Veciana, 1994). Omphalocele is also a component of several syndromes, including *Beckwith–Wiedemann*, *cloacal exstrophy*, and *pentalogy of Cantrell*. Neonatal survival approximates 90 percent for isolated cases and 80 percent in those with other structural abnormalities (Raitio, 2021; Springett, 2014). Isolated defects containing liver are typically delivered via cesarean to decrease the risk for fetal trauma and bleeding.

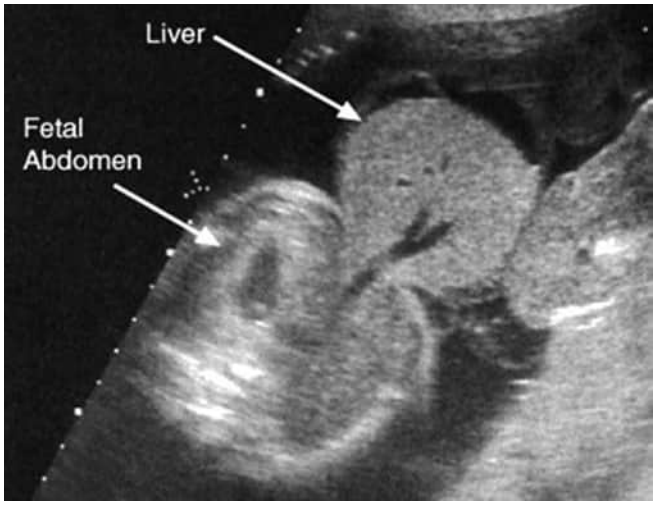

FIGURE 15-52 Omphalocele. Transverse view of the abdomen showing a large, round, membrane-covered ventral wall defect containing exteriorized liver.

Body Stalk Anomaly

Also known as *limb-body-wall complex* or *cyllosoma*, this rare, lethal anomaly is characterized by abnormal body wall formation. Typically, *no* abdominal wall is visible, and the abdominal organs extrude into the extraamnionic coelom (Fig. 15-53). The body and placenta are closely approximated or fused, and

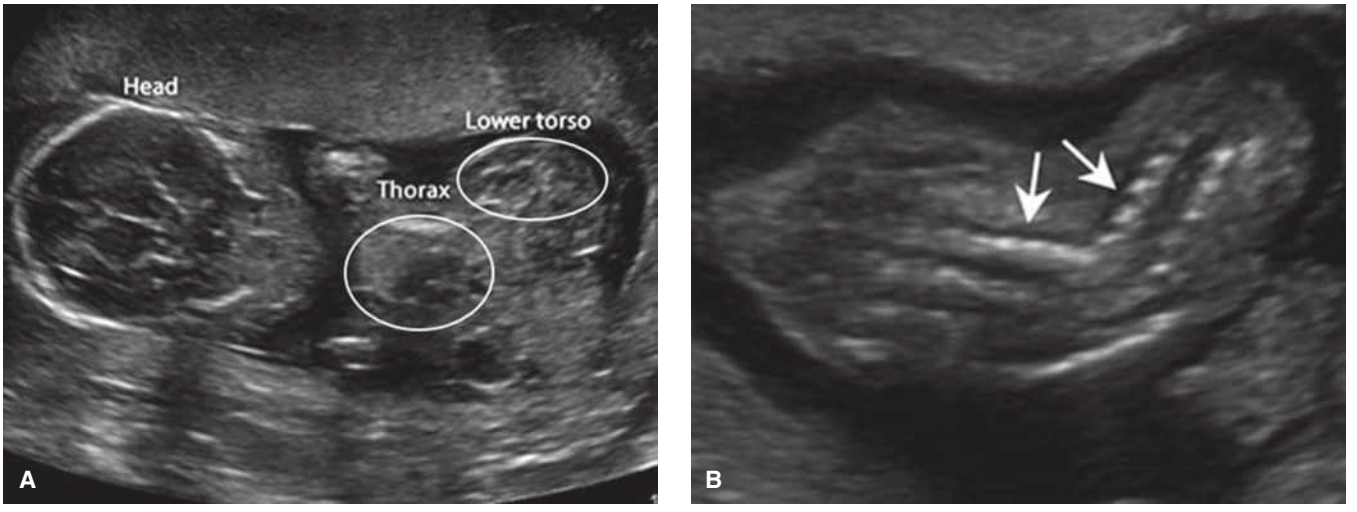

FIGURE 15-53 Body-stalk anomaly. **A.** This 15-week fetus has no visible abdominal wall. The thorax is disproportionately small compared with the head, and the small lower torso is deviated to the side. Arrows point to the large mass of extruded abdominal organs. **B.** Acute-angle scoliosis. Arrows depict the abnormal curvature of the spine. (Reproduced with permission from Deirdre Snelson, RDMS.)

the umbilical cord is extremely short. Acute-angle scoliosis is another feature, and amnionic bands are often identified.

Kidneys and Genitourinary Tract

The fetal kidneys are visible adjacent to the spine, frequently in the first trimester and routinely by 18 weeks' gestation (Fig. 15-54). The length of the kidney approximates 20 mm at 20 weeks and grows about 1.1 mm each week thereafter (Chitty, 2003).

The fetal bladder is also readily seen in the second trimester as a round, anechoic structure in the anterior midline of the pelvis. With application of Doppler, the bladder is outlined by the two superior vesical arteries as they become the umbilical arteries of the umbilical cord (Chap. 6, p. 114). The fetal ureters and urethra are not visible sonographically unless abnormally dilated.

After 18 weeks' gestation, the kidneys are the major source of amnionic fluid (Chap. 14, p. 256). Normal amnionic fluid volume in the second half of pregnancy suggests urinary tract patency and at least one functioning kidney.

External genitalia are a component of the detailed examination and are part of the standard examination in multifetal gestations and when medically indicated (American Institute of Ultrasound in Medicine, 2019). Identification may aid counseling in pregnancies at risk for an X-linked genetic condition. Examples of normal and ambiguous genitalia are shown in Figure 15-55. Disorders of sexual development are discussed in Chapter 3 (p. 35).

Renal Pelvis Dilatation

Present in 1 to 5 percent of fetuses, this finding is also called urinary tract dilatation or hydronephrosis. In 40 to 90 percent of cases, and particularly when mild, renal pelvis dilatation is transient or physiological and does not represent an underlying abnormality (Ismaili, 2003; Nguyen, 2010). In approximately one third of cases, a urinary tract abnormality is confirmed in the neonatal period. Of these, *ureteropelvic junction (UPJ) obstruction* and *vesicoureteral reflux (VUR)* are the most frequent.

The fetal renal pelvis diameter is measured anterior-to-posterior in a transverse plane. Calipers are placed on the inner border of the fluid collection (Fig. 15-56). Although various thresholds have been defined, the pelvis is typically considered dilated if it exceeds 4 mm in the second trimester or 7 mm at approximately 32 weeks' gestation (Nguyen, 2014; Reddy, 2014). The second-trimester threshold is used to identify pregnancies that warrant subsequent third-trimester evaluation.

The Society for Fetal Urology categorized renal pelvis dilatation based on a metaanalysis of more than 100,000 screened pregnancies (Table 15-2) (Lee, 2006; Nguyen, 2010). Provided that the finding is isolated, the degree of dilation correlates with

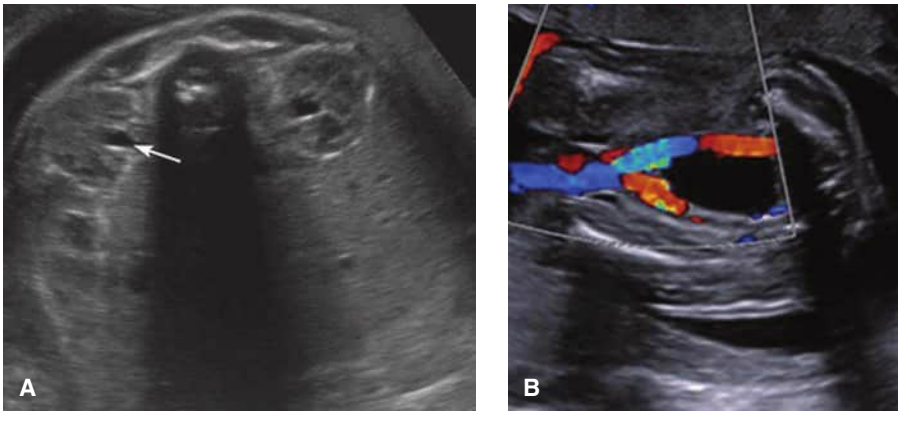

FIGURE 15-54 Normal fetal kidneys and bladder. **A.** The kidneys are visible adjacent to the spine in this 29-week fetus. A small amount of urine is often visible within the renal pelvis (*arrow*). **B.** Normal fetal bladder, outlined by the two superior vesical arteries as they become the umbilical arteries.

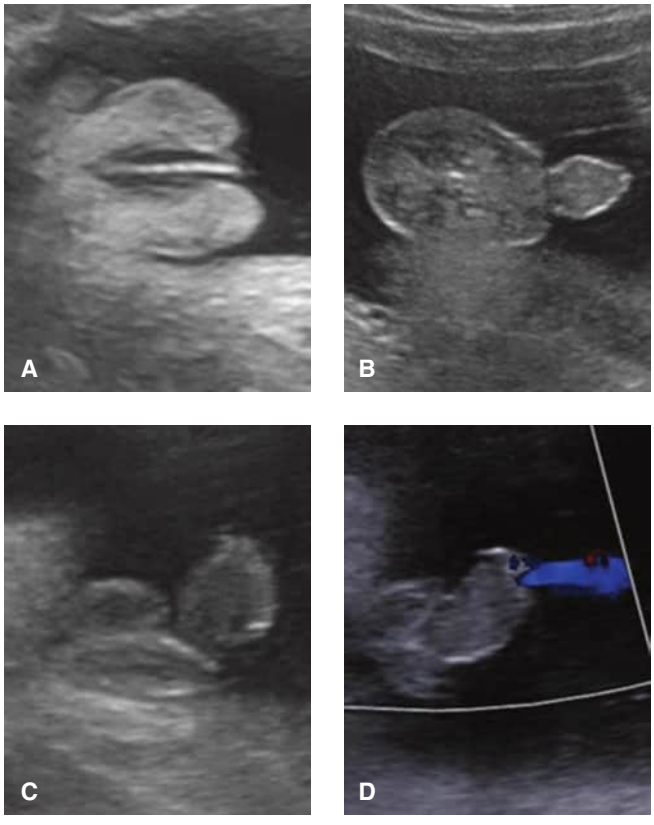

FIGURE 15-55 Normal and ambiguous genitalia. **A.** Female labia. **B.** Male penis and scrotum. **C.** Ambiguous genitalia with a phallus and bifid scrotum. **D.** With this condition, color Doppler can assist locating the urethral meatus, which is pinpointed here by the urine stream (*blue*).

the likelihood of an underlying abnormality. Associated calyceal dilation, cortical thinning, or dilation elsewhere along the urinary tract confer increased risk (Nguyen, 2014). Mild pyelectasis in the second trimester is a minor aneuploidy marker associated with a slightly increased risk for trisomy 21, particularly when other findings or risk factors are also present (Fig. 17-3, p. 340).

Ureteropelvic Junction Obstruction. This condition is the most common abnormality associated with renal pelvis dilatation. The birth prevalence is 1 in 1000 to 2000, and males are affected three times more often than females (Williams, 2007; Woodward, 2002). Obstruction is generally functional rather than anatomical, and it is bilateral in up to a fourth of cases. The likelihood of UPJ obstruction ranges from 5 percent with mild renal pelvis dilatation to more than 50 percent with severe dilatation (Lee, 2006).

TABLE 15-2. Risk for Postnatal Urinary Abnormality According to Degree of Renal Pelvis Dilation

Dilation	Second Trimester	Third Trimester	Postnatal Abnormality
Mild	4 to <7 mm	7 to <9 mm	12%
Moderate	7 to ≤10 mm	9 to ≤15 mm	45%
Severe	>10 mm	>15 mm	88%

Modified from Lee, 2006; Nguyen, 2010.

Duplicated Renal Collecting System. In this anatomical anomaly, the upper and lower poles of the kidney—called moieties—are each drained by a separate ureter (Fig. 15-57). Duplication is found in approximately 1 in 4000 pregnancies, is more common in females, and is bilateral in 15 to 20 percent of cases (James, 1998; Vergani, 1998; Whitten, 2001). Sonographically, an intervening tissue band separates two distinct renal pelves. Hydronephrosis or ureteral dilation may develop due to abnormal implantation of one or both ureters within the bladder—a relationship that reflects the anatomical *Weigert-Meyer* rule. The upper pole ureter tends to develop obstruction from a ureterocele within the bladder, whereas the lower pole ureter has a shortened intravesical segment that predisposes to VUR (see Fig. 15-57). Thus, both moieties may become dilated from different etiologies, and both are at risk for loss of function.

Renal Agenesis

The estimated prevalence of bilateral renal agenesis is 1 in 8000 births, whereas that of unilateral renal agenesis is 1 in 1000 births (Cragan, 2009; Dolk, 2010; Sheih, 1989; Wiesel, 2005). With an absent kidney, color Doppler imaging of the descending aorta demonstrates absence of the ipsilateral renal artery (Fig. 15-58). In addition, the ipsilateral adrenal gland typically enlarges to fill the renal fossa, termed the *lying down adrenal sign* (Hoffman, 1992).

If renal agenesis is bilateral, no urine is produced, and the resulting anhydramnios leads to pulmonary hypoplasia, limb contractures, and distinctive facies. When this combination results from renal agenesis, it is called *Potter syndrome*, after Dr. Edith Potter, who described it in 1946. When these abnormalities result from severely decreased amniotic fluid volume from another etiology, such as bilateral multicystic dysplastic kidney or autosomal

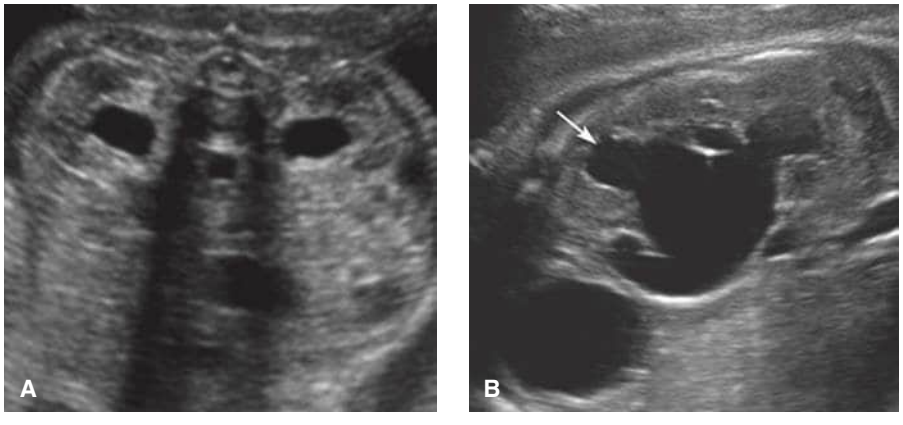

FIGURE 15-56 Renal pelvis dilatation. **A.** The anterior-posterior diameter of the renal pelves measured 7 mm in the transverse plane in this 34-week fetus. **B.** Sagittal image at 32 weeks depicts renal pelvis dilatation with rounded calyces (*arrow*) in the setting of ureteropelvic junction obstruction.

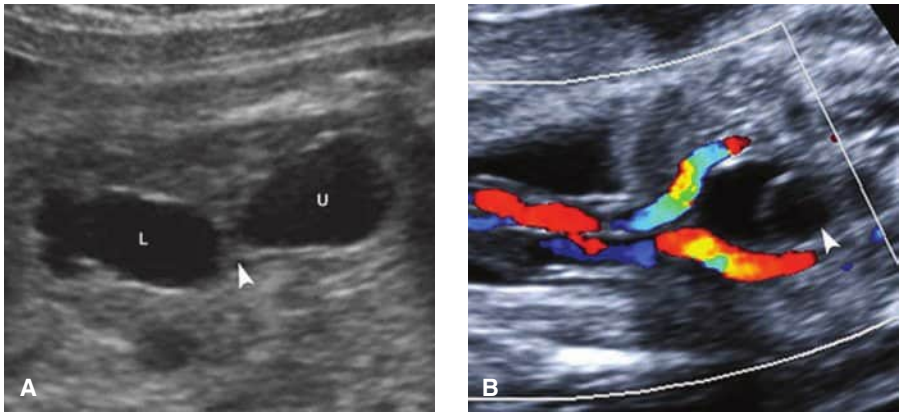

FIGURE 15-57 Duplicated renal collecting system. **A.** Renal pelvis dilatation is visible in both the upper (*U*) and lower (*L*) pole moieties, which are separated by an intervening band of renal tissue (*arrowhead*). **B.** A ureterocele (*arrowhead*) is visible within the bladder. Color Doppler depicts the superior vesical arteries.

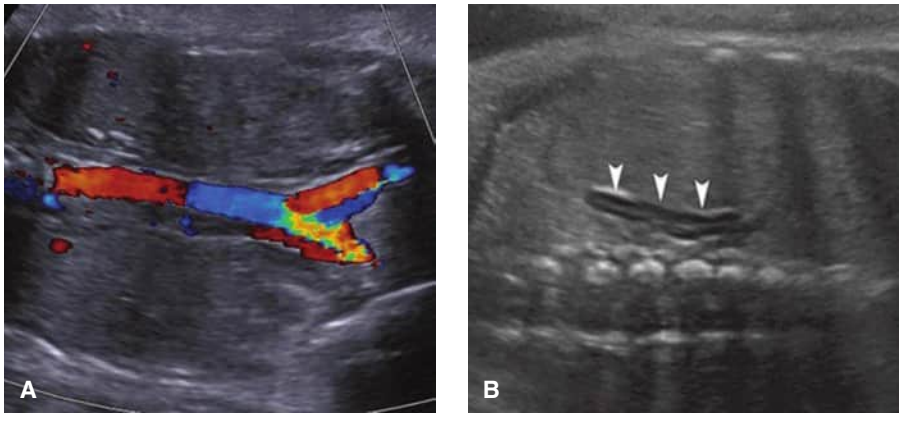

FIGURE 15-58 Renal agenesis. **A.** Coronal image of a fetus with bilateral renal agenesis in which color Doppler of the abdominal aorta is used to demonstrate absence of the renal arteries. **B.** In this fetus with unilateral renal agenesis, arrowheads point to the adrenal gland (*arrowheads*) filling the renal fossa, which is the "lying-down" adrenal sign.

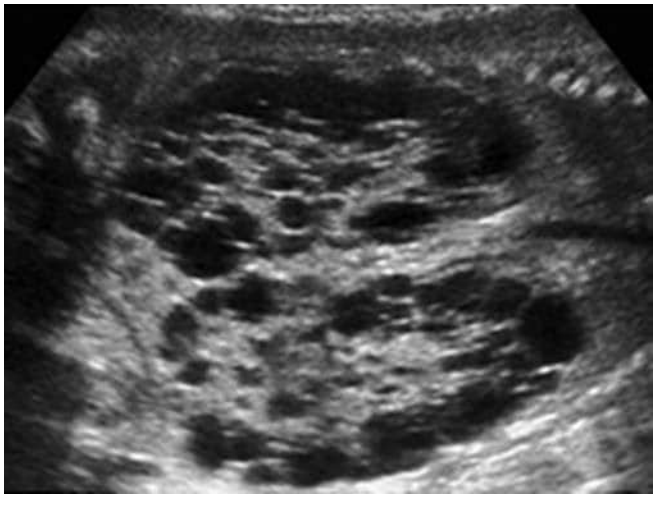

FIGURE 15-59 Multicystic dysplastic kidneys. Coronal view of the fetal abdomen demonstrates enlarged kidneys that are filled with cysts of varying size and contain no visible renal pelvis or normal-appearing renal tissue.

recessive polycystic kidney disease, it is called *Potter sequence.* The prognosis for these abnormalities is extremely poor.

Multicystic Dysplastic Kidney

This severe form of renal dysplasia results in a nonfunctioning kidney. The nephrons and collecting ducts form abnormally, such that primitive ducts are surrounded by fibromuscular tissue, and the ureter is atretic (Hains, 2009). Sonographically, the kidney contains numerous, variably sized, smooth-walled cysts that do not communicate with the renal pelvis and are surrounded by echogenic cortex (Fig. 15-59).

Unilateral multicystic dysplastic kidney (MCDK) has a prevalence of 1 in 4000 births. Contralateral renal abnormalities are present in 30 to 40 percent—most frequently VUR or UPJ obstruction (Schreuder, 2009). Nonrenal anomalies have been reported in 25 percent of cases. Cystic dysplasia may occur as a component of many genetic syndromes (Lazebnik, 1999; Schreuder, 2009). If MCDK is isolated and unilateral, the prognosis is generally good. Bilateral MCDK is found in approximately 1 in 12,000 births. It is associated with severely decreased amnionic fluid volume starting early in gestation. This leads to Potter sequence and a poor prognosis.

Polycystic Kidney Disease

Of the hereditary polycystic diseases, only the infantile form of *autosomal recessive polycystic kidney disease (ARPKD)* may be reliably diagnosed prenatally. ARPKD is a chronic, progressive disease of the kidneys and liver that results in cystic dilation of the renal collecting ducts and in congenital hepatic fibrosis (Turkbey, 2009). The carrier frequency of a disease-causing mutation in the *PKHD1* gene approximates 1 in 70, and the birth prevalence is 1 in 20,000 (Zerres, 1998). The phenotypes of ARPKD range from lethal pulmonary hypoplasia at birth to a presentation in late childhood or even adulthood with predominantly hepatic manifestations. Sonographically, ARPKD displays abnormally large kidneys that may fill or even distend the fetal abdomen and have a solid, ground-glass texture (Fig. 15-60). Severe oligohydramnios confers a poor prognosis.

Autosomal dominant polycystic kidney disease (ADPKD), which is far more common, usually does not manifest until adulthood (Chap. 56, p. 1001). Even so, some fetuses with ADPKD have mild renal enlargement and enhanced renal echogenicity in the setting of normal amnionic fluid volume.

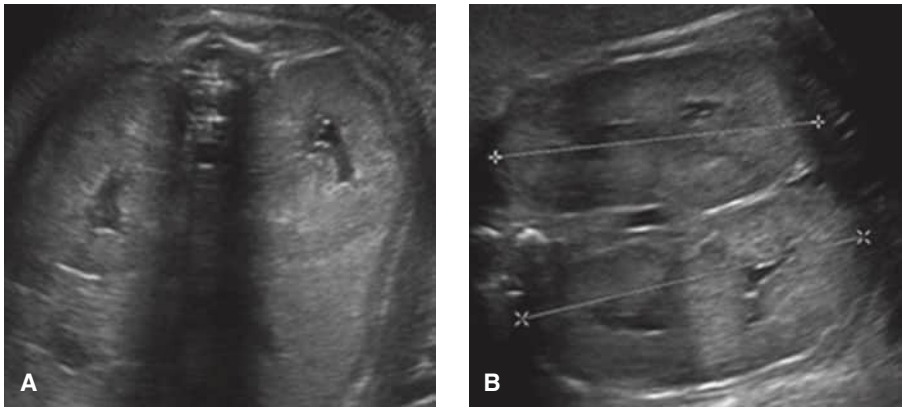

FIGURE 15-60 Autosomal recessive polycystic kidney disease (ARPKD). Transverse **(A)** and coronal **(B)** images of a 29-week fetus with marked renal enlargement. The kidneys measure 7 cm in length and have a ground-glass appearance. There is anhydramnios.

The differential diagnosis for these findings includes several genetic syndromes, aneuploidy, or normal variant.

Bladder Outlet Obstruction

Distal obstruction of the urinary tract is more frequent in male fetuses, and the most common etiology is *posterior urethral valves*. It may be diagnosed as early as the first trimester in some cases (Fig. 15-61). The bladder is markedly dilated, with accompanying dilation of the proximal urethra, which is termed the "keyhole" sign. Oligohydramnios, particularly before midpregnancy, portends pulmonary hypoplasia and poor prognosis. The kidneys may initially manifest severe hydroureteronephrosis but later develop cystic renal dysplasia or become small and echogenic. Outcome may be poor even with normal amnionic fluid volume. Associated anomalies occur in 40 percent of cases, and aneuploidy has been reported in 5 to 8 percent (Hayden, 1988; Hobbins, 1984; Mann, 2010). Evaluation and potential fetal therapy for bladder outlet obstruction is discussed in Chapter 19 (p. 376).

SKELETON

The standard examination includes demonstrating the presence of the arms, legs, hands, and feet (American Institute of Ultrasound in Medicine, 2018). The detailed examination includes, in addition, the number and position of the digits—fingers and toes (Fig. 15-62).

The Nosology and Classification of Genetic Skeletal Disorders includes 461 skeletal anomalies in 42 groups, characterized according to their molecular phenotype, clinical features, or radiographic findings (Mortier, 2019). More than 90 percent of skeletal disorders now have a known genetic basis, with pathogenic variants identified in more than 400 genes. The two types of skeletal dysplasias are *osteochondrodysplasias*—the generalized abnormal development of bone and/or cartilage, and *dysostoses*—which are abnormalities of individual bones. In addition to these *malformations*, skeletal abnormalities include *deformations*, as with some cases of clubfoot, and *disruptions* such as limb-reduction defects.

■ Skeletal Dysplasias

The prevalence of skeletal dysplasias approximates 3 in 10,000 births. Two groups account for more than half of all cases: the *fibroblast growth factor 3 (FGFR3) chondrodysplasia* group and the *osteogenesis imperfecta* and decreased bone density group. Each occurs in 0.8 in 10,000 births (Stevenson, 2012).

Evaluation of a pregnancy with suspected skeletal dysplasia includes a survey of every long bone, as well as the hands and feet, skull size and shape, clavicles, scapulae, thorax, and spine. Reference tables are used to determine which long bones are affected and ascertain the degree of shortening (Appendix, p. 1239). Involvement of all long bones is termed *micromelia*, whereas predominant involvement of only the proximal, intermediate, or distal long bone segments is termed *rhizomelia*, *mesomelia*, and *acromelia*, respectively. The degree of ossification should be noted, as should presence of bowing or fractures.

Although precise characterization may elude prenatal diagnosis, it is frequently possible to determine whether a skeletal dysplasia is lethal. Lethal dysplasias show profound long bone

FIGURE 15-61 Bladder outlet obstruction. **A.** The bladder (*B*) is so large that it fills the abdomen in this 13-week fetus. **B.** By 18 weeks, the kidneys (*K*) have become brightly echogenic. **C.** The bladder is markedly dilated and thick-walled, with dilation of the proximal urethra, termed the "keyhole" sign (*arrow*).

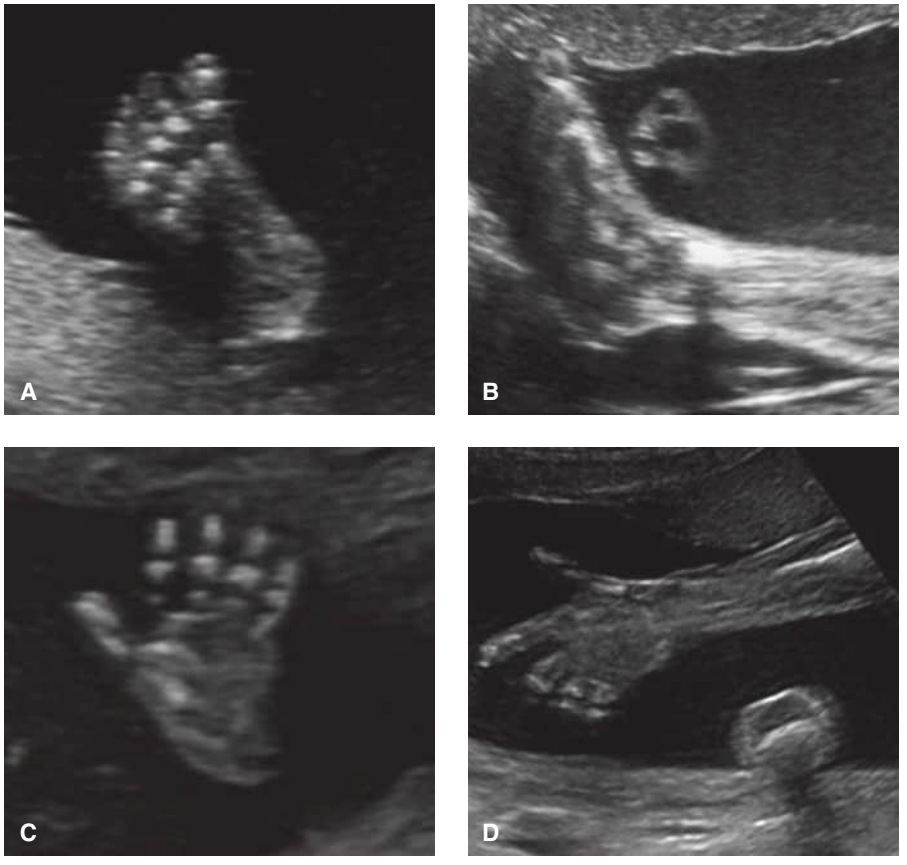

FIGURE 15-62 Normal extremities. **A.** Footprint with toes identified. **B.** Normal ankle position. **C.** Hand with fingers identified. **D.** Normal hand and forearm position.

shortening, often with measurements far below the 5th percentile, and display femur length-to-abdominal circumference ratios <16 percent (Nelson, 2014; Rahemtullah, 1997; Ramus, 1998). Other sonographic abnormalities are generally evident. Pulmonary hypoplasia is suggested by a thoracic circumference <80 percent of the abdominal circumference value, a thoracic circumference <2.5th percentile, and a cardiac circumference >50 percent of the thoracic circumference value (Appendix, p. 1238). Affected pregnancies may also develop hydramnios and/or hydrops.

The FGFR3 chondrodysplasias include *achondroplasia*, *hypochondroplasia*, and *thanatophoric dysplasia*. Achondroplasia is the most common nonlethal skeletal dysplasia. An impressive 98 percent of cases are due to a specific point mutation in the *FGFR3* gene. Inheritance is autosomal dominant, and 80 percent of cases result from a new mutation. Achondroplasia is characterized by long bone shortening that is predominantly *rhizomelic*, an enlarged head with frontal bossing, depressed nasal bridge, exaggerated lumbar lordosis, and a trident configuration of the hands. Intelligence is usually normal. The femur and humerus measurements may not fall below the 5th percentile until the early third trimester. In homozygotes, who represent 25 percent of the offspring of heterozygous parents, the condition is characterized by greater long bone shortening and is lethal.

The other major class of FGFR3 dysplasias, *thanatophoric dysplasia*, is the most common lethal skeletal disorder. It is characterized by severe micromelia, and affected fetuses—particularly those with type II—may develop a characteristic cloverleaf skull deformity (*Kleeblattschädel*) due to craniosynostosis. Genetic testing is confirmatory.

Osteogenesis imperfecta represents a group of skeletal dysplasias typified by hypomineralization. There are multiple types, and more than 90 percent of cases are characterized by a mutation in the *COL1A1* or *COL1A2* gene. Type II, also called the perinatal form, is lethal. The skull displays a profound lack of ossification, and gentle pressure on the maternal abdomen from the ultrasound transducer results in visible skull deformation (Fig. 15-63). Other features include multiple in-utero fractures and ribs that appear "beaded." Inheritance is autosomal dominant, such that all cases result from either new mutations or gonadal mosaicism. Another skeletal dysplasia that creates severe hypomineralization is *hypophosphatasia*, which has an autosomal recessive inheritance.

Polydactyly

The most common skeletal abnormality is polydactyly, which occurs in approximately 1 in 1000 births. It is *post-axial* if on the side of the ulna or fibula and *pre-axial* if on the side of the

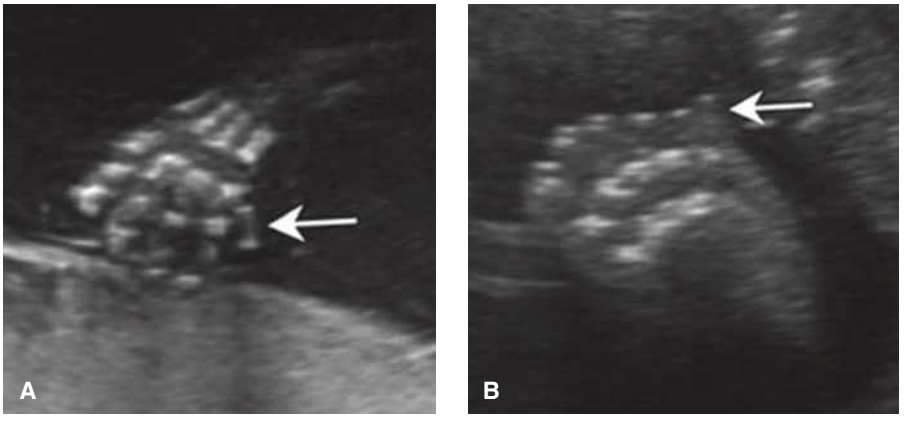

FIGURE 15-63 Post-axial polydactyly. **A.** In this image of the hand, the arrow points to a rudimentary digit adjacent to the little finger. **B.** Foot with 6 toes in a fetus with trisomy 13. The arrow points to the extra digit.

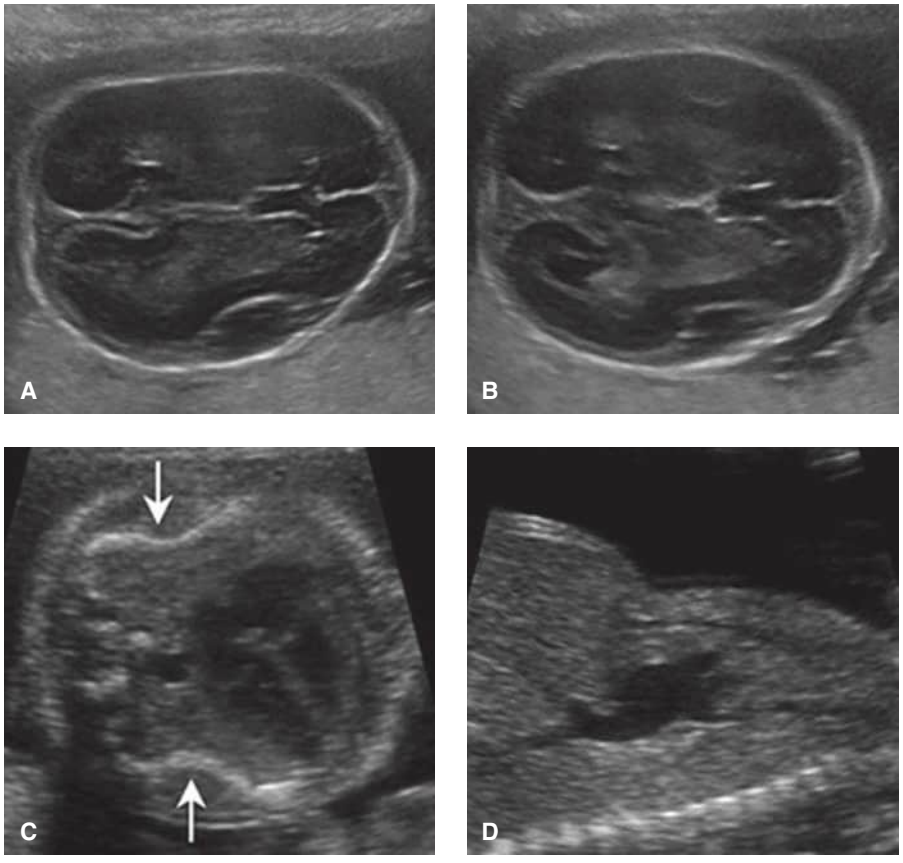

FIGURE 15-64 Osteogenesis imperfecta, Type IIa. **A.** Due to lack of skull ossification, gentle ultrasound transducer pressure on the maternal abdomen results in visible deformation (flattening) of the skull in this 24-week fetus. **B.** When the transducer pressure is removed, the skull shape returns to normal. **C.** In the four-chamber view of the heart, in-utero fractures lead to abrupt angulation of the ribs (*arrows*). **D.** The thorax is markedly smaller than the abdomen in this sagittal image.

radius or tibia (Fig. 15-64). The extra digit is often rudimentary, and in the absence of a bony component, prenatal detection may be limited. Post-axial polydactyly is more common and is frequently inherited in an autosomal dominant fashion. Polydactyly is also a feature of syndromes such as Meckel-Gruber and trisomy 13.

■ Clubfoot—Talipes Equinovarus

This disorder is notable for a deformed talus and shortened Achilles tendon. The affected foot is abnormally fixed and positioned with *equinus* (downward pointing), *varus* (inward rotation), and forefoot adduction. Most cases are considered malformations, with a multifactorial genetic component. However, an association with environmental factors and with early amniocentesis suggests that deformation also plays a role (Tredwell, 2001). Sonographically, the footprint is visible in the same plane as the tibia and fibula (Fig. 15-65).

The prevalence of clubfoot approximates 1 in 1000 births, and the male:female ratio is 2:1 (Carey, 2003; Pavone, 2012). Clubfoot is bilateral in approximately 50 percent of cases. At least 50 percent of affected individuals have associated abnormalities, such as neural-tube defects, arthrogryposis, and myotonic dystrophy and other genetic syndromes (Mammen, 2004; Sharma, 2011). If there are other abnormalities, aneuploidy is present in 30 percent. In contrast, the aneuploidy rate is <4 percent when clubfoot appears isolated (Lauson, 2010; Sharma, 2011). Thus, a careful search for associated abnormalities is warranted, and chromosomal microarray analysis may be considered.

■ Limb-Reduction Defects

Documentation of the arms and legs is a component of the standard examination. The absence or hypoplasia of all or part of one or more extremities is a *limb-reduction defect*. The birth prevalence is 4 to 8 in 10,000 (Kucik, 2012; Stoll, 2010; Vasluian, 2013). Approximately half of these are isolated defects, up to one third occur as part of a recognized syndrome, and individuals in the remaining cases have other coexisting anomalies (Stoll, 2010; Vasluian, 2013). Upper extremities are affected more frequently than lower ones. A terminal *transverse limb defect* lacks part or all of a distal limb to create a stump (Fig. 15-66). This is more common than a *longitudinal defect*, which is complete or partial absence of the long bone(s) on only one side of a given extremity.

Absence of an entire extremity is termed *amelia*. *Phocomelia*, associated with thalidomide exposure, is an absence of one or more long bones with the hands or feet attached to the trunk (Chap. 8, p. 155). Limb-reduction defects are associated with numerous genetic syndromes, such

FIGURE 15-65 Talipes equinovarus or clubfoot. This condition is diagnosed by visualizing the "footprint" in the same plane as the tibia and fibula.

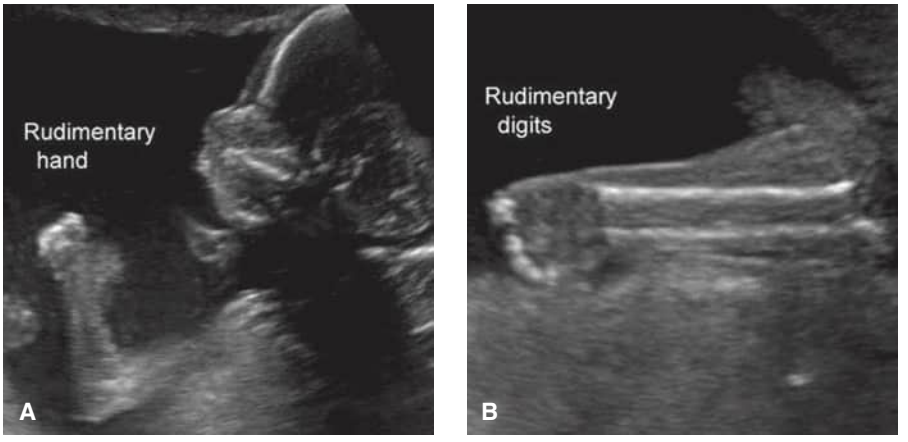

FIGURE 15-66 Transverse limb-reduction defect. **A.** At 18 weeks' gestation, only a rudimentary hand was visible. **B.** By 24 weeks, the radius and ulna were normal in size and appearance, and small rudimentary digits were evident.

as *Roberts syndrome*, an autosomal recessive condition characterized by *tetraphocomelia.* A *clubhand deformity*, usually from an absent radius, is a component of the *thrombocytopenia-absent radius syndrome* and is also associated with trisomy 18 (Fig. 16-5, p. 312). Limb-reduction defects may occur in the setting of a disruption such as amnionic-band sequence (Chap. 6, p. 113). They have also been associated with chorionic villus sampling when performed before 10 weeks' gestation (Fig. 17-5, p. 346).

CHAPTER 16

Genetics

Genetics is the study of genes, heredity, and the variation of inherited characteristics. Medical genetics addresses the etiology and pathogenesis of human diseases that are at least partially genetic in origin, as well as their prediction and prevention. Whereas a gene is a specific sequence of deoxyribonucleic acid (DNA) on a single chromosome that codes for a particular protein, a *genome* is the entirety of all genes that make up an organism. *Genomics* is the study of how genes function and interact with one other. Chromosomal, mendelian, and nonmendelian genetic conditions are reviewed in this chapter. Prenatal and preimplantation genetic testing and newborn genetic screening are discussed in Chapters 17 and 32, respectively.

Genetic disease is common. Two to 3 percent of newborns have a recognized structural abnormality, another 3 percent are diagnosed with an abnormality by age 5 years, and yet another 8 to 10 percent are found to have a functional or developmental abnormality before reaching adulthood.

GENOMICS IN OBSTETRICS

The Human Genome Project was an international research program that sequenced the 3 billion base pairs and more than 20,000 genes that make up the human genome. It paved the way for research into gene organization and function in an effort to understand the molecular basis of disease. More than 99 percent of our DNA is identical. The coding regions of DNA—*exons*—constitute only 1.5 percent of the genome. An *exome* is the entirety of all the exons that an organism contains. *Introns* are DNA sequences involved in coding regulation and make up 24 percent of the genome. Intergenic DNA composes the remainder.

Our genetic code varies once every 200 to 500 base pairs, usually as a single-nucleotide polymorphism (SNP). Thus, whole genome sequencing and whole exome sequencing, described later (p. 327), hold tremendous potential to further elucidate genetic variants in disease.

Toward this goal, genetic and genomic databases are maintained by the National Center for Biotechnology Information (2021). These are freely accessible and can be indispensable to providers who offer counseling and testing for genetic conditions. The *GeneReviews* database has in-depth clinical information for more than 800 genetic conditions, including diagnostic criteria and management considerations. The *Genetic Testing Registry (GTR)* database contains information for nearly 80,000 genetic tests and instructions for specimen collection and transport to individual laboratories throughout

the world (National Center for Biotechnology Information, 2021). The National Library of Medicine (2021) has also established a genetic information database, the *MedlinePlus Genetics,* which is intended for the lay population. It provides explanations of more than 1300 genetic conditions, a glossary of genetic concepts, and links to more comprehensive medical resources.

CHROMOSOMAL ABNORMALITIES

Chromosomal abnormalities figure prominently in genetic disease. They account for >50 percent of first-trimester miscarriages, approximately 20 percent of second-trimester losses, and 6 to 8 percent of stillbirths and early-childhood deaths (Reddy, 2012; Stevenson, 2004; Wou, 2016). Based on data from population-based registries, chromosomal abnormalities are identified in 0.4 percent of recognized pregnancies (Wellesley, 2012). Most of these are aneuploidies. Trisomy 21 accounts for >50 percent, trisomy 18 for nearly 15 percent, and trisomy 13 for 5 percent of cases (Fig. 16-1). If no karyotypic abnormality is identified in a fetus with a structural anomaly, additional testing with chromosomal microarray analysis is anticipated to detect a chromosomal deletion or duplication—a *copy number variant*—in approximately 6.5 percent of cases (American College of Obstetricians and Gynecologists, 2020c).

Standard Nomenclature

Chromosomal abnormalities are described using the International System for Human Cytogenomic Nomenclature (McGowan-Jordan, 2020). Abnormalities fall into two broad categories: *abnormal chromosome number*, such as trisomy, and *abnormal chromosome structure*, such as a DNA segment deletion or duplication. Each chromosome has a short arm, termed the "p" or petit arm, and a long arm, known as the "q" arm, selected because it is the next letter in the alphabet. The two arms are separated by the centromere.

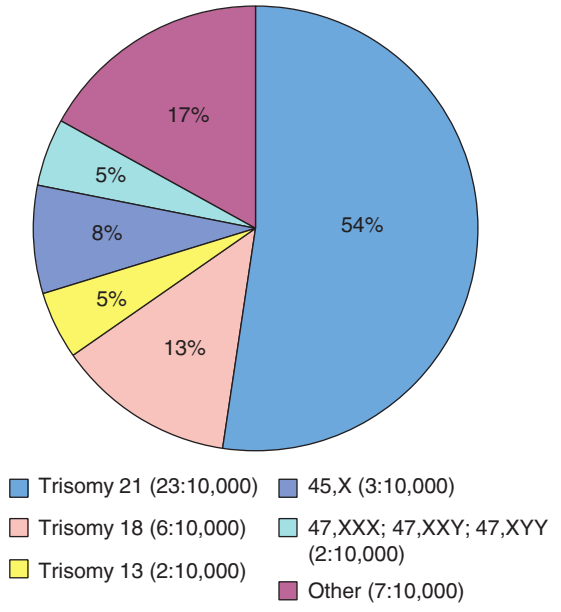

FIGURE 16-1 Prevalence and relative proportion of selected chromosomal abnormalities from EUROCAT (European Surveillance of Congenital Anomalies) population-based registries that included >10,000 aneuploid live births, fetal deaths, and pregnancy terminations, 2000–2006.

When reporting a karyotype, the total number of chromosomes is listed first, corresponding to the number of centromeres. This is followed by the sex chromosomes, XX or XY, and then by a description of any structural variation. Specific chromosomal abnormalities are indicated by standard abbreviations, such as del (deletion), inv (inversion), and t (translocation). The affected region or bands of the arms are then reported, so that the reader will know the exact location. Examples are shown in Table 16-1.

Nomenclature is similar for fluorescence in situ hybridization (FISH), a technique used to rapidly identify a specific chromosome abnormality (p. 325). The abbreviation *ish* applies when in situ hybridization is performed on metaphase cells and *nuc ish* when performed on interphase nuclei. If the result is normal, ish is followed by the probe's specific chromosomal region, such as 22q11.2, and then the name of the probe and the number of signals visualized—for example, HIRAx2. If a deletion is identified, *del* is included before the chromosomal region, and the name of the probe is followed by a minus sign (HIRA–), as shown in Table 16-1. The 22q11.2 deletion syndrome is discussed later (p. 315).

For chromosomal microarray analysis (CMA), the designation begins with the abbreviation *arr* (p. 348). This is followed by the version of the genome build to which the nucleotide designations are aligned, such as GRCh38 for Genome Reference Consortium human build 38. Next, the number of the chromosome containing the abnormality is listed, followed by the p or q arm, and then the specific bands in question. CMA reports also include the affected base pair coordinates and thus convey the exact size and location for every abnormality identified (see Table 16-1). The information is reported in the same way whether the alteration is pathogenic or is of uncertain clinical significance.

Abnormalities of Chromosome Number

The most easily recognized chromosomal abnormalities are numerical. *Aneuploidy* is the inheritance of either an extra chromosome—resulting in trisomy, or loss of a chromosome—*monosomy*. This differs from *polyploidy*, which is an abnormal number of whole haploid chromosome sets. For example, triploidy has 69 chromosomes. The estimated incidence of various numerical chromosomal abnormalities is shown in Figure 16-1 (Wellesley, 2012).

Autosomal Trisomies

Trisomy usually results from nondisjunction, which is the failure of normal chromosomal pairing and separation during meiosis. Nondisjunction may occur if the chromosomes: (1) fail to pair up, (2) pair up properly but separate prematurely, or (3) fail to separate. Although each chromosome pair is equally likely to have a segregation error, trisomies other than 21, 18, or 13 rarely result in term pregnancies. Each of these autosomal

TABLE 16-1. Examples of Karyotype Designations Using the 2020 International System for Human Cytogenomic Nomenclature

Karyotype	Description
46,XX	Normal female chromosome constitution
47,XY,+21	Male with trisomy 21
47,XX,+21/46,XX	Female who is a mosaic of trisomy 21 cells and cells with normal constitution
46,XY,del(4)(p14)	Male with terminal deletion (del) of the short arm of chromosome 4 at band p14
46,XX,dup(5)(p14p15.3)	Female with duplication (dup) of the short arm of chromosome 5 from band p14 to band p15.3
45,XY,der(13;14)(q10;q10)	Male with balanced robertsonian translocation (der) of the long arms of chromosomes 13 and 14—the karyotype now has one normal 13, one normal 14, and the translocation chromosome, reducing the normal 46 chromosome complement to 45
46,XX,t(11;22)(q23;q11.2)	Female with a balanced reciprocal translocation (t) between chromosomes 11 and 22, with breakpoints at 11q23 and 22q11.2
46,XY,inv(3)(p21q13)	Male with inversion (inv) of chromosome 3 that extends from p21 to q13—a pericentric inversion because it includes the centromere
46,X,r(X)(p22.1q27)	Female with one normal X and one ring (r) X chromosome, with the regions distal to p22.1 and q27 deleted from the ring
46,X,i(X)(q10)	Female with one normal X chromosome and an isochromosome (i) of the long arm of the other X
ish 22q11.2(HIRAx2)	FISH of metaphase cells using a probe for the HIRA locus of the 22q11.2 region, with 2 signals identified (no evidence of microdeletion)
ish del(22)(q11.2q11.2) (HIRA-)	FISH of metaphase cells using a probe for the HIRA locus of the 22q11.2 region, with only one signal identified, consistent with the microdeletion
arr[GRCh38] 18p11.32q23 (102328_79093443)x3	Microarray analysis (arr), genome build GRCh38, showing a single copy gain on chromosome 18 from band p11.32 to band q23 (essentially the entire chromosome), consistent with trisomy 18
arr[GRCh38] 4q32.2q35.1 (163146681_183022312)x1	Microarray analysis (arr), genome build GRCh38, showing a copy loss on the long arm of chromosome 4 at bands q32.2 through q35.1 (19.9 Mb)
arr[GRCh38] 15q11.2q26 (23123715_101888908)x2 hmz	SNP microarray analysis (arr), genome build GRCh 38, showing homozygosity for the entire long arm of chromosome 15

FISH = fluorescence in situ hybridization; GRCh38 = Genome Reference Consortium human build 38; HIRA = histone cell cycle regulator; SNP = single nucleotide polymorphism.
Used with permission from Dr. Kathleen S. Wilson.

trisomies has a spectrum of phenotypic severity. Some fetuses come to attention earlier in a pregnancy due to multiple major organ abnormalities or hydrops fetalis (p. 328). Others have more subtle findings or are detected only through prenatal screening tests (Chap. 17, p. 337). Survival data are based on cases with better prognosis, and this factors into counseling.

The likelihood that a pregnancy will be complicated by an autosomal trisomy rises steeply with maternal age and particularly after age 35 (Fig. 16-2) (Mai, 2013). From birth until ovulation, oocytes are suspended in midprophase of meiosis I. If nondisjunction occurs after completion of meiosis, one gamete will have two copies of the affected chromosome, which leads to trisomy if fertilized. The other gamete, receiving no copy of the affected chromosome, is nullisomic and will be monosomic if fertilized. It is estimated that 10 to 20 percent of oocytes are aneuploid secondary to meiotic errors compared with 3 to 4 percent of sperm. After a pregnancy with an autosomal trisomy, the risk for any autosomal trisomy in a future pregnancy approximates 1 percent until the woman's age-related risk exceeds this. Screening and prenatal diagnosis of autosomal trisomies are discussed in Chapter 17 (p. 333). Parental chromosomal studies are not indicated unless the abnormality was caused by an unbalanced translocation or other structural rearrangement (p. 315).

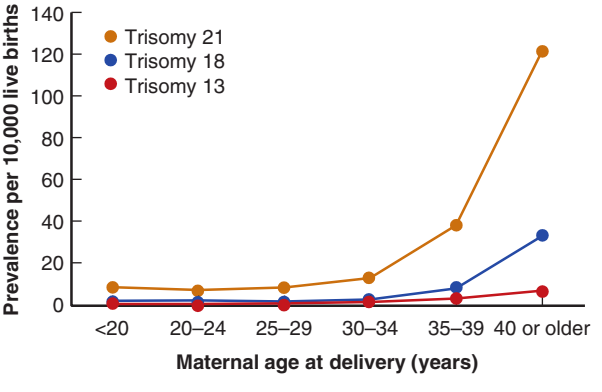

FIGURE 16-2 Prevalence of autosomal trisomies according to maternal age found in population-based birth defect surveillance programs in the United States, 2006–2010.

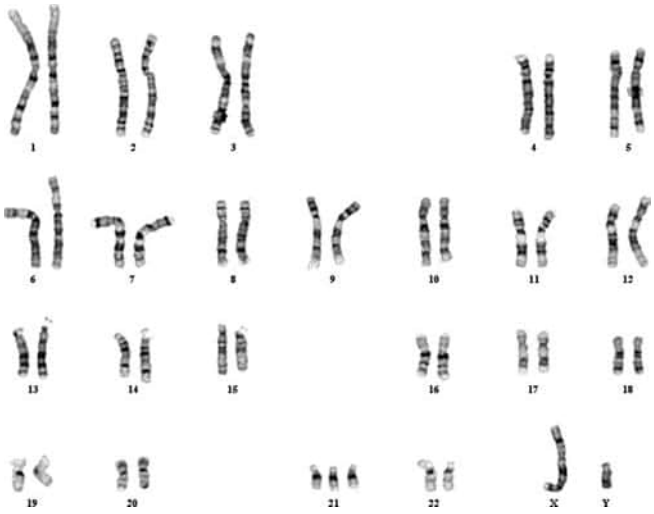

FIGURE 16-3 Male karyotype with trisomy 21 (47,XY,+21), consistent with Down syndrome. (Reproduced with permission from Dr. Prasad Koduru.)

Trisomy 21—Down Syndrome. In 1866, J. L. H. Down described a group of intellectually disabled children with distinctive physical features. Nearly 100 years later, Lejeune (1959) demonstrated that Down syndrome stems from an autosomal trisomy (Fig. 16-3). Trisomy 21 causes 95 percent of Down syndrome cases. The nondisjunction event occurs during meiosis I in approximately 75 percent of cases and in meiosis II in the remainder. Because chromosome 21 is acrocentric, a robertsonian translocation (p. 315) may occur, and this accounts for 3 to 4 percent of Down syndrome births. The remaining 1 to 2 percent are caused by isochromosome 21 or mosaicism for chromosome 21 (p. 317).

Down syndrome is the most common nonlethal trisomy. It is identified in approximately 1 in 450 pregnancies (Loane, 2013). In the United States, fetal losses and pregnancy terminations yield an estimated prevalence of 1 case per 740 live births (Mai, 2013; Parker, 2010). The fetal death rate beyond 20 weeks' gestation approximates 5 percent. Coinciding with the rise in overall number of pregnancies in women aged 35 years and older, the proportion of pregnancies with Down syndrome has increased approximately 33 percent during the past four decades (Loane, 2013; Parker, 2010; Shin, 2009). Most Down syndrome births at Parkland Hospital now occur in women in this age group (Hussamy, 2019).

If major anomalies and minor aneuploidy markers are considered, 50 to 75 percent of pregnancies affected by Down syndrome are found to have a sonographic abnormality (Chap. 17, p. 340) (American College of Obstetricians and Gynecologists, 2020d; Hussamy, 2019). A major structural malformation is detected in the second trimester in approximately one third of cases. The most prevalent anomalies in affected children are cardiac and gastrointestinal. Cardiac abnormalities occur in approximately 50 percent, particularly endocardial cushion defects and ventricular septal defects (Figs. 15-39A and 15-39B, p. 291) (Bergstrom, 2016; Freeman, 2008; Stoll, 2015). Gastrointestinal abnormalities are identified in 6 to 12 percent and include esophageal atresia, duodenal atresia, and Hirschsprung disease (Fig. 15-48, p. 296) (Bull, 2011; Stoll, 2015).

Other health problems are also common with Down syndrome. These include hearing loss in 75 percent, optical refractive errors in 50 percent, cataracts in 15 percent, obstructive sleep apnea in 60 percent, thyroid disease in 15 percent, transient myeloproliferative disorder in 10 percent of newborns, early-onset Alzheimer's disease in 70 percent of adults, and a higher incidence of leukemia (Bull, 2011; Hartley, 2015). Women with Down syndrome are fertile, and nearly one third of their offspring will have Down syndrome. Males with Down syndrome have markedly reduced spermatogenesis and are almost always sterile. The average intelligence quotient (IQ) score is 35 to 70. Social skills in affected children are usually higher than predicted by their IQ scores.

Characteristic features of Down syndrome are shown in Figure 16-4. Typical findings include brachycephaly; epicanthal folds and up-slanting palpebral fissures; Brushfield spots, which are whitish spots on the periphery of the iris; a flat nasal bridge; and hypotonia. Infants often have loose skin at the

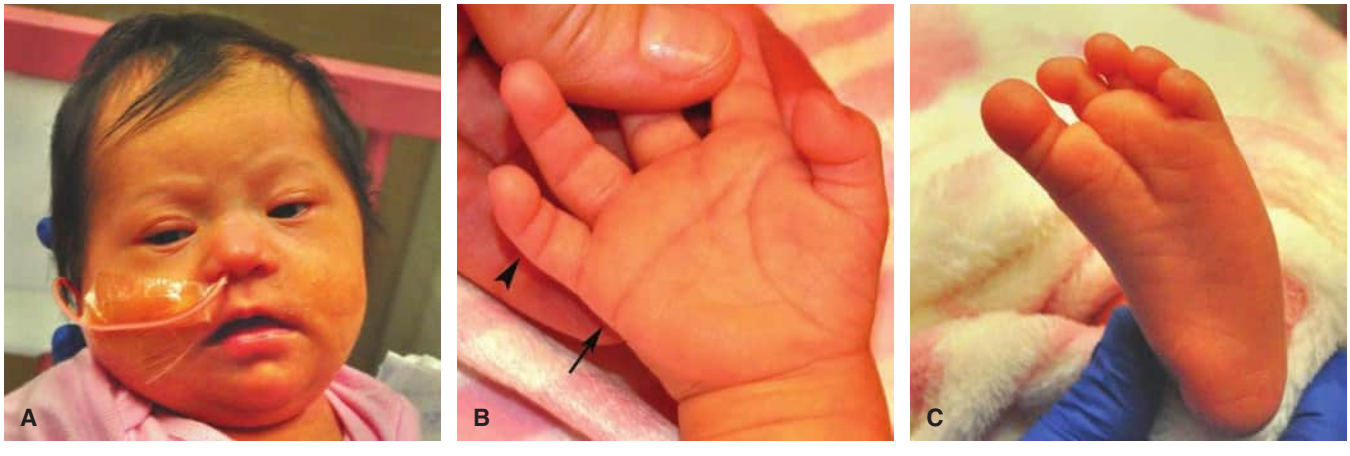

FIGURE 16-4 Newborn with Down syndrome, karyotype 47,XX,+21 (trisomy 21). **A.** Characteristic facial features include epicanthal folds and a flattened nasal bridge. **B.** The hand has a single palmar crease (*arrow*) and hypoplasia of the middle phalanx of the fifth digit (*arrowhead*). **C.** The "sandal gap" between the first and second toes is also known as hallux varus. (Reproduced with permission from Dr. Aldeboran N. Rodriguez.)

nape of the neck, a prominent space or "sandal-gap" between the first and second toes, short fingers, a single palmar crease, and clinodactyly of the fifth digit, in which hypoplasia of the middle phalanx causes inward curvature. Discussed in Chapter 17, some of these findings are seen during prenatal ultrasound examination.

Data suggest that approximately 95 percent of liveborn infants with Down syndrome survive the first year. The 10-year survival rate is at least 90 percent overall and is 99 percent if major malformations are absent (Rankin, 2012; Vendola, 2010). Average life expectancy is 55 to 60 years. Several organizations offer education and support for prospective parents faced with prenatal diagnosis of Down syndrome. These include the March of Dimes, National Down Syndrome Congress (www.ndsccenter.org), and National Down Syndrome Society (www.ndss.org).

Trisomy 18—Edwards Syndrome. The association between this constellation of abnormalities and an autosomal trisomy was first described by Edwards (1960). In population-based series of abortuses, stillbirths, and live births, trisomy 18 approximates 1 per 2000 recognized pregnancies (Goel, 2019; Loane, 2013; Parker, 2010). High in-utero lethality and termination of many affected pregnancies explains a live birth prevalence of just 1 per 6600 to 10,000. Unlike Down syndrome and Patau syndrome, which may result from a robertsonian translocation because they involve acrocentric chromosomes, Edwards syndrome uncommonly stems from a chromosomal rearrangement.

Virtually every organ can be affected by trisomy 18. Common major anomalies include heart defects in more than 90 percent, particularly ventricular septal defects. Cerebellar vermian agenesis, myelomeningocele, diaphragmatic hernia, omphalocele, imperforate anus, and renal anomalies such as horseshoe kidney are others (Rosa, 2011; Springett, 2015; Watson, 2008). Sonographic images of these abnormalities are shown in Chapter 15. Frequent cranial and extremity abnormalities in affected fetuses include a "strawberry-shaped" cranium, abnormally wide cavum septum pellucidum, choroid plexus cysts, micrognathia, clenched hands with overlapping digits, radial aplasia with hyperflexed wrists, and rockerbottom or clubbed feet (Fig. 16-5) (Abele, 2013). Importantly, choroid plexus cysts only raise the risk for trisomy 18 in the setting of other risk factors, such as fetal structural abnormalities or an abnormal aneuploidy screening test result (Reddy, 2014).

Pregnancies with trisomy 18 that reach the third trimester often develop fetal-growth restriction, and the mean birthweight is <2500 g (Lin, 2006; Rosa, 2011). When undiagnosed, trisomy 18 has resulted in emergency cesarean for "fetal distress" in nearly 50 percent of cases (Schneider, 1981; Houlihan, 2013). Mode of delivery and management of heart rate abnormalities should be discussed in advance. Discussed in Chapter 35 (p. 628), perinatal palliative care consultation should be offered (American College of Obstetricians and Gynecologists, 2019).

In the National Birth Defects Prevention Study, median neonatal survival with trisomy 18 was 8 days, and the 5-year survival rate was 12 percent (Meyer, 2016). Not unexpectedly, major anomalies lower survival rates. Data from the Society of Thoracic Surgeons indicate that infants with trisomy 18 who undergo cardiac surgery have mortality rates 3 to 5 times higher than those without trisomy 18 (Cooper, 2019). Thus, among the minority with trisomy 18 who survive until birth, the condition is severely life limiting.

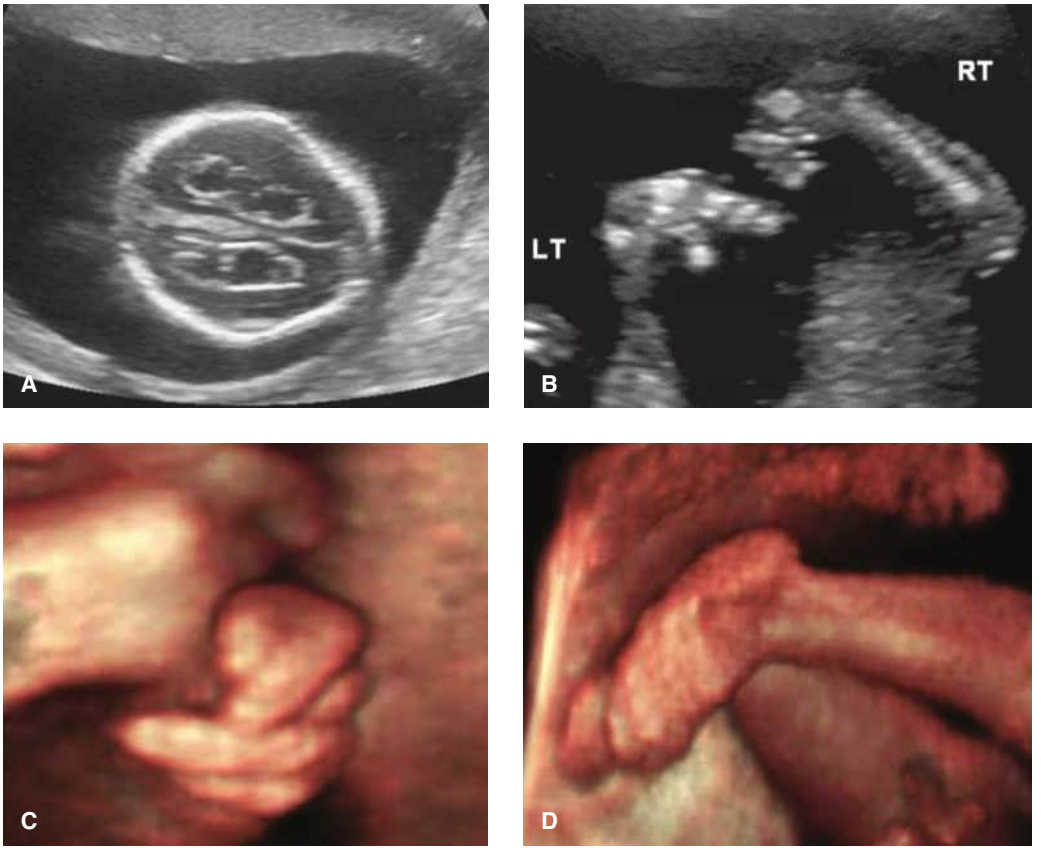

FIGURE 16-5 Trisomy 18—Edwards Syndrome. **A.** This transventricular sonographic view shows fetal choroid plexus cysts and an angulated "strawberry-shaped" skull. **B.** Radial clubhand is manifested as a single forearm bone (radius), with the hands in a fixed, hyperflexed position at right angles to the forearms. **C.** This three-dimensional (3-D) sonographic image shows the characteristic hand position of clenched fist with overlapping digits. **D.** 3-D sonographic image displays a rockerbottom foot (vertical talus).

Trisomy 13—Patau Syndrome. This constellation of fetal abnormalities and their association with an autosomal trisomy was first described by Patau and colleagues (1960). The incidence of trisomy 13 approximates 1 case in 5000 recognized pregnancies, which includes abortuses and stillbirths. Most affected fetuses are lost or terminated. The live birth prevalence is 1 per 12,000 to 18,000 (Goel, 2019; Loane, 2013; Parker, 2010).

At least 80 percent of pregnancies with Patau syndrome result from trisomy 13. With rare exception, the remainder are caused by a robertsonian translocation involving chromosome 13. The most common translocation involves chromosomes 13 and 14, der(13;14)(q10;q10), which is carried by approximately 1 in 1300 phenotypically normal individuals. Among translocation carriers, fewer than 2 percent give birth to a live infant with Patau syndrome.

Trisomy 13 may be associated with abnormalities of any organ system. Abnormalities of the brain, heart, kidneys, and extremities are the most frequent. Holoprosencephaly, usually the alobar type, is present in two thirds of cases and often is accompanied by severe facial abnormalities (Fig. 15-13, p. 279). These may include hypotelorism or cyclopia, microphthalmia, and nasal abnormalities that range from a single nostril to a proboscis. Cardiac defects are found in up to 90 percent (Shipp, 2002). Other abnormalities that suggest trisomy 13 include cephalocele, microcephaly, omphalocele, cystic renal dysplasia, polydactyly, rockerbottom feet, aplasia cutis, and cleft lip-palate, which may be median (Lin, 2007; Springett, 2015). Sonographic images of several of these are shown in Chapter 15. Affected fetuses often also have bilateral echogenic intracardiac foci. For the fetus or newborn with a cephalocele, cystic kidneys, and polydactyly, the differential diagnosis includes trisomy 13 and the autosomal-recessive Meckel–Gruber syndrome.

Trisomy 13 is life limiting, even more so than trisomy 18 (Domingo, 2019). In the National Birth Defects Prevention Study, median survival of neonates with trisomy 13 was 5 days, and the 5-year survival rate was below 10 percent (Meyer, 2016). Occasionally children with trisomy 13 have been candidates for palliative surgical procedures. Most of these have a milder phenotype that lacks brain, cardiac, gastrointestinal, or genitourinary abnormalities (Nelson, 2016). Counseling regarding prenatal diagnosis and management options is similar to that described for trisomy 18.

Unlike other aneuploidies, fetal trisomy 13 confers risk to the pregnant woman. Continuing pregnancies have at least a 25-percent risk for hypertensive complications (Dotters-Katz, 2018; Tuohy, 1992). The risk for preeclampsia with severe features is increased more than tenfold and often develops prior to 32 weeks' gestation. Chromosome 13 contains the gene for soluble fms-like tyrosine kinase-1 (sFlt-1), which is an antiangiogenic protein associated with preeclampsia (Chap. 40, p. 694). Investigators have documented overexpression of the sFlt-1 protein by trisomic 13 placentas and in serum of women with preeclampsia (Bdolah, 2006; Silasi, 2011).

Other Trisomies. Live births are extremely rare with any other autosomal trisomy. Trisomy 22 has been described in case reports and series (Heinrich, 2013; Kehinde, 2014). Affected fetuses have severe growth restriction, microcephaly with an abnormal-shaped cranium, midface hypoplasia, and cardiac and genitourinary abnormalities. Trisomy 16 is the most prevalent trisomy among first-trimester losses, accounting for 16 percent. Trisomies 21 and 22 are also common among first trimester losses. Trisomy 1 has never been reported.

Monosomy

Nondisjunction creates an equal number of nullisomic and disomic gametes. As a rule, missing chromosomal material is more devastating than extra chromosomal material, and almost all monosomic conceptuses are lost before implantation. The one exception is monosomy for the X chromosome (45,X), Turner syndrome, which is discussed subsequently. Unlike autosomal trisomies, which increase in incidence with maternal age, monosomy and maternal age lack an association.

Polyploidy

This is defined as more than two complete haploid chromosomal sets. Polyploidy accounts for approximately 20 percent of spontaneous abortions but is rarely found later in gestation.

Triploid pregnancies have three haploid sets, 69 chromosomes. If extra set of chromosomes is paternal, the result is *diandric triploidy*, and if maternal, *digynic triploidy*, relevant because the phenotype reflects the parent of origin. This is an example of *imprinting* (p. 322). Diandric or type I triploidy occurs after fertilization of one egg by two sperm or by one abnormal diploid sperm. Diandric triploidy produces a partial molar pregnancy, discussed in Chapter 13 (p. 237). With digynic or type II triploidy, the extra chromosomal set is maternal, and the egg fails to undergo the first or second meiotic division before fertilization. Digynic triploid placentas do not develop molar changes. However, the fetus usually develops asymmetrical growth restriction. Although diandric triploidy accounts for the majority of triploid conceptions, the early loss rate is so high that two thirds of triploid pregnancies identified beyond the first trimester are digynic (Jauniaux, 1999).

Triploidy is recognized in 1 per 5000 pregnancies (Zalel, 2016). It is considered lethal, and fetuses with either the diandric or digynic form typically have multiple structural anomalies. The brain, heart, kidneys, and extremities are commonly affected (Massalska, 2017; Zalel, 2016). Counseling, prenatal diagnosis, and delivery management are similar to those for trisomies 18 and 13. The recurrence risk for a woman whose triploid fetus survived past the first trimester is 1 to 1.5 percent, and thus prenatal diagnosis is offered in future pregnancies.

Tetraploid pregnancies have four haploid sets of chromosomes, resulting in either 92,XXXX or 92,XXYY. This suggests a postzygotic failure to complete an early cleavage division. The conceptus invariably succumbs, and the recurrence risk is minimal.

Sex Chromosome Abnormalities

45,X—Turner Syndrome. First described by Turner (1938), this syndrome later was found to be caused by monosomy X (Ford, 1959). The birth prevalence of Turner syndrome is approximately 1 in 2500 girls (Cragan, 2009; Dolk, 2010). The missing X chromosome is paternally derived in 80 percent of cases (Cockwell, 1991; Hassold, 1990).

Turner syndrome is the only monosomy compatible with life, but it is also the most common aneuploidy in first-trimester losses, accounting for 20 percent. This is explained by its wide range in phenotype. Approximately 98 percent of affected conceptuses are so abnormal that they abort early in the first trimester. Of the remainder, many manifest large, septated cystic hygromas in the late first or early second trimester, often in the setting of edema that progresses to hydrops fetalis. When cystic hygromas are accompanied by hydrops, the prognosis is extremely poor (Chap. 15, p. 286).

Fewer than 1 percent of pregnancies with Turner syndrome result in a liveborn neonate. Of these, only half are actually monosomy X—approximately a fourth have mosaicism for monosomy X, such as 45,X/46,XX or 45,X/46,XY, and another 15 percent have isochromosome X. It is thought that surviving individuals with 45,X may have had the benefit of "rescue" by an additional cell line containing 46,XX during critical phases of development that was subsequently lost (Hook, 2014).

Abnormalities associated with Turner syndrome include left-sided cardiac defects—such as coarctation of the aorta, hypoplastic left heart syndrome, or bicuspid aortic valve—in 30 to 50 percent; renal anomalies, particularly horseshoe kidney; and hypothyroidism. Other features are short stature, broad chest with widely spaced nipples, congenital lymphedema—puffiness over the dorsum of hands and feet, and a "webbed" posterior neck resulting from cystic hygromas. Intelligence scores are generally in the normal range, but there may be impairments in visual-spatial organization, nonverbal problem solving, and interpretation of social cues. A consensus guideline is available that addresses screening and treatment for the range of health problems affected individuals face (Graveholt, 2017). Growth hormone is typically administered in childhood to ameliorate short stature. More than 90 percent have ovarian dysgenesis and require estrogen repletion at puberty. An exception is mosaicism involving the Y chromosome, as this confers risk for germ cell neoplasm—regardless of whether the child is phenotypically male or female. Accordingly, eventual prophylactic bilateral gonadectomy is indicated (Cools, 2011; Schorge, 2020).

47,XXX. Approximately 1 in 1000 female newborns has an additional X chromosome—47,XXX (Berglund, 2020). The extra X is maternally derived in more than 90 percent of cases. The prevalence of 47,XXX is weakly associated with maternal age, and cell-free DNA screening has resulted in increased diagnoses. No specific pattern of malformations has been described, but genitourinary problems and seizure disorders are more common (Wigby, 2016). Affected infants do not have a characteristic appearance. When children do come to attention, features may include tall stature, hypertelorism, epicanthal folds, kyphoscoliosis, clinodactyly, and hypotonia (Tartaglia, 2010; Wigby, 2016). More than one third are diagnosed with a learning disability, half have attention deficit disorder, and overall cognitive scores are in the low-average range. Pubertal development is unaffected. Primary ovarian insufficiency has been reported. In the absence of prenatal diagnosis, it is estimated that 47,XXX is ascertained in only 10 percent of affected children (Tartalgia, 2010).

Females with two or more extra X chromosomes—48,XXXX or 49,XXXXX—are likely to have physical abnormalities apparent at birth. These abnormal X complements are associated with intellectual disability. For both males and females, the IQ score is lower with each additional X chromosome.

47,XXY—Klinefelter Syndrome. This is the most common sex chromosome abnormality. It occurs in approximately 1 in 700 male infants (Radicioni, 2010). The additional X chromosome is maternally or paternally derived with equal propensity (Jacobs, 1995; Lowe, 2001). There is a weak association with advanced maternal and paternal age.

Like 47,XXX, newborns with 47,XXY usually appear phenotypically normal and do not have a higher incidence of anomalies. As children, boys are typically taller than average and have normal prepubertal development. However, they have gonadal dysgenesis, do not undergo normal virilization, and require testosterone supplementation. They may develop gynecomastia. IQ scores usually lie in the average to low-average range, with increased rates of delayed language development (Boada, 2009; Girardin, 2011). Initiation of hormone replacement was previously recommended to begin in adolescence. However, more recent research suggests that therapy earlier in childhood results in improved working memory and executive functioning and a decrease in anxiety disorders (Samango-Sprouse 2019; Tran, 2019).

47,XYY. This aneuploidy occurs in approximately 1 in 1000 male newborns (Berglund, 2020). As with 47,XXX and XXY individuals, affected boys tend to be tall. A third have macrocephaly, nearly two thirds demonstrate hypotonia, and tremors are common (Bardsley, 2013). Rates of major anomalies are not elevated, although hypertelorism and clinodactyly may be identified in more than half. Pubertal development is normal, and fertility is unimpaired. Affected individuals do have increased rates of oral and written language impairments, attention deficit disorder, developmental delays, and autism spectrum disorder (Bardsley, 2013; Joseph, 2018).

Males with more than two Y chromosomes—48,XYYY—or with both additional X and Y chromosomes—48,XXYY or 49,XXXYY—are more likely to have congenital abnormalities, medical problems, and intellectual disability (Tartaglia, 2011).

■ Abnormalities of Chromosome Structure

Structural chromosomal abnormalities include deletions, duplications, translocations, isochromosomes, inversions, ring chromosomes, and mosaicism (see Table 16-1). Identification of a structural chromosomal abnormality in offspring raises two primary questions. First, what phenotypic or later developmental abnormalities are associated with the finding? Second, is parental karyotype evaluation indicated? In other words, are the parents at increased risk of carrying this abnormality, and if so, what is their risk of having future affected offspring?

Deletions and Duplications

A chromosome with a deletion has a stretch of DNA that is missing, whereas one with a duplication has a region that is included twice. Most deletions and duplications occur during

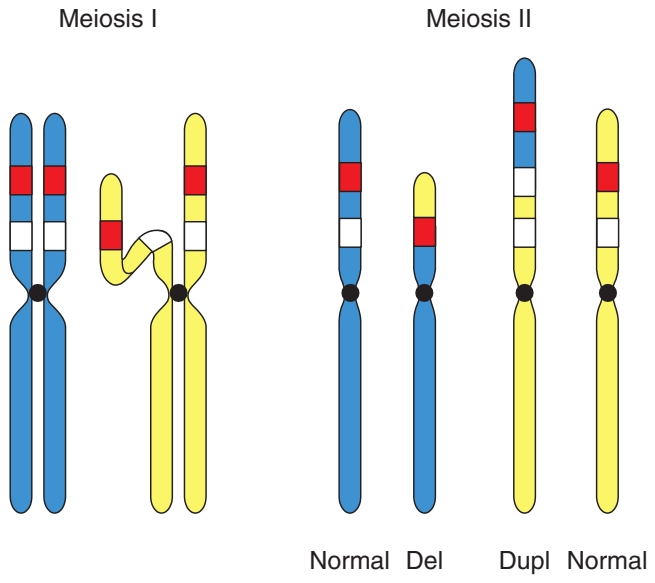

FIGURE 16-6 A mismatch during pairing of homologous chromosomes may lead to a deletion in one chromosome and a duplication in the other. Del = deletion; Dupl = duplication.

meiosis and result from malalignment or mismatching during the pairing of homologous chromosomes. The misaligned segment may then be deleted, or if the mismatch remains when the two chromosomes recombine, it may result in a deletion in one chromosome and duplication in the other (Fig. 16-6). When a deletion or duplication is identified in a fetus or infant, parental karyotyping should be offered, because if either parent carries a balanced translocation, the recurrence risk in subsequent pregnancies is significantly increased. Deletions involving DNA segments large enough to be seen with standard cytogenetic karyotyping are identified in approximately 1 in 7000 births. Common deletions may be referred to by eponyms—for example, del 5p is called *cri du chat syndrome*.

Microdeletions and Microduplications. When a deletion or duplication is smaller than 3 to 5 million base pairs, it is too small to be detected with a standard karyotype analysis. CMA permits identification of these microdeletions and microduplications (p. 325). When CMA is used, the region of DNA that is missing or duplicated is termed a *genomic copy number variant.* A microdeletion or duplication may involve a stretch of DNA that contains multiple genes. This causes a *contiguous gene syndrome*, which can encompass serious but unrelated phenotypic abnormalities (Schmickel, 1986). In some cases, a microduplication may involve the exact DNA region that causes a recognized microdeletion syndrome (Table 16-2). When a specific microdeletion syndrome is suspected clinically, it is confirmed using either CMA or FISH.

22q11.2 Microdeletion Syndrome. This syndrome is also known as DiGeorge syndrome, Shprintzen syndrome, and velocardiofacial syndrome. It is the most common microdeletion, with a prevalence of 1 case in 3000 to 6000 births. Inheritance is autosomal dominant—offspring of affected individuals have a 50-percent chance of inheriting the syndrome. However, more than 90 percent of cases arise from a de-novo mutation. The full deletion contains 3 million base pairs, encompasses 40 genes, and includes 180 different features (Shprintzen, 2008). This is emblematic of a contiguous gene syndrome and poses counseling challenges because features can vary widely, even among family members. With prenatal diagnosis of an affected fetus, genetic testing is offered to the pregnant patient and her partner.

Approximately 75 percent of affected individuals have an associated conotruncal cardiac anomaly, such as tetralogy of Fallot, truncus arteriosus, interrupted aortic arch, or ventricular septal defect (McDonald-McGinn, 2015). Immune deficiency, such as T-cell lymphopenia, also develops in 75 percent. More than 70 percent have velopharyngeal insufficiency or cleft palate. Characteristic facial features include short palpebral fissures, bulbous nasal tip, micrognathia, short philtrum, and small or posteriorly rotated ears. Learning disabilities, autism spectrum disorder, and intellectual disability also are common. Other manifestations include hypocalcemia, renal anomalies, esophageal dysmotility, hearing loss, behavioral disorders, and psychiatric illness, particularly schizophrenia.

Chromosomal Translocations

These are DNA rearrangements in which a DNA segment breaks away from one chromosome and attaches to another. The rearranged chromosomes are called derivative (der) chromosomes. The two types are reciprocal and robertsonian translocations.

Reciprocal Translocations. A double-segment or reciprocal translocation results when breaks occur in two different chromosomes and the broken fragments are exchanged. Each affected chromosome receives a fragment of the other. If no chromosomal material is gained or lost, the translocation is considered balanced. The prevalence of reciprocal translocations approximates 1 in 600 births.

The carrier of a balanced translocation will usually have a normal phenotype. However, repositioning of specific genes within chromosomal segments may cause major structural or developmental abnormalities in approximately 6 percent of apparently balanced translocation carriers. Using CMA technology, up to 20 percent of individuals who appear to have a balanced translocation are found instead to have missing or redundant DNA segments (Manning, 2010).

Balanced translocation carriers are at risk to produce unbalanced gametes, resulting in abnormal offspring. As shown in Figure 16-7, if an oocyte or sperm contains a translocated chromosome, fertilization results in an unbalanced translocation—monosomy for part of one affected chromosome and trisomy for part of the other. In general, translocation carriers identified after the birth of an abnormal child have a 5- to 30-percent risk of producing liveborn offspring with an unbalanced translocation. Carriers identified for other reasons, for example, during an infertility evaluation, have only a 5-percent risk. This risk is lower because gametes are so abnormal that conceptions are nonviable.

Robertsonian Translocations. These involve only the *acrocentric* chromosomes—13, 14, 15, 21, and 22. Acrocentric

TABLE 16-2. Selected Microdeletion Syndromes

Syndrome	Prevalence	Location	Features
Alagille	1:70,000	20p12.2	Cholestasis (paucity of intrahepatic bile ducts), cardiac disease, skeletal disease, ocular abnormalities, dysmorphic facies
Angelman	1:12,000 to 1:20,000	15q11.2–q13 (maternal genes)	Dysmorphic facies—"happy puppet" appearance, intellectual disability, ataxia, hypotonia, seizures
Cri-du-chat	1:20,000 to 1:50,000	5p15.2–15.3	Abnormal laryngeal development with "cat-like" cry, hypotonia, intellectual disability
Kallmann syndrome	1:30,000 males	Xp22.3	Hypogonadotropic hypogonadism, anosmia
Langer-Giedion	Rare	8q23.3	Trichorhinophalangeal syndrome, dysmorphic facies, skeletal abnormalities, sparse hair
Miller-Dieker	Rare	17p13.3	Neuronal migration abnormalities with lissencephaly and microcephaly (profound impairment), dysmorphic facies
Prader-Willi	1:10,000 to 1:30,000	15q11.2–q13 (paternal genes)	Obesity, hypotonia, hypogonadotropic hypogonadism, small hands and feet, intellectual disability
Retinoblastoma	1:280,000	13q14.2	Retinoblastoma, retinoma (benign neoplasm), non-retinal (second primary) tumors
Rubenstein-Taybi	1:100,000 to 1:125,000	16p13.3	Dysmorphic facies, broad thumbs and toes, intellectual disability, increased tumor risk
Smith-Magenis	1:15,000 to 1:25,000	17p11.2	Dysmorphic facies, speech delay, hearing loss, sleep disturbances, self-destructive behaviors, intellectual disability
Velocardiofacial syndrome	1:3000 to 1:6000	22q11.2	Conotruncal cardiac defects, cleft palate, velopharyngeal incompetence, thymic and parathyroid abnormalities, intellectual disability
WAGR	1:500,000	11p13	Wilms tumor, aniridia, genitourinary anomalies. intellectual disability (mental retardation)
Williams-Beuren	1:7500 to 1:10,000	7q11.23	Dysmorphic facies, dental malformation, aortic and peripheral pulmonary artery stenosis, intellectual disability
Wolf-Hirschhorn	1:20,000 to 1:50,000	4p16.3	Dysmorphic ("Greek helmet") facies, delayed growth and development, cleft lip/palate, coloboma, cardiac septal defects
X-linked ichthyosis	1:6000	Xp22.3	Steroid sulfatase deficiency, corneal opacities

Prevalence reflects live births.
Data from National Library of Medicine, 2021; Johns Hopkins University, 2021.

chromosomes have extremely short p arms, and the p arms contain redundant copies of genes coding for ribosomal RNA. In a robertsonian translocation, the q arms of two acrocentric chromosomes fuse at one centromere to form a derivative chromosome, and the other centromere and both p arms are lost. The lost DNA is present in multiple copies on other acrocentric chromosomes, and thus the translocation carrier is usually phenotypically normal. Because the number of centromeres determines the chromosome count, a robertsonian translocation carrier has only 45 chromosomes.

Balanced robertsonian carriers have reproductive difficulties. During fertilization, if the derivative chromosome pairs with a normal haploid chromosome, the resulting offspring will have trisomy. If the fused chromosomes are homologous, that is, from the same chromosome pair, the carrier can produce only unbalanced gametes. Each egg or sperm contains either both copies of the translocated chromosome, which would result in trisomy if fertilized, or no copy, which would result in monosomy. If the fused chromosomes are nonhomologous, four of the six possible gametes would be abnormal.

Robertsonian translocations are found in 1 in 1000 individuals. The risk to have an abnormal offspring approximates 15 percent if a robertsonian translocation is carried by the mother and 2 percent if carried by the father. However, robertsonian translocations are not a major cause of miscarriage and are identified in fewer than 5 percent of couples evaluated for recurrent pregnancy loss. If a fetus or child is found to have a translocation trisomy, both parents should be offered karyotype analysis. If neither parent is a carrier, the recurrence risk is extremely low. The most common robertsonian translocation

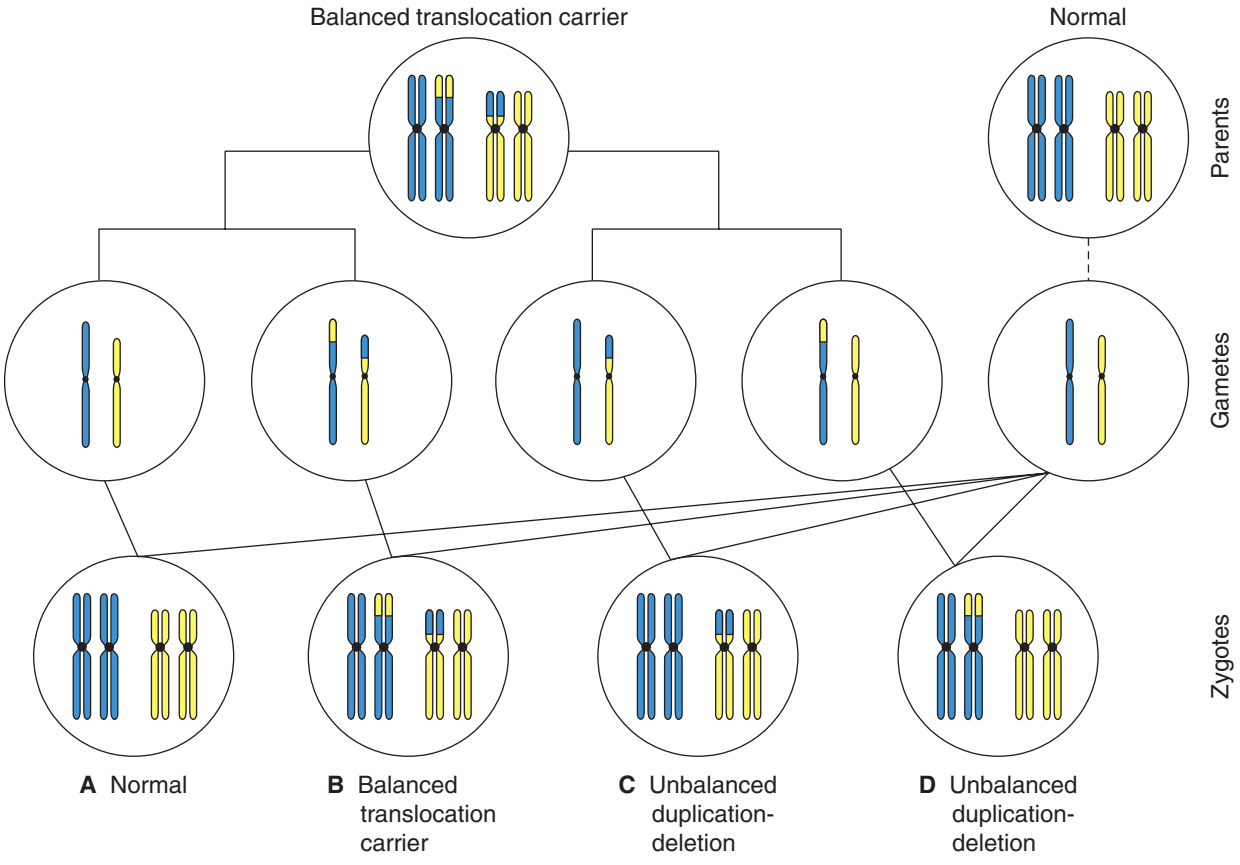

FIGURE 16-7 A carrier of a balanced translocation may produce offspring who are also carriers of the balanced rearrangement **(B)**, offspring with unbalanced translocations **(C, D)**, or offspring with normal chromosomal complements **(A)**.

is der(13;14)(q10;q10), which accounts for up to 20 percent of cases of Patau syndrome (p. 313).

Isochromosomes

When either two p arms or two q arms from the same chromosome fuse together, an isochromosome results. This may occur if the centromere breaks transversely instead of longitudinally during meiosis II or mitosis. Alternately, an isochromosome can result from a meiotic error in a chromosome with a robertsonian translocation. If the isochromosome is acrocentric, it is composed of two q arms and will behave like a homologous robertsonian translocation. Such a carrier is phenotypically normal but can produce only abnormal, unbalanced gametes. If the isochromosome is nonacrocentric, it may be composed of either two p arms or two q arms. Functionally this results in trisomy of the genes on the arms that are present and monosomy of the genes on the arms that are lost. Thus, the carrier is usually phenotypically abnormal and produces abnormal gametes. The most common isochromosome involves the long arm of the X chromosome, i(Xq), which is the etiology of 15 percent of cases of Turner syndrome.

Chromosomal Inversions

When the same chromosome breaks in two places, the intervening genetic material may invert before the breaks are repaired. Although no genetic material is lost or duplicated, an inversion may alter gene function. There are two types—pericentric and paracentric inversions.

Pericentric Inversion. This results from breaks in both the p and q arms of a chromosome, such that the inverted material spans the centromere (Fig. 16-8). A pericentric inversion causes problems in chromosomal alignment during meiosis and confers significant risk for the carrier to produce abnormal gametes and abnormal offspring. The observed risk of abnormal offspring is 5 to 10 percent if ascertainment is made after the birth of an abnormal child. The risk is only 1 to 3 percent if prompted by another indication. An important exception is inv(9)(p11q12), a pericentric inversion on chromosome 9 that is a normal variant and present in approximately 1 percent of the population.

Paracentric Inversion. If one arm of a chromosome suffers the two breaks, the inverted material does not include the centromere, and the inversion is paracentric (see Fig. 16-8). The carrier makes either normal balanced gametes or gametes that are so abnormal as to preclude fertilization. Thus, although infertility may be a problem, the risk of having an abnormal offspring is extremely low.

Ring Chromosome

If a deletion occurs at each end of the same chromosome, the ends may come together to form a ring chromosome. The telomere regions at the ends of each chromosome contain redundant nucleoprotein complexes that stabilize the chromosome. If only the telomeres are lost, all necessary genetic material is retained, and the carrier is balanced. If a deletion extends more

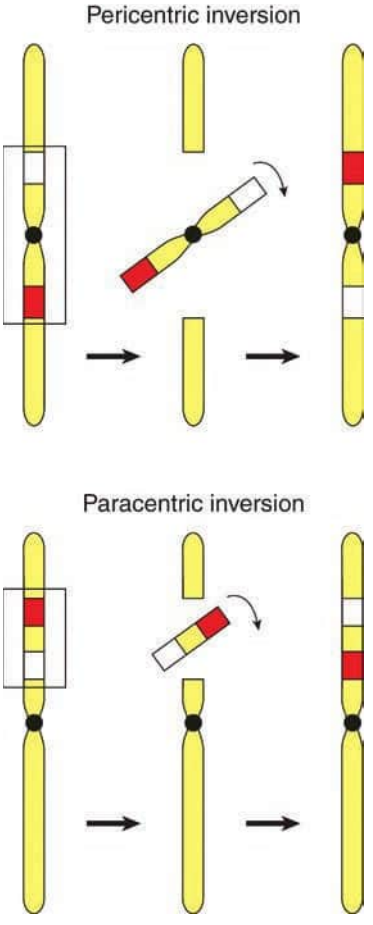

FIGURE 16-8 Pericentric inversion involves the centromere, whereas paracentric inversion does not. Individuals with pericentric inversions are at risk to have offspring with a duplication/deletion. Those with paracentric inversions are at increased risk for early pregnancy loss.

proximally than the telomere, the carrier is likely to be phenotypically abnormal. An example of this is the ring X chromosome, which may result in Turner syndrome.

■ Mosaicism

A mosaic individual has two or more cytogenetically distinct cell lines that are derived from a single zygote. Phenotypic expression of mosaicism depends on several factors, including whether the cytogenetically abnormal cells involve the fetus, part of the fetus, just the placenta, or some combination. Mosaicism is found in approximately 0.3 percent of amnionic fluid cultures (Carey, 2014). When abnormal cells are present in only a single flask of amnionic fluid, the finding is likely pseudomosaicism, caused by cell-culture artifact (Bui, 1984; Hsu, 1984). When abnormal cells involve multiple cultures, however, true mosaicism is more likely. Further testing verifies a second cell line in 60 to 70 percent of these fetuses (Hsu, 1984; Worton, 1984).

Confined Placental Mosaicism

Mosaicism involving a gene abnormality is detected in 1 to 2 percent of chorionic villus sampling specimens. Amniocentesis should be offered. In a series of more than 1000 pregnancies with mosaicism at chorionic villus sampling, subsequent amniocentesis identified true fetal mosaicism in 13 percent. Confined placental mosaicism accounted for 85 percent of cases, and uniparental disomy, discussed later (p. 322), was found in 2 percent (Malvestiti, 2015). If mosaicism is detected for a chromosome known to contain imprinted genes—such as chromosomes 6, 7, 11, 14, or 15—testing for uniparental disomy should be considered, as there may be fetal consequences (Grati, 2014a).

Although outcomes with confined placental mosaicism are generally good, risks of fetal-growth restriction and stillbirth are higher (Reddy, 2009). Fetal-growth restriction may stem from impaired functioning of the aneuploid placental cells (Baffero, 2012). In a recent series of 5500 pregnancies undergoing chorionic villus sampling, the preterm birth rate in pregnancies with confined placental mosaicism was 45 percent, and 50 percent of affected newborns were small for gestational age (Toutain, 2018). Placental mosaicism for trisomy 16 confers a particularly poor prognosis, with as few as 1 in 3 pregnancies resulting in normal outcome (Grau Madsen, 2018).

Gonadal Mosaicism

Also called germline mosaicism, this refers to having one cell line in gametes and another in somatic cells. A genetic abnormality that is confined to gamete cells will affect all cells in the offspring. Thus, gonadal mosaicism can account for apparently de-novo diseases in the offspring of normal parents. Because spermatogonia and oogonia divide throughout fetal life, and spermatogonia continue to divide throughout adulthood, a meiotic error can occur in germ cells that were previously normal. New mutations identified in an offspring whose father is older than 40 may arise through this mechanism, as discussed later (p. 319) (Wilkie, 2017). Gonadal mosaicism also explains the 6-percent recurrence risk after the birth of a child with a disease caused by a "new" mutation.

MODES OF INHERITANCE

A monogenic or *mendelian* disorder is caused by a mutation or alteration in a single locus or gene in one or both members of a gene pair. Types of mendelian inheritance include autosomal dominant, autosomal recessive, X-linked, and Y-linked (Table 16-3). Other monogenic inheritance patterns include mitochondrial inheritance, uniparental disomy, imprinting, and trinucleotide repeat expansion.

■ Relationship between Phenotype and Genotype

When considering inheritance, it is the phenotype that is dominant or recessive, not the genotype. If a disease is dominant, a normal gene directs the production of normal protein, but the phenotype will be abnormal because of protein produced by the abnormal gene. A heterozygous carrier of a recessive disease may produce detectable levels of an abnormal gene product but have no features of the condition, because the phenotype is directed by the product of the normal co-gene. For example,

TABLE 16-3. Selected Monogenic (Mendelian) Disorders

Autosomal Dominant
Achondroplasia
Acute intermittent porphyria
Adult polycystic kidney disease
Antithrombin III deficiency
BRCA1 and BRCA2 breast and/or ovarian cancer
Ehlers-Danlos syndrome
Familial adenomatous polyposis
Familial hypercholesterolemia
Hereditary hemorrhagic telangiectasia
Hereditary spherocytosis
Huntington disease
Hypertrophic obstructive cardiomyopathy
Long QT syndrome
Marfan syndrome
Myotonic dystrophy
Neurofibromatosis type 1 and 2
Tuberous sclerosis
von Willebrand disease
Autosomal Recessive
α_1-Antitrypsin deficiency
Congenital adrenal hyperplasia
Cystic fibrosis
Gaucher disease
Hemochromatosis
Homocystinuria
Phenylketonuria
Sickle-cell anemia
Tay-Sachs disease
Thalassemia syndromes
Wilson disease
X-Linked
Androgen insensitivity syndrome
Chronic granulomatous disease
Color blindness
Fabry disease
Fragile X syndrome
Glucose-6-phosphate deficiency
Hemophilia A and B
Hypophosphatemic rickets
Muscular dystrophy—Duchenne and Becker
Ocular albinism type 1 and 2

erythrocytes from carriers of sickle-cell anemia contain approximately 30 percent hemoglobin S, but because the other 70 percent is hemoglobin A, these cells do not usually sickle in vivo.

Heterogeneity

Genetic heterogeneity explains how different genetic mechanisms may result in the same phenotype. *Locus heterogeneity* indicates that a specific disease phenotype can be caused by mutations in different genetic loci. It also explains why some diseases appear to follow more than one type of inheritance. For example, retinitis pigmentosa may develop following mutations in at least 35 different genes or loci and may result in autosomal dominant, autosomal recessive, or X-linked forms. *Allelic heterogeneity* describes how different mutations of the same gene may affect presentation of a particular disease. For example, although only one gene has been associated with cystic fibrosis—the *cystic fibrosis conductance transmembrane regulator* gene—more than 2000 mutations in this gene have been described and result in variable disease severity (Chaps. 17, p. 342 and 54, p. 968). *Phenotypic heterogeneity* explains how different disease states can arise from different mutations in the same gene. As an example, mutations in the *fibroblast growth factor receptor 3 (FGFR3)* gene may result in several different skeletal disorders, including achondroplasia and thanatophoric dysplasia, both of which are discussed in Chapter 15 (p. 302).

Autosomal Dominant Inheritance

If only one copy of a gene pair determines the phenotype, that gene is considered to be dominant. Carriers have a 50-percent chance of passing on the affected gene with each conception. A gene with a dominant mutation generally specifies the phenotype in preference to the normal gene. That said, not all individuals will necessarily manifest an autosomal dominant condition the same way. Factors that affect the phenotype of an autosomal dominant condition include penetrance, expressivity, and presence of codominant genes.

Penetrance

This characteristic describes whether a dominant gene is expressed. A gene with recognizable phenotypic expression in all individuals has complete penetrance. Penetrance is incomplete if some carriers express the gene but others do not. A gene that is expressed in 80 percent of individuals is 80-percent penetrant. Incomplete penetrance explains why some autosomal dominant diseases may appear to "skip" generations.

Expressivity

Individuals with the same autosomal dominant trait may manifest the condition differently, even within the same family. Genes with variable expressivity can produce disease manifestations that range from mild to severe. Examples include neurofibromatosis, tuberous sclerosis, and adult polycystic kidney disease.

Codominant Genes

If two different alleles in a gene pair are both expressed in the phenotype, they are considered to be codominant. Blood type, for example, is determined by expression of dominant A and B red-cell antigens that can be expressed simultaneously. Another example of codominance is the group of genes responsible for hemoglobin production. If one gene directs production of hemoglobin S and the other directs production of hemoglobin C, that individual will produce both S and C hemoglobin (Chap. 59, p. 1053).

Advanced Paternal Age

Paternal age older than 40 is associated with increased risk for spontaneous genetic mutations. Spermatogonia undergo

mitotic division every 16 days, and the many replications raise the risk for single base-pair mutations. As a result, offspring of older fathers are at risk for new autosomal dominant disorders and X-linked carrier states. Several in particular have been termed *paternal age effect* disorders (Goriely 2012). These include mutations in the *fibroblast growth factor receptor 2 (FGFR2)* gene, which may cause craniosynostosis syndromes such as Apert, Crouzon, and Pfeiffer syndromes; mutations in the *FGFR3* gene, which may result in achondroplasia and thanatophoric dysplasia; and mutations in the *RET proto-oncogene,* which may cause multiple endocrine neoplasia syndromes (Toriello, 2008).

Using whole genome sequencing to study SNPs among offspring of older fathers, Kong and associates (2012) found an increase of approximately two mutations for each year of paternal age past 40. The absolute risk for any specific condition is low, because individual autosomal dominant disorders are uncommon. Thus, no screening or testing is specifically recommended.

Autosomal Recessive Inheritance

Recessive diseases develop only when both gene copies are abnormal. Unless carriers are screened for a specific disease, they usually are recognized only after the birth of an affected child or the diagnosis of an affected family member. If a couple has a child with an autosomal recessive disease, the recurrence risk is 25 percent for each subsequent pregnancy. Thus, 1/4 of offspring will be homozygous normal, 2/4 will be heterozygous carriers, and 1/4 will be homozygous abnormal. In other words, three of four children will be phenotypically normal, and 2/3 of phenotypically normal siblings are actually carriers.

A heterozygous carrier of a recessive condition is only at risk to have affected children if her or his partner is heterozygous or homozygous for the disease. Genes for rare autosomal recessive conditions have low prevalence in the general population. Thus, the likelihood that a partner will be a gene carrier is small, unless there is consanguinity or the partner is a member of an at-risk group. Carrier screening is discussed in Chapter 17 (p. 342). Preimplantation genetic testing allows a blastocyst to be genetically evaluated prior to intrauterine transfer during in vitro fertilization and is described also in Chapter 17 (p. 348).

Inborn Errors of Metabolism

Most of these autosomal recessive diseases result from absence of a crucial enzyme, leading to incomplete metabolism of proteins, lipids, or carbohydrates. The metabolic intermediates that build up are toxic to various tissues and may result in intellectual disability or other abnormalities.

Phenylketonuria. Also known as phenylalanine hydroxylase (PAH) deficiency, this autosomal recessive disease is caused by mutations in the *PAH* gene. PAH metabolizes phenylalanine to tyrosine, and homozygotes have diminished or absent enzyme activity. This leads to abnormally high levels of phenylalanine, which results in progressive intellectual impairment, autism, seizures, motor deficits, and neuropsychological abnormalities (Blau, 2010). Because phenylalanine competitively inhibits tyrosine hydroxylase, which is essential for melanin production, affected individuals also have hair, eye, and skin hypopigmentation. More than 600 *PAH* gene mutations have been characterized, and the carrier frequency varies by ethnicity. For those of Northern European origin, carrier frequency is 1 in 50, such that the disease affects up to 1 in 10,000 newborns (American College of Obstetricians and Gynecologists, 2020b). Prompt diagnosis and restriction of dietary phenylalanine beginning early in infancy are essential to prevent neurological damage. All states mandate newborn screening for phenylketonuria (PKU).

Phenylalanine restriction alone would result in inadequate protein consumption, and phenylalanine-free amino acid–based supplementation is required. Maintenance of phenylalanine concentrations in the range of 2 to 6 mg/dL (120 to 360 μmol/L) is recommended from at least 3 months prior to pregnancy and continuing throughout pregnancy (American College of Obstetricians and Gynecologists, 2020b).

Unfortunately, phenylalanine is actively transported to the fetus. Women with PKU whose phenylalanine levels remain above the recommended range during pregnancy are at risk to have otherwise normal (heterozygous) offspring who sustain significant in utero damage as a result of being exposed to toxic phenylalanine concentrations. Hyperphenylalaninemia raises the risk for miscarriage and for PKU embryopathy, which is characterized by intellectual disability, microcephaly, seizures, growth impairment, and cardiac anomalies. Among women on unrestricted diets, the risk to have a child with intellectual disability exceeds 90 percent, microcephaly develops in more than 70 percent, and as many as 1 in 6 children have cardiac defects. The Maternal Phenylketonuria Collaborative Study, which included 572 pregnancies followed more than 18 years, reported that maintenance of serum phenylalanine levels in the recommended range significantly reduced the fetal abnormality risk and resulted in normal childhood IQ scores (Koch, 2003; Platt, 2000).

Approximately 25 to 50 percent of individuals with PKU experience a significant decline in phenylalanine levels when treated with the synthetic PAH cofactor tetrahydrobiopterin (sapropterin) (Vockley, 2014). Based on registry data, sapropterin is considered a treatment option for those in whom phenylalanine levels remain elevated despite dietary therapy (Grange, 2014). Preconceptional counseling and consultation with providers from experienced PKU centers is recommended.

Consanguinity

In medical genetics, a union is consanguineous if between second cousins or closer relatives. Although uncommon in Western countries, the global estimate of consanguineous parentage approximates 10 percent of the population (Oniya, 2019). More than 1 billion people are estimated to live in countries in which 20 to 50 percent of marriages are consanguineous (Romeo, 2014). First-degree relatives share half of their genes, second-degree relatives share a fourth, and third-degree relatives—first cousins—share one eighth. Because of the potential for shared deleterious genes, consanguinity confers an increased risk to have offspring with otherwise rare autosomal recessive diseases or multifactorial disorders. In population-based

series, first cousins have *twice* the risk for offspring with congenital abnormalities (Sheridan, 2013; Stoltenberg, 1997). Consanguinity is also associated with a greater rate of stillbirth (Kapurubandara, 2016). Because CMA performed using a SNP platform may identify consanguinity, it is important that preprocedural counseling include this possibility.

Incest is defined as a sexual relationship between first-degree relatives such as parent-child or brother-sister and is universally illegal. Progeny of such unions carry the highest risk of abnormal outcomes. Older studies reported that up to 40 percent of offspring were abnormal as a result of recessive and multifactorial disorders (Baird, 1982; Freire-Maia, 1984).

X-Linked and Y-Linked Inheritance

Most X-linked diseases are recessive. Common examples include color blindness, hemophilia A and B, and Duchenne and Becker muscular dystrophy. A male with an X-linked recessive gene is usually affected by the disease it causes, because he lacks a second X chromosome to express the normal dominant gene. However, a male with an X-linked disease cannot have affected sons because they do not receive his X chromosome. When a woman carries a gene causing an X-linked recessive condition, each son has a 50-percent risk of being affected, and each daughter has a 50-percent chance of being a carrier.

Women with an X-linked recessive gene are generally unaffected by the disease it causes. In some cases, however, the random inactivation of one X chromosome in each cell—termed lyonization—is skewed, and female carriers may have features of the condition. For example, approximately 10 percent of female carriers of hemophilia A will have factor VIII levels less than 30 percent of normal, and a similar proportion of female hemophilia B carriers have factor IX levels less than 30 percent. Levels below these thresholds confer a greater risk for abnormal bleeding when affected women give birth (Plug, 2006). Indeed, even with higher levels, carriers are reported to be at increased risk for bleeding complications (Olsson, 2014). Female carriers of Duchenne or Becker muscular dystrophy carry an elevated risk for cardiomyopathy, and periodic evaluation for cardiac dysfunction and neuromuscular disorders is recommended (American Academy of Pediatrics, 2008).

X-linked dominant disorders mainly affect females, because they tend to be lethal in males. Two examples are vitamin D–resistant rickets and incontinentia pigmenti. An important exception is fragile X syndrome, discussed subsequently.

The prevalence of Y-linked disorders is low. The Y-chromosome carries genes important for sex determination and various cellular functions related to spermatogenesis and bone development. Deletion of genes on the long arm of Y results in severe spermatogenic defects, whereas genes at the tip of the short arm are critical for chromosomal pairing during meiosis and for fertility.

Mitochondrial Inheritance

Human cells contain hundreds of mitochondria, each with its own genome and associated replication system. Oocytes have approximately 100,000 mitochondria. Sperm have only about 100, and the latter are destroyed after fertilization. Each mitochondrion has multiple copies of a 16.5-kb circular DNA molecule that contains 37 genes. Mitochondrial DNA encodes peptides required for oxidative phosphorylation and encodes ribosomal and transfer RNAs.

Mitochondria are inherited exclusively from the mother. Thus, although males and females both can be affected by a mitochondrial disorder, a male cannot transmit the condition to his offspring. When a cell replicates, mitochondrial DNA sorts randomly into each of the resulting cells, a process termed replicative segregation. As a consequence of replicative segregation, any mitochondrial mutation will be propagated randomly into the newly formed cells. Because each cell holds multiple copies of mitochondrial DNA, the mitochondrion may contain only normal or only abnormal DNA, termed *homoplasmy.* Alternatively, it may contain both normal and mutated DNA, namely *heteroplasmy*. If a heteroplasmic oocyte is fertilized, the relative proportion of mutated DNA may affect whether the individual manifests a given mitochondrial disease. It is not possible to predict the potential degree of heteroplasmy among offspring, and this poses challenges for genetic counseling.

There are 33 mitochondrial diseases or conditions with known molecular bases (Johns Hopkins University, 2020). Examples include myoclonic epilepsy with ragged red fibers (MERRF), Leber optic atrophy, Kearns-Sayre syndrome, Leigh syndrome, and several forms of mitochondrial myopathy and cardiomyopathy.

DNA Triplet Repeat Expansion

Mendel's first law is that genes are passed unchanged from parent to progeny, and barring new mutations, this is often true. Certain genes, however, contain a region of DNA trinucleotide repeats that can expand during parent-to-child transmission. The expansion can occur during male meiosis, as in Huntington disease, or during female meiosis, as in fragile X syndrome. Clinically, DNA triplet repeat expansion is manifested by *anticipation*—a phenomenon in which a disease may manifest at an earlier age or become more severe with each successive generation. Examples of DNA triplet repeat diseases are shown in Table 16-4.

Fragile X Syndrome

This is the most common inherited intellectual disability. Fragile X syndrome affects approximately 1 in 3600 males and 1 in

TABLE 16-4. Some Disorders Caused by DNA Triplet Repeat Expansion

Dentatorubral-pallidoluysian atrophy
Fragile X syndrome
Friedreich ataxia
Huntington disease
Spinal and bulbar muscular atrophy
Myotonic dystrophies
Spinocerebellar ataxias

4000 to 6000 females (American College of Obstetricians and Gynecologists, 2020a). It is caused by expansion of a repeated trinucleotide DNA segment—cytosine-guanine-guanine (CGG)—at chromosome Xq27.3. When the CGG repeat number reaches a critical size—the full mutation—the *fragile X mental retardation 1 (FMR1)* gene becomes methylated and inactivated. Inactivation halts expression of the FMR1 protein, which is abundant in nerve cells and necessary for normal cognitive development.

Individuals with fragile X syndrome may have speech and language problems, attention-deficit/hyperactivity disorder, and autism or autistic-like behaviors. Intellectual disability is generally more severe in males, in whom average IQ scores are 35 to 45 (Nelson, 1995). The syndrome has characteristic phenotypic features—a narrow face with large jaw, prominent ears, connective tissue abnormalities, and macroorchidism in postpubertal males.

Both the sex of the affected individual and the number of CGG repeats determine the degree of clinical impairment. Clinically, four groups have been described (American College of Obstetricians and Gynecologists, 2020a):

- Full mutation—more than 200 repeats
- Premutation—55 to 200 repeats
- Intermediate—45 to 54 repeats
- Unaffected—fewer than 45 repeats.

Full mutations are expressed in all males and many females. Males with full mutations typically have significant cognitive and behavioral abnormalities and phenotypic features. In females, random X chromosome inactivation results in variable expression, and the disability may be much less severe. With rare exception, the parent of origin of repeat expansion that leads to a full mutation is female (Monaghan, 2013).

Counseling for a premutation is more complex. The woman with a fragile X premutation may have offspring with the full mutation, and the risk ranges from ≤5 percent with fewer than 70 CGG repeats to >95 percent with 100 to 200 CGG repeats (Nolin, 2003). Expansion is extremely unlikely in a male premutation carrier, but all of his daughters will carry the premutation. Among women with no risk factors, approximately 1 in 250 carries a fragile X premutation, and in those with a family history of intellectual disability, the risk approximates 1 in 90 (Cronister, 2008).

Fragile X premutation carriers may themselves experience significant health consequences. Males with a premutation are at risk for the fragile X tremor ataxia syndrome (FXTAS), which is characterized by memory loss, executive function deficits, anxiety, and dementia (Monaghan, 2013). Females are at decreased risk for FXTAS, but they have a 20-percent risk for fragile X-associated primary ovarian insufficiency (POI).

Carrier screening is recommended for women with a family history of fragile X syndrome, for those with unexplained intellectual disability, developmental delay, or autism, and for women with POI (American College of Obstetricians and Gynecologists, 2020a). Prenatal diagnosis can be accomplished by amniocentesis or chorionic villus sampling. Either type of specimen can be used to evaluate the CGG repeat number, but chorionic villus sampling may not accurately determine *FMR1* gene methylation status.

Imprinting

Usually, one copy of each gene is inherited from each parent, and both copies are expressed. Imprinting refers to the situation in which gene expression varies according to the parent of origin. With *maternal imprinting*, a gene inherited from the mother is transcriptionally silent and the gene inherited from the father is active. *Paternal imprinting* is the opposite. This phenomenon explains the phenotypic differences that occur in triploid pregnancies according to whether the extra chromosomal set is maternal or paternal (p. 313).

Imprinting affects gene expression by epigenetic control, that is, it modifies the phenotype without altering the underlying genetic structure or genotype. Importantly, the effect may be reversed in a subsequent generation, because a female who inherits an imprinted gene from her father will pass it in her oocytes with a maternal—rather than paternal—imprint, and vice versa.

An example of imprinting can be found in two very different diseases associated with the same region of DNA. *Prader-Willi syndrome* is characterized by pronounced hyperphagia with obesity, along with short stature, small hands and feet, and mild mental retardation. In more than 70 percent of cases, Prader-Willi is caused by microdeletion or disruption of a DNA segment on the paternal chromosome 15, 15q11.2-q13. The remaining cases are due to maternal uniparental disomy or due to maternal gene imprinting with the paternal gene inactivated.

In contrast, individuals with *Angelman syndrome* have normal stature and weight but severe intellectual disability, absent speech, seizures, ataxia, jerky arm movements, and paroxysms of inappropriate laughter. In approximately 70 percent of cases, Angelman syndrome is caused by microdeletion for the 15q11.2-q13 DNA segment on the mother's chromosome 15. This segment contains a gene that codes for *ubiquitin protein ligase E3A*, an important neural protein. Paternal gene imprinting defects—with maternal genes inactivated—account for 2 to 3 percent, and 2 percent result from paternal uniparental disomy. Table 16-5 lists selected diseases that can involve imprinting.

Uniparental Disomy

This occurs when both members of a chromosome pair are inherited from the same parent. Uniparental disomy usually

TABLE 16-5. Some Disorders That Can Involve Imprinting

Disorder	Chromosomal Region	Parental Origin
Angelman	15q11.2–q13	Maternal
Beckwith-Wiedemann	11p15.5	Paternal
Myoclonus-dystonia	7q21	Maternal
Prader-Willi	15q11.2–q13	Paternal
Pseudohypoparathyroidism	20q13.2	Variable
Russell-Silver syndrome	7p11.2	Maternal

Data from Johns Hopkins University, 2021.

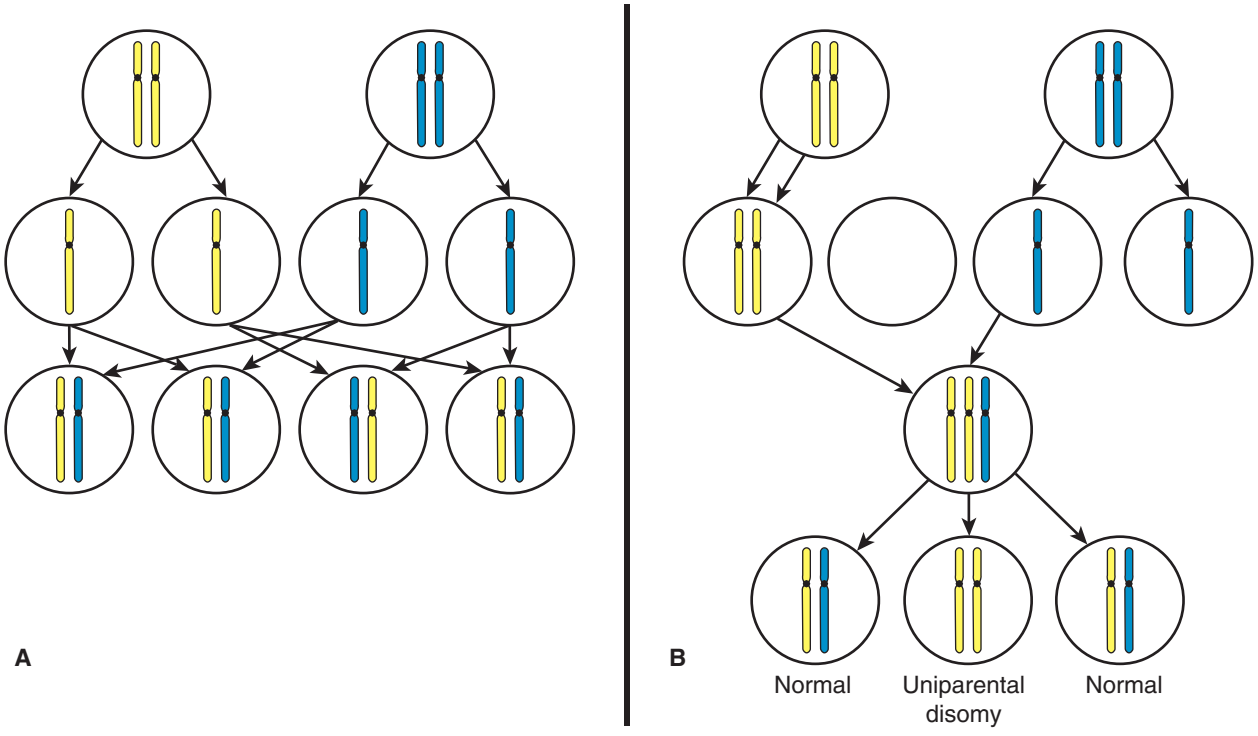

FIGURE 16-9 Mechanism of uniparental disomy arising from trisomic "rescue." **A.** In normal meiosis, one member of each pair of homologous chromosomes is inherited from each parent. **B.** If nondisjunction results in a trisomic conceptus, one homologue is sometimes lost. In a third of cases, loss of one homologue leads to uniparental disomy.

has no clinical consequences, because gene expression is not generally affected by the parent of origin and because both copies of a chromosome pair are not usually identical. However, if chromosomes 6, 7, 11, 14, or 15 are involved, offspring are at increased risk for an abnormality because of parent-of-origin differences in gene expression, that is, because of imprinting (Shaffer, 2001). Several genetic mechanisms may cause uniparental disomy, the most common of which is trisomic rescue, shown in Figure 16-9. After a nondisjunction event produces a trisomic conceptus, one of the three homologues may be lost, resulting in uniparental disomy for that chromosome in approximately one third of cases.

Uniparental *isodisomy* occurs when an individual receives two identical copies of one chromosome from the same parent. This mechanism has explained cases of cystic fibrosis in which only one parent is a carrier but the fetus inherits two copies of the same gene mutation (Spence, 1988; Spotila, 1992).

Multifactorial Inheritance

Traits or diseases that are determined by the combination of multiple genes and environmental factors are considered to have multifactorial inheritance (Table 16-6). Polygenic traits are determined by the combined effects of more than one gene. Many congenital and acquired conditions and common traits display multifactorial inheritance. Examples include malformations such as neural-tube defects, cardiac defects, and facial clefts; diseases such as diabetes and atherosclerosis; and traits such as head size or height. Multifactorial abnormalities tend to recur in families, but not according to a mendelian pattern. If a couple has had 1 child with a multifactorial birth defect, the risk that another child will be affected is empirically 3 to 5 percent. This risk declines exponentially with successively more distant family relationships.

Multifactorial traits that have a normal distribution in the population are termed continuously variable. A measurement that is more than two standard deviations above or below the population mean may be considered abnormal. Continuously variable traits tend to be less extreme in the offspring of affected individuals, because of the statistical principle of regression to the mean.

TABLE 16-6. Characteristics of Multifactorial Diseases

There is a genetic contribution
No mendelian pattern of inheritance
No evidence of single-gene disorder
Nongenetic factors are also involved in disease causation
Lack of penetrance despite predisposing genotype
Monozygotic twins may be discordant
Familial aggregation may occur
Relatives are more likely to have disease-predisposing alleles
Expression more common among close relatives
Greater concordance in monozygotic than dizygotic twins
Becomes less common in less closely related relatives—fewer predisposing alleles

Adapted from Nussbaum, 2016.

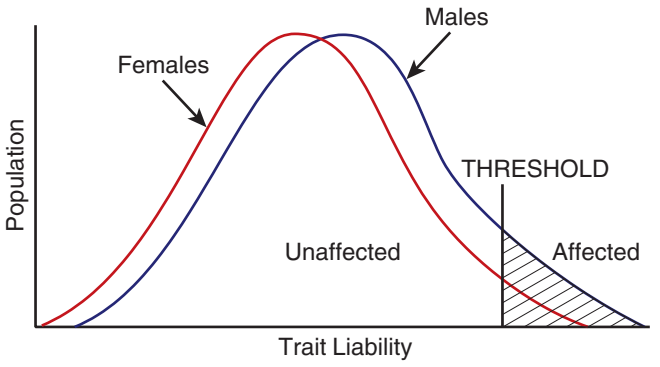

FIGURE 16-10 Schematic example of a threshold trait, such as pyloric stenosis, which has a predilection for males. Each gender is normally distributed, but at the same threshold, more males than females will develop the condition.

Threshold Traits

Some multifactorial traits do not appear until a threshold is exceeded. Genetic and environmental factors that create propensity or liability for the trait are themselves normally distributed, and only individuals at extremes of the distribution exceed the threshold and exhibit the trait or defect. The phenotypic abnormality is thus an all-or-none phenomenon.

Certain threshold traits have a clear male or female predominance. If an individual of the less affected gender has the characteristic or defect, the risk is greater in his or her offspring (Fig. 16-10). An example is pyloric stenosis, which is approximately four times more common in males (Krogh, 2012). A female with pyloric stenosis has likely inherited more predisposing genetic factors than are necessary to produce the defect in a male, and the recurrence risk for her children or siblings is thus higher than the expected 3 to 5 percent. Her brothers and sons would have the highest liability because they not only will inherit more than the usual number of predisposing genes but also are the more susceptible gender.

The recurrence risk for threshold traits is also greater if the defect is severe. For example, the recurrence risk after the birth of a child with bilateral cleft lip and palate approximates 8 percent, but it is only about 4 percent following a child with unilateral cleft lip alone.

Cardiac Defects

Structural cardiac anomalies are the most common birth defects, with a birth prevalence of 8 cases per 1000. The risk of having a child with a cardiac anomaly approximates 5 to 6 percent if the mother has the defect and 2 to 3 percent if the father is affected (Burn, 1998). Selected left-sided lesions, including hypoplastic left heart syndrome, coarctation of the aorta, and bicuspid aortic valve, may have recurrence risks four- to sixfold higher (Lin, 1988; Lupton, 2002; Nora, 1988). Observed recurrence risks for specific cardiac malformations are listed in Table 52-4 (p. 920).

Neural-tube Defects

Risk for developing a neural-tube defect (NTD) is influenced by family history, hyperthermia, hyperglycemia, teratogen exposure, obesity, ethnicity, and fetal gender. More than 50 years ago, Hibbard and Smithells (1965) postulated that abnormal folate metabolism was responsible for many NTDs. However, most NTD cases do not occur in the setting of maternal folic acid deficiency, and it has become clear that the gene-nutrient interactions underlying folate-responsive NTDs are complex. For a woman with a prior affected child, the 3- to 5-percent recurrence risk declines by at least 70 percent with 4 mg/d of periconceptional oral folic acid supplementation (Grosse, 2007; MRC Vitamin Study Research Group, 1991). Periconceptional folic acid supplementation also appears to ameliorate the fetal NTD risk in women with pregestational diabetes and in those with exposure to antiepileptic medications, fever during embryogenesis, and obesity (Kerr, 2017; Petersen, 2019). Sonographic features of NTDs are described in Chapter 15 (p. 276), their prevention with folic acid is discussed in Chapter 9 (p. 168), and fetal therapy for myelomeningocele is reviewed in Chapter 19 (p. 372).

GENETIC TESTS

All pregnant women should have the option of prenatal aneuploidy *screening* and prenatal genetic *diagnosis* (American College of Obstetricians and Gynecologists, 2018). Screening for fetal aneuploidy may be either serum analyte-based or cell-free DNA-based. Prenatal genetic carrier screening tests for cystic fibrosis and spinal muscular atrophy carrier status also are routinely offered. Additional carrier screening tests are offered to at-risk individuals. Expanded genetic carrier screening panels also are available. The American College of Obstetricians and Gynecologists considers ethnic-specific, panethnic, and expanded carrier screening acceptable strategies (American College of Obstetricians and Gynecologists, 2020a). These screening tests are discussed in Chapter 17 (p. 342).

For prenatal genetic diagnosis, the most commonly used tests are chromosomal microarray analysis (CMA), cytogenetic analysis (karyotyping), and fluorescence in situ hybridization (FISH). Testing may be performed on amnionic fluid or chorionic villi. In selected circumstances, whole genome or whole exome sequencing may be considered, but these are not recommended for routine use. To diagnose a specific disease whose genetic basis is known, DNA-based tests are often employed, typically using polymerase chain reaction (PCR) for rapid amplification of DNA sequences.

■ Cytogenetic Analysis

Also known as karyotyping, cytogenetic analysis tests for numerical chromosomal abnormalities—aneuploidy or polyploidy. It can also identify balanced or unbalanced structural rearrangements of at least 5 to 10 megabases in size. Karyotyping has diagnostic accuracy exceeding 99 percent.

Any tissue containing dividing cells or cells that can be stimulated to divide is suitable for cytogenetic analysis. The dividing cells are arrested in metaphase, and their chromosomes are stained to reveal light and dark bands. The most commonly used technique is Giemsa staining, which yields the G-bands shown in Figure 16-3. Each chromosome has a unique banding pattern that permits its identification and detection of

deleted, duplicated, or rearranged segments. The accuracy of cytogenetic analysis rises with the number of bands produced. Metaphase banding routinely yields 450 to 550 visible bands per haploid chromosome set, whereas prophase banding generally yields 850 bands.

Only dividing cells can be evaluated, so the growth of cultured cells affects the rapidity with which results are obtained. Amnionic fluid, which contains amniocytes, epithelial cells, and gastrointestinal mucosal cells, will usually yield results in 7 to 10 days (Chap. 17, p. 344). Fetal blood cells may provide results in 36 to 48 hours but are rarely needed. If fetal skin fibroblasts are evaluated postmortem, stimulation of cell growth can be more difficult. Cytogenetic analysis may take 2 to 3 weeks in such cases and has largely been replaced by CMA (Chap. 35, p. 627).

Fluorescence In Situ Hybridization

This technique is most commonly used for rapid identification of a specific chromosomal abnormality, such as trisomy 21, 18, or 13. Because of its 1- to 2-day turnaround time, FISH is typically selected for cases in which findings may alter pregnancy management. It may also be used to verify a suspected deletion syndrome, such as the 22q11.2 microdeletion (p. 315), although CMA is preferred. The American College of Obstetricians and Gynecologists (2018) recommends that decision-making based on FISH should incorporate clinical information consistent with the suspected diagnosis. Supportive data may be an abnormal aneuploidy screening test result, a sonographic finding, or a confirmatory diagnostic test such as karyotyping or CMA.

To perform FISH, cells are fixed onto a glass slide, and fluorescent-labeled probes are hybridized to the fixed chromosomes (Fig. 16-11). Each probe is a DNA sequence that is complementary to a chromosome region or gene being investigated. If the DNA sequence is present, hybridization is detected as a bright signal visible by microscopy. The number of signals indicates the number of chromosomes or genes of that type in the cell. FISH does not provide information on the entire chromosomal complement but merely the chromosomal or gene region of interest. Figure 16-12 shows an example of interphase FISH using α-satellite probes for chromosomes 18, X, and Y to confirm trisomy 18.

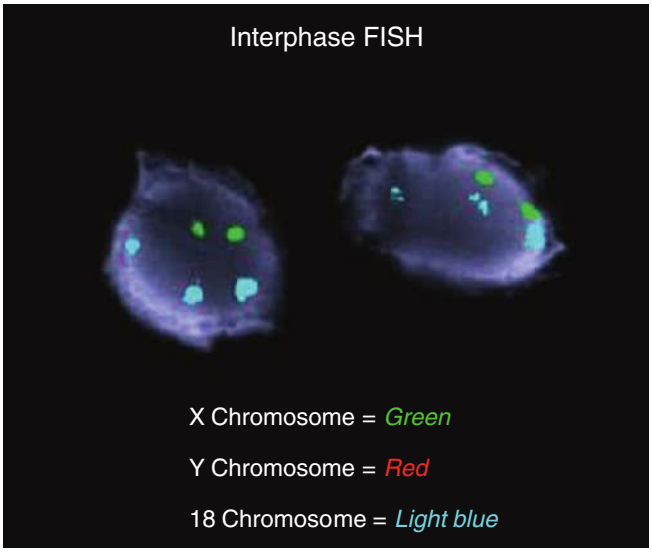

FIGURE 16-12 Interphase fluorescence in situ hybridization (FISH) using α-satellite probes for chromosomes 18, X, and Y. In this case, the three light blue signals, two green signals, and absence of red signals indicate that this is a female fetus with trisomy 18. (Reproduced with permission from Dr. Frederick Elder.)

Chromosomal Microarray Analysis

This test is 100 times more sensitive than karyotyping and detects microduplications and microdeletions as small as 50 to 100 kilobases. Direct CMA, which is performed on uncultured cells, can yield results in 3 to 7 days. If cultured cells are required, results may take 10 to 14 days (American College of Obstetricians and Gynecologists, 2018).

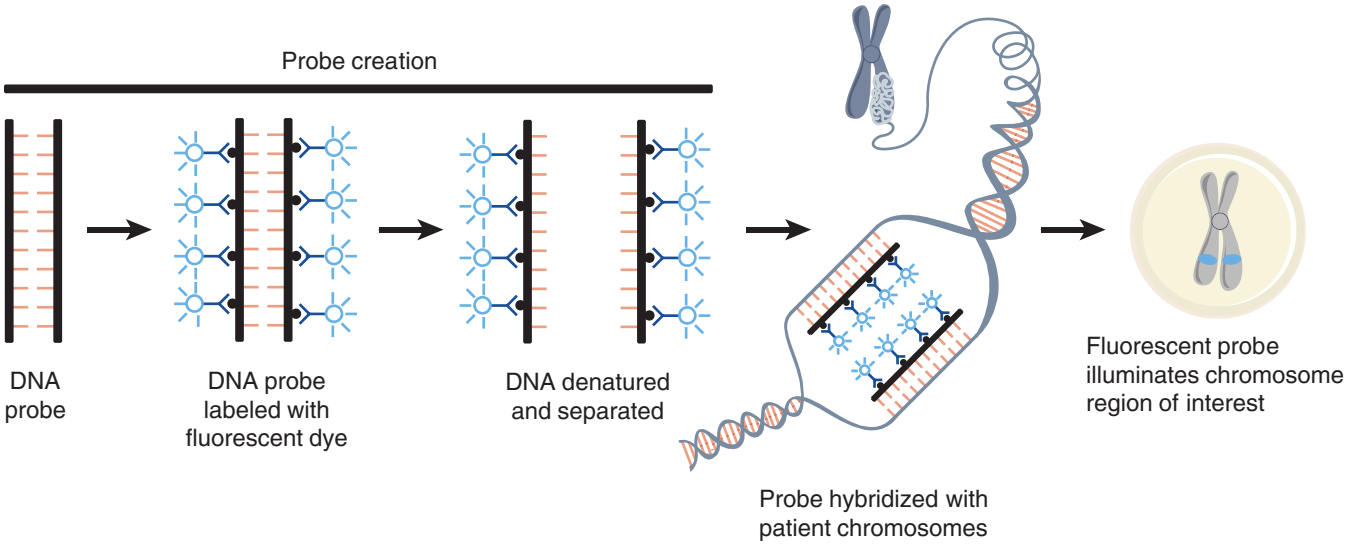

FIGURE 16-11 Steps in fluorescence in situ hybridization (FISH).

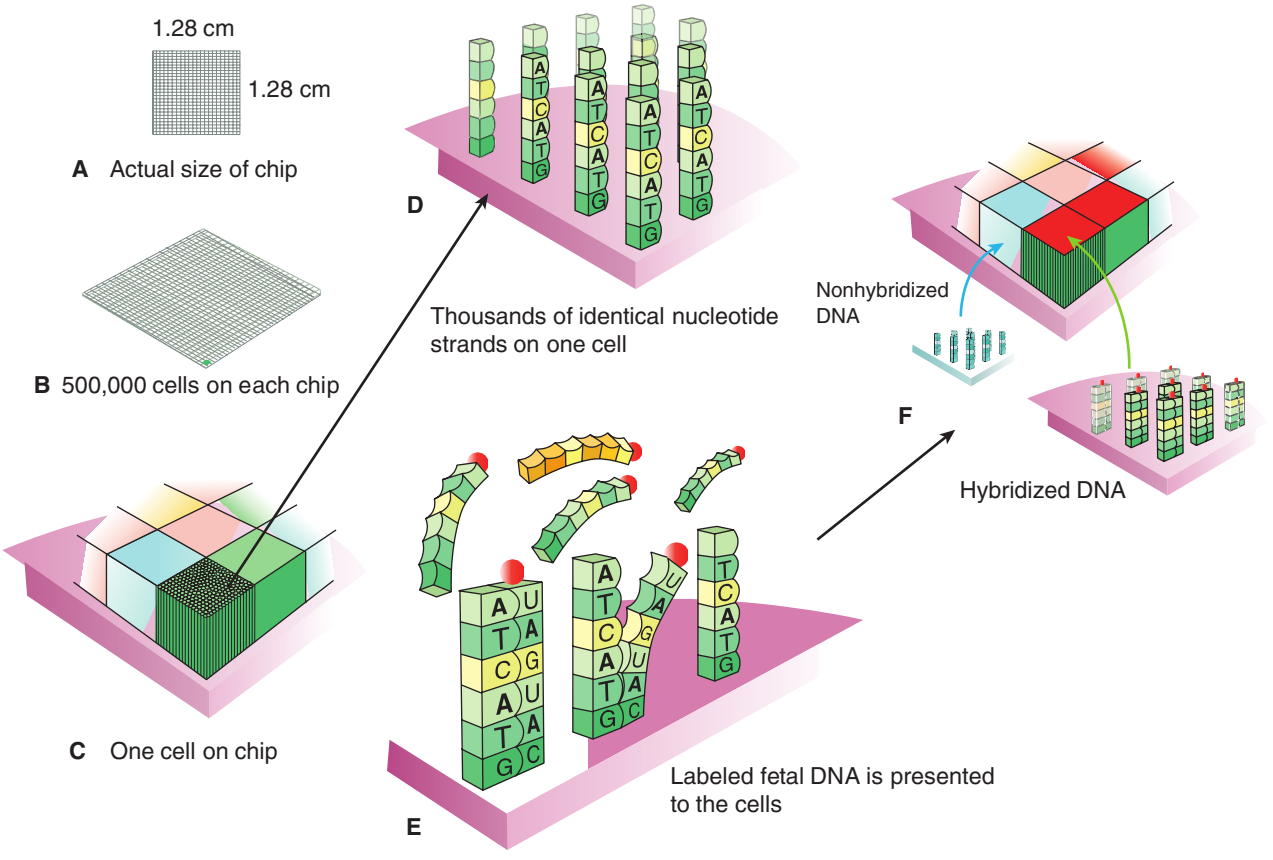

FIGURE 16-13 Chromosomal microarray analysis. **A.** Actual microarray chip size. **B.** Each chip contains thousands of cells (squares). **C** & **D.** Each cell contains thousands of identical oligonucleotides on its surface and is unique in its nucleotide content. **E.** During genetic analysis, a mixture containing tagged fetal DNA is presented to the chip. Complementary DNA sequences bind. **F.** If a laser is shined on the chip, DNA sequences that have bound will glow thus identifying a matching sequence. (Modified with permission from Doody KJ: Treatment of the infertile couple. In Hoffman BL, Schorge JO, Schaffer JI, et al (eds): Williams Gynecology, 2nd ed. New York, NY: McGraw Hill; 2012.)

Microarrays use either a comparative genomic hybridization (CGH) platform, a SNP platform, or a combination of the two. The CGH microarray platform compares specimen DNA with a normal control sample. Shown in Figure 16-13, the CGH chip contains reference DNA fragments of known sequence—oligonucleotides. Fetal DNA from the amniocentesis or chorionic villus sampling specimen is labeled with a fluorescent dye and then hybridized to the DNA on the chip. Normal control DNA is labeled with a different probe and also hybridized to the same chip. The intensity of the fluorescent signals from the two samples is compared. With a SNP array, the chip contains known DNA sequence variants, that is, single-nucleotide polymorphisms. When fetal DNA is labeled and hybridized to the chip, the fluorescent signal intensity indicates copy number variation.

Both types of platforms detect aneuploidy, unbalanced translocations, and microdeletions and microduplications. In addition, SNP arrays are able to identify triploidy and can detect *absence of heterozygosity*. The latter can occur with uniparental disomy, in which both copies of a chromosome are inherited from one parent. Absence of heterozygosity may also occur with consanguinity, and counseling prior to performance of an SNP array should include this possibility (p. 321). Importantly, neither type of array platform currently detects balanced chromosomal rearrangements. For this reason, couples with recurrent pregnancy loss should be offered karyotyping as the first-line test (Society for Maternal-Fetal Medicine, 2016).

In addition to identifying pathogenic copy number variants, CMA may detect variants that are unable to be classified as benign or pathologic and thus are considered to be of uncertain clinical significance. In recent series, these variants of uncertain significance are identified in approximately 1 percent of prenatal specimens (Brady, 2014; Chong, 2019; Wang, 2018). Not unexpectedly, variants of uncertain significance may be a source of distress to families, even with comprehensive pretest counseling.

Clinical Applications

In pregnancies at increased risk for autosomal trisomy based on aneuploidy screening results, karyotyping or FISH plus karyotyping should be offered, and CMA should be made available (American College of Obstetricians and Gynecologists, 2018). Clinicians are increasingly offering CMA in this setting. If the karyotype is normal, CMA has identified clinically relevant copy number variants in approximately 6.5 percent of pregnancies with fetal abnormalities and in 1 to 2 percent of those without obvious fetal abnormality (Callaway, 2013; Chong, 2019). The American College of Obstetricians and Gynecologists (2018) and the Society for Maternal-Fetal Medicine (2016) recommend CMA as the first-tier test when fetal structural abnormalities are identified. If a particular

anomaly that strongly suggests a specific aneuploidy is identified, such as an endocardial cushion defect (trisomy 21) or alobar holoprosencephaly (trisomy 13), then karyotyping or FISH may be offered as the initial test. Genetic counseling should include information regarding the benefits and limitations of both CMA and karyotyping. Each should be made available to women who elect prenatal diagnosis (Society for Maternal-Fetal Medicine, 2016). CMA may identify instances of autosomal dominant genetic disorders that have not yet manifested in an affected parent, and it may also identify instances of nonpaternity.

For stillbirth evaluation, CMA is significantly more likely than standard karyotyping to provide a genetic diagnosis, in part because it does not require dividing cells. The Stillbirth Collaborative Research Network found that when karyotyping was uninformative, approximately 6 percent of cases had either aneuploidy or a pathogenic copy number variant identified with CMA (Reddy, 2012). In a recent metaanalysis of more than 900 stillbirths with normal karyotype, CMA identified pathogenic copy number variants in 6 percent with structural abnormalities and 3 percent with no abnormalities evident (Martinez-Portilla, 2019). Overall, CMA yielded results 15 percent more often than karyotyping alone.

Whole Genome and Whole Exome Sequencing

Most fetuses with structural abnormalities have a normal karyotype and a normal CMA result. Whole genome sequencing (WGS) is a technique for analyzing the entire genome. Whole exome sequencing (WES) analyzes only the DNA coding regions, which account for approximately 1.5 percent of the genome. These next-generation sequencing tools are increasingly used postnatally to evaluate suspected genetic syndromes and intellectual disability.

Several prospective, multicenter series have evaluated WES for pregnancies in which fetuses have structural abnormalities, no karyotypic evidence of aneuploidy, and normal CMA. WES identified genetic abnormalities in approximately 10 percent of such cases (Lord, 2019; Petrovski, 2019). Utility was higher in cases with cardiac, skeletal, or multiorgan system anomalies.

Importantly, WGS and WES have significant limitations in their current form. These include prohibitively long turnaround times, high costs, and increased rates of false-positive and false-negative results and variants of uncertain significance (American College of Medical Genetics, 2012; Atwal, 2014). In addition, because sequencing is generally performed on the fetus and parents simultaneously, one parent may be identified or suspected to have an unrelated but medically actionable finding, which further complicates counseling (American College of Obstetricians and Gynecologists, 2020c). As a result, the clinical utility of this promising technology for prenatal cases is currently limited, and it is not recommended for routine clinical use.

Fetal DNA in the Maternal Circulation

Fetal cells are present in maternal blood at a very low concentration, only 2 to 6 cells per milliliter (Bianchi, 2006). Intact fetal cells sometimes persist in the maternal circulation for decades following delivery. Persistent fetal cells may engraft in the mother, causing microchimerism (Chap. 62, p. 1109). This has been implicated in maternal autoimmune diseases such as scleroderma, systemic lupus erythematosus, and Hashimoto thyroiditis (Kinder, 2017). From the standpoint of prenatal diagnosis, use of intact fetal cells from maternal blood is limited by low cell concentration, cell persistence into successive pregnancies, and difficulties in distinguishing fetal and maternal cells. Cell-free DNA overcomes these limitations.

Cell-free DNA

Also known as cell-free fetal DNA or noninvasive prenatal screening (NIPS), this screening test uses DNA fragments derived from maternal cells and from apoptotic placental trophoblast cells. "Fetal" is thus a misnomer. Cell-free DNA is reliably detected in maternal blood after 9 to 10 weeks' gestation (Bianchi, 2018). The proportion of total cell-free DNA that is placental is called the fetal fraction, and it accounts for approximately 10 percent of the total circulating cell-free DNA in maternal plasma. Unlike intact fetal cells, cell-free DNA is cleared within minutes from maternal blood.

Current clinical applications of cell-free DNA are aneuploidy screening and Rh D genotyping (Fig. 16-14). Commercial laboratories have also offered two other applications of cell-free DNA: (1) screening for selected microdeletion and microduplication syndromes and (2) genome-wide screening for deletions and duplications larger than 7 megabase pairs. Currently, prospective data on these promising applications are limited, and neither is recommended for routine screening (American College of Obstetricians and Gynecologists, 2020c).

Additional applications for cell-free DNA are on the horizon. In research settings, numerous single-gene disorders have been detected and include skeletal dysplasias, hemoglobinopathies, cystic fibrosis, congenital adrenal hyperplasia, hemophilia, muscular dystrophy, myotonic dystrophy, and spinal muscular atrophy (Camunas-Soler, 2018; Jenkins, 2018; Zhang, 2019).

Aneuploidy Screening. Several different assay platforms are used to screen for fetal autosomal trisomies and sex chromosomal aneuploidies. These include massively parallel sequencing, which is a WGS technique; chromosome-selective or targeted sequencing; and analysis of SNPs (American College of Obstetricians and Gynecologists, 2018, 2020c). By simultaneously sequencing millions of chromosome-specific DNA fragments, investigators can identify whether the proportion or ratio of fragments from one chromosome is higher than expected. Thus, samples from women with a Down syndrome fetus will have a larger proportion of DNA sequences from chromosome 21.

The screening performance of cell-free DNA is excellent. In a metaanalysis of 35 studies of largely high-risk pregnancies, the pooled sensitivity to detect Down syndrome was 99.7 percent, and to identify trisomies 18 and 13, 98 and 99 percent, respectively (Gil, 2017). For each, the specificity was at least 99.9 percent, such that the cumulative false-positive rate was below 1 percent. Aneuploidy screening reports commonly include information about fetal sex, which may be clinically useful if the fetus is at risk for an X-linked disorder or for congenital adrenal hyperplasia (Chap. 17, p. 335). In a metaanalysis, the

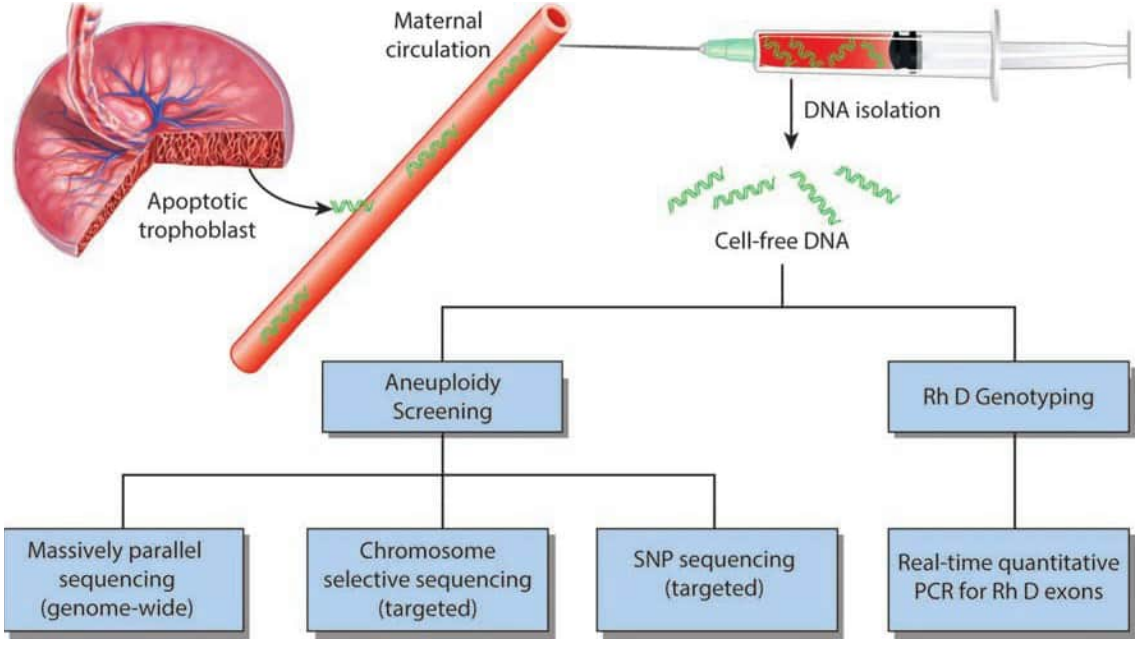

FIGURE 16-14 Cell-free DNA screening. These DNA fragments are derived from apoptotic trophoblast cells. Screening for autosomal trisomies and sex chromosomal aneuploidies may be performed using whole-genome sequencing, chromosome-selective or -targeted sequencing, and analysis of single-nucleotide polymorphisms (SNPs). Real-time quantitative polymerase chain reaction (PCR) also may be used to target specific regions or sequences, a technique used for Rh D genotyping.

sensitivity of cell-free DNA testing for fetal sex determination was reported to be 95 percent between 7 and 12 weeks' gestation and 99 percent after 20 weeks (Devaney, 2011).

Causes of false-positive and false-negative screening results are listed in Table 16-7. As with any other screening test, diagnostic confirmation should be performed before irreversible medical intervention. Cell-free DNA screens do not yield a result in 2 to 4 percent of cases. This may be due to assay failure, high assay variance, or low fetal fraction (Norton, 2012; Pergament, 2014; Quezada, 2015). Importantly, such pregnancies carry a greater risk for fetal aneuploidy. In addition, results may not reflect the fetal DNA complement but rather may indicate confined placental mosaicism, early demise of an aneuploid co-twin, maternal mosaicism, or rarely, occult maternal malignancy (Bianchi, 2015; Curnow, 2015; Grati, 2014b; Wang, 2014). Recommendations for counseling are discussed in Chapter 17 (p. 336).

TABLE 16-7. Selected Etiologies Creating Inaccurate Cell-free DNA Results

Abnormality not detected—false negative
Low fetal fraction
Fetal chromosomal abnormality
Multifetal gestation
Maternal obesity
Low-molecular-weight heparin
Confined placental mosaicism (normal placenta, aneuploid fetus)
Normal fetus but abnormal screen—false positive
Confined placental mosaicism (normal fetus, aneuploid placenta)
Multifetal gestation with loss of aneuploid fetus
Maternal aneuploidy (e.g. 47,XXX)
Maternal mosaicism (e.g. 46,XX/45,X) or fetal mosaicism
Maternal cancer (lymphoma, breast, colon, leukemia, others)
Vitamin B_{12} deficiency

Data from Bianchi, 2018.

Rh D Genotype Evaluation. Many fetuses of Rh D-negative women are also Rh D-negative. In a predominantly white population, this prevalence approaches 40 percent. Fetal Rh D genotype assessment from maternal blood can eliminate administration of anti-D immune globulin in such cases, thereby reducing costs and potential risk. When Rh D alloimmunization is suspected, early identification of an Rh D-negative fetus might avoid unnecessary middle cerebral artery Doppler assessment or amniocentesis. Evaluation using cell-free DNA is done using real-time PCR to target several exons of the *RHD* gene, typically exons 4, 5, 7, and 10.

Rh D-genotyping is performed routinely with cell-free DNA in Denmark, Finland, and the Netherlands (Clausen, 2012; de Haas, 2016; Haimila, 2017). In population-based studies of more than 35,000 Rh D-negative women screened at 24 to 27 weeks' gestation, the false-negative rate—in which Rh D-negative status was missed—was only 0.03 percent. The false-positive rate—in which Rh immune globulin would be given unnecessarily—was less than 1 percent (de Haas, 2016; Haimila, 2017). Similar results were reported from the United Kingdom, although the false-negative rate was higher in the first trimester. Investigators concluded that false-negative screening results might increase the alloimmunization risk but by less than 1 case per million births (Chitty, 2014). Rh D alloimmunization is discussed in Chapter 18 (p. 353).

CHAPTER 17

Prenatal Diagnosis

Prenatal diagnosis is the science of identifying congenital abnormalities and genetic conditions in the fetus. It encompasses the diagnosis of structural malformations with specialized ultrasound, screening tests for aneuploidy, carrier screening for genetic diseases, and diagnostic tests performed on chorionic villi and amnionic fluid.

Based on population-based registry data including births, fetal deaths, and pregnancy terminations, 4 per 1000 pregnancies have a chromosomal abnormality (Wellesley, 2012). If chromosomal microarray analysis (CMA) is performed on chorionic villi or amnionic fluid, an additional 4 per 1000 are found to have a pathogenic copy number variant, such as a microdeletion or microduplication (Srebniak, 2017). It is important for all pregnant women to be offered both screening and diagnostic tests.

The goal of prenatal diagnosis is to provide accurate information about short- and long-term prognosis, recurrence risk, and potential therapy. Nondirective counseling and provision of unbiased knowledge are paramount. Management of an affected pregnancy that includes diagnostic testing, discussion of potential fetal therapy options and postnatal care, and decisions related to expectant management or pregnancy termination are all incorporated into counseling (Flessel, 2011). Fetal imaging of congenital anomalies is discussed in Chapter 15, fetal therapy in Chapter 19, and pregnancy termination in Chapter 11.

HISTORICAL PERSPECTIVE

Nearly 50 years ago, Brock (1972, 1973) observed that pregnancies complicated by neural-tube defects had higher levels of alpha-fetoprotein (AFP) in maternal serum and amnionic fluid. Widespread serum screening began in 1977, after a collaborative trial from the United Kingdom established the association between elevated maternal serum AFP levels (MSAFP) and fetal open neural-tube defects (Wald, 1977). Screening at 16 to 18 weeks' gestation detected 90 percent of fetuses with anencephaly and 80 percent of those with open spina bifida, similar to current screening performance (American College of Obstetricians and Gynecologists, 2019c).

The terms *level I* and *level II* ultrasound were coined in this context. In the California MSAFP Screening Program of the 1980s and early 1990s, the first step in evaluation of an abnormally elevated MSAFP was a level I ultrasound examination. This screening examination demonstrated that one third of pregnancies with MSAFP elevation had incorrect gestational age, multifetal gestation, or fetal demise as the etiology (Filly, 1993). Amniocentesis was then offered to the remaining two thirds. If the amnionic fluid AFP concentration was elevated, a level II ultrasound examination was performed to detect and characterize a fetal abnormality.

Additionally, an elevated amnionic fluid AFP level prompted a concurrent assay for amnionic fluid acetylcholinesterase.

TABLE 17-1. Estimated Risks for Fetal Trisomy 21 and Any Aneuploidy According to Maternal Age and Timing of Diagnosis

	Trisomy 21			Any Aneuploidy	
Age	Chorionic Villus Sampling	Amniocentesis	Delivery	Amniocentesis	Delivery
35	1/249	1/280	1/356	1/132	1/204
36	1/196	1/220	1/280	1/105	1/167
37	1/152	1/171	1/218	1/83	1/130
38	1/117	1/131	1/167	1/65	1/103
39	1/89	1/100	1/128	1/53	1/81
40	1/68	1/76	1/97	1/40	1/63
41	1/51	1/57	1/73	1/31	1/50
42	1/38	1/43	1/55	1/25	1/39
43	1/29	1/32	1/41	1/19	1/30
44	1/21	1/24	1/30	1/15	1/24
45	1/16	1/18	1/23	1/12	1/19

Adapted from Hook, 1983; Snidjers, 1999.

Because acetylcholinesterase leaks from the exposed neural tissue into the amnionic fluid, presence of both analytes was used to confirm the diagnosis. However, other fetal abnormalities are associated with elevated amnionic fluid AFP and positive assay results for acetylcholinesterase. These include ventral wall defects, esophageal atresia, fetal teratoma, cloacal exstrophy, and skin abnormalities such as epidermolysis bullosa.

Most neural-tube defects are now detected with a standard ultrasound examination, and the detailed ultrasound examination is the preferred diagnostic test (American College of Obstetricians and Gynecologists, 2019c; Dashe, 2006). Level II ultrasound is no longer an appropriate synonym for detailed ultrasound examination, because the study now includes a much more comprehensive evaluation of fetal anatomy (Chap. 14, p. 251).

As MSAFP screening was being adopted, the designation "advanced maternal age" (AMA) became popular. A 1979 National Institutes of Health Consensus Development Conference recommended advising pregnant women who were 35 years and older about the possibility of amniocentesis for fetal karyotyping. The threshold was based on the greater risk for selected fetal chromosomal abnormalities with increasing maternal age (Table 17-1). There was also an assumption that the loss rate attributable to amniocentesis was equivalent to the fetal Down syndrome risk at maternal age 35. *This is no longer the case.*

In 1984, Merkatz and colleagues reported that midtrimester MSAFP levels were lower in pregnancies with trisomies 21 and 18 than in unaffected pregnancies. Maternal age was incorporated into the calculation, which enabled assignment of a specific risk (DiMaio, 1987; New England Regional Genetics Group, 1989). The MSAFP screen detected approximately 25 percent of cases of fetal trisomy 21 when the threshold ratio for a positive result was set at 1:270—the approximate second-trimester risk at maternal age 35. This trisomy 21 risk threshold and the associated 5-percent false-positive rate became standards that remain in use in some laboratories.

ANEUPLOIDY SCREENING

Aneuploidy is the presence of one or more extra chromosomes, usually resulting in trisomy, or loss of a chromosome—monosomy (Chap. 16, p. 309). Of recognized pregnancies with chromosomal abnormalities, trisomy 21 accounts for approximately half of cases; trisomy 18 accounts for 15 percent; trisomy 13, for 5 percent; and the sex chromosomal abnormalities—45,X, 47,XXX, 47,XXY, and 47,XYY—for approximately 12 percent. Screening tests are available for some or all of these aneuploidies.

The risk for fetal trisomy increases with maternal age, particularly after age 35 (Fig. 16-2, p. 310). The positive predictive value of all aneuploidy screening tests is higher for women aged 35 years and older. Such women account for 18 percent of deliveries in the United States (Fig. 17-1). At Parkland Hospital, the majority of Down syndrome births occur in this age group (Hussamy, 2019). Other important aneuploidy risk factors include a numerical chromosomal abnormality or structural chromosomal rearrangement in the woman or her partner—such as a balanced translocation—or a prior pregnancy with autosomal trisomy or triploidy.

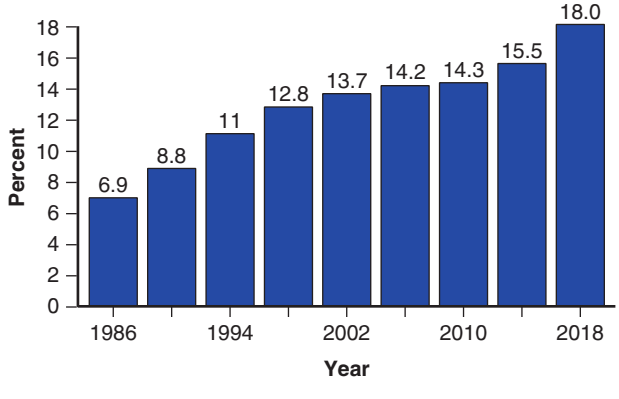

FIGURE 17-1 Trends in the percentage of births to women aged 35 to 44 years. (Data from the Centers for Disease Control and Prevention, 2015, 2019).

Broadly speaking, there are two types of aneuploidy screening tests, those that are analyte-based and those that are cell-free DNA-based. Cell-free DNA (cfDNA) screening is more sensitive and specific than analyte-based screening, and it has a much higher positive predictive value. One prospective screening study for trisomy 21 in 15,000 pregnancies found that the average positive predictive value was 80 percent for cfDNA but only 3 percent for first-trimester screening (Norton, 2015). However, analyte-based screening has the unusual benefit that an abnormal result may indicate a genetic abnormality for which screening was not specifically performed (p. 337). The position of the American College of Obstetricians and Gynecologists (2020e) is that no one screening test is superior in all circumstances. No aneuploidy screening test is diagnostic, and prenatal diagnosis is strongly recommended before acting upon a result.

There are selected circumstances in which aneuploidy screening is *not* recommended. Following diagnosis of a major fetal abnormality, prenatal diagnosis with amniocentesis or chorionic villus sampling is advised. The fetal risk cannot be normalized with a negative aneuploidy screening result. Screening results can be falsely negative, and major abnormalities confer risk for genetic syndromes not identified through screening tests. Analyte-based screening tests are not valid in the setting of an abnormality that affects the AFP component, such as a neural-tube defect or ventral-wall defect. Additionally, all aneuploidy screening methods are less accurate in twin gestations and are invalid in triplet gestations and higher-order multiples.

Aneuploidy screening should be an informed patient choice that incorporates the patient's clinical circumstances, values, interests, and goals. Counseling should be individualized, with the understanding that at least 20 percent of women prefer not to receive aneuploidy screening, even when financial barriers are removed (Kuppermann, 2014). Elements of counseling prior to aneuploidy screening are listed in Table 17-2. The screening test(s) offered and elected may depend on factors such as gestational age, provider location or practice setting, and the patient's out-of-pocket costs.

Test Characteristics

Validity characteristics convey information about how well an aneuploidy screening test differentiates affected from unaffected pregnancies. The sensitivity, also known as the detection rate, is the proportion of fetuses with a particular aneuploidy who are detected by the screening test. The converse is the false-negative rate. If a woman elects a first-trimester aneuploidy screen with a sensitivity of 80 percent for trisomy 21, the false-negative rate is 20 percent, so the test is anticipated to miss 1 in 5 affected pregnancies.

Specificity is the proportion of *unaffected* pregnancies with a negative screening result. The converse of specificity is the

TABLE 17-2. Aneuploidy Screening Counseling Elements

All pregnant women have 3 options: screening, diagnostic testing, and no screening or testing.
The purpose of a screening test is to provide information, not to dictate a course of action.
Diagnostic testing is safe and effective and provides information that screening does not.
There are differences between a screening test and a diagnostic test.
Screening evaluates whether the pregnancy is at increased risk for specific conditions and estimates the degree of risk. Screening does not provide information regarding all genetic abnormalities.
With a negative screening test result, the risk is decreased but not eliminated.
With a positive screening result, a diagnostic test is recommended if the patient wants to know whether the fetus is affected.
Irreversible management decisions should not be based on screening test results.
Cell-free DNA screening does not always provide a result, and the aneuploidy risk is increased in such cases.
Basic information is provided regarding the conditions for which screening is performed and the limitations of the screening test.
Information may include prevalence of a genetic condition, associated abnormalities, and prognosis.
Diagnosis may aid earlier identification of associated abnormalities.
In the case of trisomy 18 or 13, diagnosis may affect pregnancy management if complications arise such as growth restriction or nonreassuring fetal heart rate.
All screening tests are less effective in multifetal gestations.
Phenotypic expression of sex chromosome aneuploidies varies widely.
A-priori risk for fetal aneuploidy may affect whether a woman elects a screening test or diagnostic test.
Age-related risk information may be found in reference tables.
If a patient has had a prior fetus with autosomal trisomy, robertsonian translocation, or other chromosomal abnormality, additional evaluation and counseling are recommended.
If a major fetal abnormality has been identified with ultrasound, a diagnostic test is preferred, and aneuploidy screening is not recommended.

American College of Obstetricians and Gynecologists, 2020e; Dashe, 2016.

TABLE 17-3. Positive Predictive Value of Cell-Free DNA Screening for Autosomal Trisomies and Sex Chromosome Abnormalities, According to Maternal Age at Term

Maternal Age	Trisomy 21	Trisomy 18	Trisomy 13	45,X	47,XXX	47,XXY	47,XYY
20	48%	14%	6%	41%	27%	29%	25%
25	51%	15%	7%	41%	27%	29%	25%
30	61%	21%	10%	41%	27%	29%	25%
35	79%	39%	21%	41%	28%	30%	25%
40	93%	69%	50%	41%	45%	52%	25%
45	98%	90%	NA	41%	73%	77%	NA

NA = not available.
Positive predictive values were obtained using the Cell Free DNA Screening Predictive Value Calculator from the Perinatal Quality Foundation, 2020.
Calculations based on prevalence at 16 weeks' gestation using sensitivities and specificities from Gil, 2015.

false-positive rate, those without aneuploidy who nonetheless screen positive. Because aneuploidies are individually uncommon, the screen-positive rate, which is the overall proportion of tests with a positive result, is usually similar to the false-positive rate. Aneuploidy screening tests generally have screen-positive rates no higher than 5 percent.

Sensitivity and specificity do not convey any information regarding individual risk. The positive predictive value (PPV) is the proportion with a positive screening result who have an aneuploid fetus. PPV may be viewed as the test result. It is usually expressed as a 1:X ratio or as a percentage. Because PPV is directly affected by disease prevalence, it is higher in women aged 35 years and older than in younger women (Table 17-3). Negative predictive value is the proportion of those with a negative screening test result who have unaffected (euploid) fetuses. Because the prevalence of aneuploidy is low, the negative predictive value of all aneuploidy screening tests generally exceeds 99 percent (Gil, 2017; Norton, 2015).

■ Cell-free DNA Screening

This screening test identifies DNA fragments derived primarily from apoptotic trophoblasts, which are placental cells undergoing programmed cell death. Thus, the term cell-free *fetal* DNA is a misnomer. Differences between placental and fetal DNA may cause false-positive and false-negative results. There are three types of assays: whole-genome sequencing, chromosome selective or targeted sequencing, and single nucleotide polymorphism analysis. CfDNA screening can be performed at any time after 9 to 10 weeks' gestation. When it was first introduced, cfDNA screening was offered primarily to pregnancies with increased aneuploidy risk, but it has since become widely available (American College of Obstetricians and Gynecologists, 2020e).

CfDNA screening is most commonly used to screen for autosomal trisomies—trisomy 21, trisomy 18, and trisomy 13. It may also be used to screen for 45,X (Turner syndrome), 47,XXX, 47,XXY, and 47,XYY. A recent metaanalysis concluded that the number of reported sex aneuploidy cases is too small for accurate assessment of screening performance (Gil, 2017). The prognosis for these sex chromosomal aneuploidies differs considerably from that of the autosomal trisomies (Chap. 16, p. 313). If screening for sex chromosomal abnormalities is elected, counseling should include this information.

CfDNA has the highest sensitivity and specificity of any aneuploidy screening test. In a metaanalysis of 35 studies of largely high-risk pregnancies, the pooled sensitivity to detect trisomy 21 was 99.7 percent, and for trisomies 18 and 13, 98 percent and 99 percent, respectively (Gil, 2017). For each of these autosomal trisomies, the specificity is 99.9 percent, and the combined false-positive rate is less than 0.2 percent. If the screening platform includes other genetic conditions, each additional condition increases the overall false-positive rate for the test.

The PPV of a positive cfDNA result is provided in the report or may be estimated from an online calculator or reference table (see Table 17-3). Because the risk estimate for each aneuploidy depends on maternal age, such information may be included as part of pretest counseling. This can help to avoid the misconception that a positive screen indicates aneuploidy—*it does not*.

Because cfDNA screening has a PPV far higher than analyte screening, it may be offered as a secondary screening test for women who wish to avoid amniocentesis. Such an approach has important caveats. If cfDNA is used as a secondary screening test and yields a negative result, the residual risk for a chromosomal abnormality may be as high as 2 percent (Norton, 2014). And, if the cfDNA result is positive, the delay in definitive diagnosis may affect management options.

In addition to the aforementioned aneuploidies, cfDNA screening is available for other genetic conditions. These include aneuploidies such as trisomies 16 and 22, specific microdeletion syndromes, and large copy number changes throughout the genome. Currently, the American College of Obstetricians and Gynecologists (2020e) does *not* recommend cfDNA screening for these other conditions. Sensitivity and specificity of cfDNA screening have not been established for them, and screening accuracy has not been validated clinically.

Limitations of cfDNA Screening

In 2 to 4 percent of pregnancies screened with cfDNA, no result is obtained. These cases are termed "no-call," or indeterminate.

TABLE 17-4. Characteristics of Screening Tests for Trisomy 21 in Singletons

Screening Test	Detection Rate	False-Positive Rate	Positive Predictive Value[a]
Quadruple screen:			
AFP, hCG, estriol, inhibin	80–82%	5%	3%
First-trimester screen:			
NT, hCG, PAPP-A	80–84%	5%	3–4%
First-trimester NT alone	64–70%	5%	
Integrated screening	94–96%	5%	5%
Sequential screening:			
Stepwise	92–97%	5.1%	5%
Contingent	91–95%	4.5%	5%
Cell-free DNA screening:			
Positive result	99%	0.1%	Table 17-3
Low fetal fraction or no result	—	2–4%	3–4%

[a]The positive predictive value represents the overall population studied and cannot be applied to any individual patient.
AFP = alpha-fetoprotein; hCG = human chorionic gonadotropin; NT = nuchal translucency; PAPP-A = pregnancy-associated plasma protein A.
Data from Aldred, 2017; Baer, 2015; Dashe, 2016; Gil, 2015; Malone, 2005b; Norton, 2015; Pergament, 2014; Quezada, 2015.

With a no-call result, the fetal aneuploidy risk is as high as 4 percent (Norton, 2015). As shown in Table 17-4, this result is similar to the average risk conferred by a positive analyte screening test result.

Low fetal fraction is a common reason for no-call results. The fetal fraction is the proportion of cfDNA in the maternal circulation that is placental rather than maternal in origin. The fetal fraction approximates 10 percent in the late first trimester, increasing slightly thereafter (Ashoor, 2013; Scott, 2018). Low fetal fraction is usually defined as <4 percent of the total, and it is more prevalent before 10 weeks' gestation and in the setting of maternal obesity (Ashoor, 2013; Juul, 2020; Scott, 2018). The no-call rate may exceed 10 to 20 percent in women whose body mass index is 40 kg/m^2 or greater (Juul, 2020). Low fetal fraction is also more common in the setting of aneuploidy, particularly trisomies 18 and 13 (Norton, 2015; Pergament, 2014). The American College of Medical Genetics and Genomics recommends that the fetal fraction be included in cfDNA reports because it assists with interpretation of results (Gregg, 2016). Pretest counseling should include the possibility of a no-call result and its clinical significance (see Table 17-2).

If the cfDNA screening test is positive or yields a no-call result, additional genetic counseling is indicated, and amniocentesis should be offered. If cfDNA screening is repeated, the risk for repeat screen failure approximates 40 percent (Dar, 2014; Quezada, 2015; Rolnik, 2018). Detailed ultrasound examination may be offered, but it is not a substitute for amniocentesis, and the residual aneuploidy risk following normal detailed ultrasound examination is unknown.

It is important to remember that cfDNA results may not reflect the fetal DNA complement. Rather, a positive result may be caused by confined placental mosaicism or early demise of an aneuploid co-twin. Alternately, it may indicate maternal aneuploidy, mosaicism, or even occult maternal malignancy (Bianchi, 2015; Curnow, 2015; Grati, 2014; Wang, 2014). If ultrasound identifies an empty second gestational sac, cfDNA screening is not recommended. The patient should be informed of such limitations prior to screening.

■ Analyte-based Aneuploidy Screening

The three categories of multiple marker-serum analyte screening are first-trimester screens, second-trimester screens, and combined first- and second-trimester screens. The serum concentration of each analyte is converted to a multiple of the median (MoM) of the unaffected population by adjusting for maternal age, maternal weight, and gestational age. The serum AFP concentration is further adjusted for maternal race and for presence of diabetes, which affect calculation of neural-tube defect risk (Greene, 1988; Huttly, 2004).

The analyte-based screening result is based on a composite likelihood ratio, and the maternal age-related risk is multiplied by this ratio. Adjustment normalizes the distribution of analyte levels and permits comparison of results from different laboratories and populations. Each woman is provided with a specific risk for trisomy 21 and for trisomy 18—or in the first trimester, for trisomy 18 or 13 in some cases. Each screening test has a predetermined value at or above which it is deemed "positive" or abnormal. For second-trimester tests, this threshold has traditionally been set at the risk for fetal Down syndrome at a maternal age of 35 years—approximately 1 in 270 in the second trimester. The trisomy 21 risk may be further modified based on selected ultrasound markers (p. 340).

A benefit of analyte screening is that pregnancies with abnormal results may have genetic abnormalities other than those for which screening was performed. For example, in a review of more than 2500 pregnancies with genetic abnormalities from the California Prenatal Screening Program, combined first- and second-trimester screening results were abnormal in 93 percent with trisomies 21 and 18 (Norton, 2016). However, results were also abnormal in 80 percent with trisomy 13, in 80 percent with 45,X, in nearly 60 percent with other sex chromosomal abnormalities, and in more than 50 percent with other genetic abnormalities. Alamillo and associates (2013) similarly identified an abnormal karyotype other than trisomies 21, 18, or 13 in 2 percent of pregnancies with abnormal first-trimester screening results, accounting for 30 percent of abnormal karyotypes in the series.

Women younger than 35 are at lower risk for the specific autosomal trisomies for which cfDNA screening is typically performed. Thus, if the goal is to select a screening test that will identify the highest proportion of fetuses with *any* chromosomal abnormality, the yield may be comparable or even slightly higher with integrated or sequential screening than with current cfDNA screening (Baer, 2015; Norton, 2014).

First-trimester Aneuploidy Screening

This test includes human chorionic gonadotropin (hCG), pregnancy-associated plasma protein A (PAPP-A), and ultrasound measurement of the nuchal translucency (NT). It is performed between 11 and 14 weeks' gestation. Pregnancies with fetal trisomy 21 are characterized by higher levels of hCG and lower PAPP-A. With trisomy 18 and trisomy 13, levels of both analytes are lower (Cuckle, 2000; Malone, 2005b).

Nuchal Translucency. This is the maximum thickness of the subcutaneous translucent area between the skin and soft tissue overlying the fetal spine at the back of the neck (Fig. 17-2). It is measured in the sagittal plane and is valid when the crown-rump length (CRL) measurement is between 38 to 45 mm and 84 mm, with the lower limit varying according to the laboratory. Measurement criteria are listed in Table 14–4 (p. 250). The NT should be imaged and measured with a high degree of precision for aneuploidy detection to be accurate. This has led to standardized training, certification, and ongoing quality review programs.

FIGURE 17-2 Sagittal image of a normal, 12-week fetus shows correct caliper placement (+) for nuchal translucency measurement. The fetal nasal bone and overlying skin are indicated. The nasal tip and the 3rd and 4th ventricles (*asterisk*), which are other landmarks that should be visible in the nasal bone image, also are shown. (Reproduced with permission from Dr. Michael Zaretsky.)

An increased NT is not a fetal abnormality but rather a marker that confers increased risk. It is helpful to differentiate from cystic hygroma, which appears sonographically as a septated hypoechoic space behind the neck that extends down the back (Fig. 15-30, p. 286). The fetal aneuploidy risk is five times greater with first-trimester cystic hygroma than with increased NT (Malone, 2005a). An increased NT measurement is associated with other genetic syndromes and various birth defects, especially fetal cardiac abnormalities (Clur 2008; Simpson, 2007). If the NT measurement is at least 3 mm or reaches the 99th percentile for CRL, a detailed ultrasound examination should be offered. Similarly, fetal echocardiography may be considered if the NT measurement is at least 3 mm and is recommended if the NT measurement is 3.5 mm or greater (American College of Obstetricians and Gynecologists, 2020e; American Institute of Ultrasound in Medicine, 2019).

As an isolated marker, NT detects only 70 percent of trisomy 21 fetuses, and for this reason it is not used to screen singleton pregnancies (Alldred, 2017; Malone, 2005b). If cfDNA screening has already been performed, the NT measurement does not improve fetal aneuploidy detection and is not recommended for this purpose (American College of Obstetricians and Gynecologists, 2020e; Reiff, 2016). NT evaluation may be helpful in multifetal gestations because serum screening is less accurate, may not be available, and cannot provide information specific to each fetus. The NT distribution is similar in twins and singletons (Cleary-Goldman, 2005).

Efficacy of First-trimester Screening. Before first-trimester screening became widely adopted, four large prospective trials were conducted, together including more than 100,000 pregnancies (Reddy, 2006). When the screen-positive rate was set at 5 percent, trisomy 21 detection was 84 percent. A recent metaanalysis also reported detection of 87 percent of trisomy 21 fetuses (Alldred, 2017). First-trimester screening similarly detects approximately 80 percent of fetuses with trisomy 18 and 50 percent with trisomy 13 (Norton, 2015).

Maternal age affects the performance of first-trimester aneuploidy screening. In women younger than age 35 at delivery, fetal trisomy 21 detection ranges from 67 to 75 percent (Malone, 2005b; Wapner, 2003). Among women older than 35 at delivery, detection is as high as 90 to 95 percent, albeit at a higher false-positive rate of 15 to 22 percent.

In twin pregnancies, serum free β-hCG and PAPP-A levels are approximately double the singleton values (Vink, 2012). Even with specific curves, a normal dichorionic co-twin will tend to normalize screening results. Thus the aneuploidy detection rate is at least 15-percent lower (Bush, 2005).

Analyte abnormalities are termed *unexplained* if prenatal diagnostic testing results are normal. There is a significant

association between serum PAPP-A levels below the 5th percentile and preterm birth, growth restriction, preeclampsia, and fetal demise (Cignini, 2016; Dugoff, 2004; Jelliffe-Pawlowski, 2015). Similarly, low levels of free β-hCG have been associated with fetal demise (Goetzl, 2004). The sensitivity and PPVs of these markers are too low to make them clinically useful as screening tests (American College of Obstetricians and Gynecologists, 2020c).

Second-trimester Aneuploidy Screening

The quadruple marker or "quad" screening test is performed from 15 through 20 or 21 weeks' gestation depending on the laboratory. Pregnancies with fetal trisomy 21 are characterized by lower MSAFP, higher hCG, lower unconjugated estriol, and higher dimeric inhibin levels. In large prospective trials, trisomy 21 detection was 81 to 83 percent at a 5-percent screen-positive rate (Malone, 2005b; Wald, 1996, 2003). In cases of trisomy 18, levels of MSAFP, hCG, and unconjugated estriol are all decreased, and inhibin is not part of the calculation. Trisomy 18 detection is similar to that for trisomy 21, but the false-positive rate is just 0.5 percent (Benn, 1999). As with first-trimester screening, aneuploidy detection rates are lower in younger women and higher in women older than 35 years at delivery. If second-trimester serum screening is used in twin pregnancies, aneuploidy detection rates are significantly lower (Vink, 2012).

Quadruple-marker screening offers no benefit over first-trimester screening from the standpoint of trisomy 21 or trisomy 18 detection. As a stand-alone test, it is generally used if women do not begin care until the second trimester or if first-trimester screening and cfDNA screening are not available. In 2019, women who initiated prenatal care beyond the first trimester made up more than 20 percent of pregnancies in the United States (Martin, 2020). As subsequently discussed, combining first- and second-trimester screening yields greater aneuploidy detection.

Maternal Serum AFP Elevation: Neural-tube Defect Screening. AFP is the major protein in fetal serum, analogous to albumin in a child or adult. Defects in fetal integument, such as neural-tube and ventral-wall defects, permit AFP to leak into the amnionic fluid and result in dramatically increased maternal serum levels. Accurate gestational age assessment is imperative because the AFP value rises by approximately 15 percent per week during the screening window (Knight, 1992).

Using an MSAFP level of 2.5 MoM as the upper limit of normal, the neural-tube defect detection rate approximates 95 percent for anencephaly and 80 percent for spina bifida, with a screen-positive rate of 1 to 3 percent (American College of Obstetricians and Gynecologists, 2019c; Palomaki, 2019). The overall PPV approximates just 2 percent. Higher screening threshold values are used in twin pregnancies, which have twice the AFP level of singletons (Cuckle, 1990). Importantly, because nearly all cases of anencephaly and most with spina bifida are detected during the standard second-trimester ultrasound examination, MSAFP screening is considered optional (American College of Obstetricians and Gynecologists, 2019c; Dashe, 2006; Norem, 2005).

TABLE 17-5. Conditions Associated with MSAFP Level Elevation

Underestimated gestational age
Multifetal gestation
Fetal death
Neural-tube defect
Gastroschisis
Omphalocele
Cystic hygroma
Esophageal or intestinal obstruction
Liver necrosis
Renal anomalies—polycystic kidneys, renal agenesis, congenital nephrosis, urinary tract obstruction
Cloacal exstrophy
Osteogenesis imperfecta
Sacrococcygeal teratoma
Congenital skin abnormality
Pilonidal cyst
Chorioangioma of placenta
Placenta intervillous thrombosis
Placental abruption
Oligohydramnios
Preeclampsia
Fetal-growth restriction
Maternal hepatoma or teratoma

MSAFP = maternal serum alpha-fetoprotein.

If the serum AFP is elevated, a detailed ultrasound examination is recommended, and characteristic sonographic findings are diagnostic (Chap. 15, p. 276). Other abnormalities and conditions also may result in MSAFP elevation (Table 17-5). Amniocentesis for measurement of amnionic fluid AFP and acetylcholinesterase levels can help to diagnose whether a myelomeningocele is open or closed, which is relevant when considering fetal surgical repair (Chap. 19, p. 372).

Most pregnancies with MSAFP elevation have no fetal abnormality. The patient should receive counseling about the benefits and limitations of detailed ultrasound examination for the diagnosis of neural-tube defects and other potential etiologies. These include other fetal abnormalities, placental abnormalities, and selected adverse pregnancy outcomes (Table 17-5). The likelihood of any abnormality or adverse outcome increases in proportion to the AFP level.

There are similarly significant associations between second-trimester elevation of either hCG or dimeric inhibin alpha levels and adverse pregnancy outcomes. The likelihood of adverse outcome is greater if multiple analytes are elevated (Dugoff, 2005). The sensitivity and positive predictive values of these markers are considered too low to be useful for screening or management. No specific program of maternal or fetal surveillance has been found to favorably affect pregnancy outcomes (Dugoff, 2010).

Low Maternal Serum Estriol Level. A maternal serum estriol level less than 0.25 MoM has been associated with two uncommon but important conditions. *Smith-Lemli-Opitz syndrome* is

an autosomal recessive condition resulting from mutations in the 7-dehydrocholesterol reductase gene. It is characterized by abnormalities of the central nervous system, heart, kidney, and extremities; with ambiguous genitalia; and with fetal-growth restriction. Detailed sonography should be offered if an unconjugated estriol level is <0.25 MoM (American Institute of Ultrasound in Medicine, 2019; Dugoff, 2010). An elevated amnionic fluid 7-dehydrocholesterol level can confirm the diagnosis.

The second condition is *steroid sulfatase deficiency*, also known as *X-linked ichthyosis*. It is typically an isolated condition, but it may also occur in the setting of a contiguous gene deletion syndrome (Chap. 16, p. 315). In such cases, it may be associated with Kallmann syndrome, chondrodysplasia punctata, and/or mental retardation (Langlois, 2009). If the estriol level is <0.25 MoM and the fetus appears to be male, chromosomal microarray analysis or fluorescence in situ hybridization to assess the steroid sulfatase locus on the X-chromosome may be considered.

Integrated and Sequential Screening

If first-trimester screening is combined with second-trimester screening, aneuploidy detection is significantly improved. Combined screening test options require that specimens are obtained at the correct gestational age and sent to the same laboratory. The first- and second-trimester components cannot be performed independently, because the false-positive rate would be higher and providing accurate risk assessment would be problematic.

Three types of screening strategies are available:

1. *Integrated screening* combines results of first- and second-trimester tests. This includes a combined measurement of fetal NT and serum analyte levels at 11 to 14 weeks' gestation plus quadruple markers at approximately 15 to 21 weeks. Trisomy 21 detection is 94 to 96 percent (see Table 17-4).
2. *Sequential screening* involves informing the patient of the results after first-trimester screening, with plan to offer prenatal diagnostic testing if the calculated risk value lies above a specified threshold. There are two testing strategies in this category:
   - With *stepwise sequential screening*, women whose first-trimester risk is at or below the threshold receive second-trimester screening. Using data from the First- and Second-Trimester Evaluation of Risk trial, when the first-trimester threshold is set at approximately 1:30, and the overall threshold is set at 1:270, stepwise sequential screening resulted in a 92-percent trisomy 21 detection rate (Cuckle, 2008). The false-positive rate remained 5 percent (see Table 17-4).
   - With *contingent sequential screening*, women are divided into high-, moderate-, and low-risk groups. Those at highest risk for trisomy 21—for example, risk >1:30, are counseled and offered diagnostic testing. Women at moderate risk, between 1:30 and 1:1500, undergo second-trimester screening, whereas those at lowest risk of <1:1500 receive negative screening test results and have no further testing (Cuckle, 2008). Using this strategy, more than 75 percent of those screened are provided with reassuring results almost immediately. Assuming that women accept diagnostic testing when informed that the risk is elevated, detection approaches 91 percent.

Ultrasound Screening

Ultrasound can improve aneuploidy screening by providing accurate gestational age assessment, by detecting multifetal gestations, and by identifying major structural abnormalities and minor aneuploidy markers. With rare exception, the aneuploidy risk associated with any major abnormality is high enough to recommend prenatal diagnosis with chromosomal microarray analysis. We do not recommend aneuploidy *screening* after

TABLE 17-6. Aneuploidy Risk Associated with Selected Major Fetal Anomalies

Abnormality	Birth Prevalence	Aneuploidy Risk (%)	Common Aneuploidies[a]
Cystic hygroma	1/5000	50–70	45,X; 21; 18; 13; triploidy
Nonimmune hydrops	1/1500–4000	10–20	21; 18; 13; 45,X, triploidy
Ventriculomegaly	1/1000–2000	5–25	13; 18; 21; triploidy
Holoprosencephaly	1/10,000–15,000	30–40	13; 18; 22; triploidy
Dandy-Walker malformation	1/12,000	40	18; 13; 21; triploidy
Cleft lip/palate	1/1000	5–15	18; 13
Cardiac defects	5–8/1000	10–30	21; 18; 13; 45,X; 22q11.2 microdeletion
Diaphragmatic hernia	1/3000–5000	5–15	18; 13; 21
Esophageal atresia	1/4000	10	18; 21
Duodenal atresia	1/10,000	30	21
Gastroschisis	1/2000	No increase	
Omphalocele	1/3000–5000	30–50	18; 13; 21; triploidy
Clubfoot	1/1000	5–30	18; 13

[a]Numbers indicate autosomal trisomies except where indicated. For example, 45,X indicates Turner syndrome.

Data from Best, 2012; Canfield, 2006; Colvin, 2005; Cragan, 2009; Dolk, 2010; Ecker, 2000; Gallot, 2007; Long, 2006; Orioli, 2010; Pavone, 2018; Pedersen, 2012; Sharma, 2011; Solomon, 2010; Walker, 2001.

detection of a major abnormality, because of the many genetic conditions are not detectable with screening tests. Counseling should include the association of the abnormality with aneuploidy (Table 17-6). A caveat is that fetal abnormalities are frequently not isolated, and associated-but-undetectable abnormalities may greatly affect prognosis.

Importantly, fetuses with trisomy 21 and other genetic syndromes may not have obvious ultrasound abnormalities. Just one third of trisomy 21 fetuses have a major abnormality identified with second-trimester ultrasound evaluations (Bromley, 2002; Hussamy, 2019; Vintileos, 1995). If major anomalies and minor aneuploidy markers are considered, 50 to 75 percent of pregnancies affected by Down syndrome are found to have a sonographic abnormality. This is not unexpected, because nearly 40 percent of infants with trisomy 21 do not have major organ system abnormalities identified in the newborn period (Hussamy, 2019). In contrast, the vast majority of fetuses with trisomies 18 and 13 and with triploidy do have ultrasound abnormalities detectable in the second trimester.

Aneuploidy Markers

For more than three decades, investigators have recognized that ultrasound detection of aneuploidy, particularly trisomy 21, may be improved by minor markers that are collectively referred to as "soft signs." Minor markers are normal variants rather than fetal abnormalities, and in the absence of aneuploidy or an associated abnormality, they do not significantly affect prognosis. One or more markers are present in at least 10 percent of pregnancies (Bromley, 2002; Nyberg, 2003). Examples are listed in Table 17-7 and depicted in Figure 17-3.

TABLE 17-7. First- and Second-Trimester Ultrasound Markers Associated with Fetal Trisomy 21

First trimester
Ductus venosus with A-wave absence or flow reversal
Nasal bone absence or hypoplasia
Nuchal translucency enlargement
Tricuspid valve regurgitation
Second trimester
Brachycephaly or shortened frontal lobes
Clinodactyly (hypoplastic middle phalanx of fifth digit)
Echogenic bowel
Flat-appearing facies
Echogenic intracardiac focus
Nasal bone absence or hypoplasia
Nuchal fold thickening
Renal pelvis dilatation
"Sandal gap" between first and second toes
Short ear length
Single transverse palmar crease
Single umbilical artery
Short femur
Short humerus
Subclavian artery aberrant (right side)
Widened iliac angle

Markers listed alphabetically.

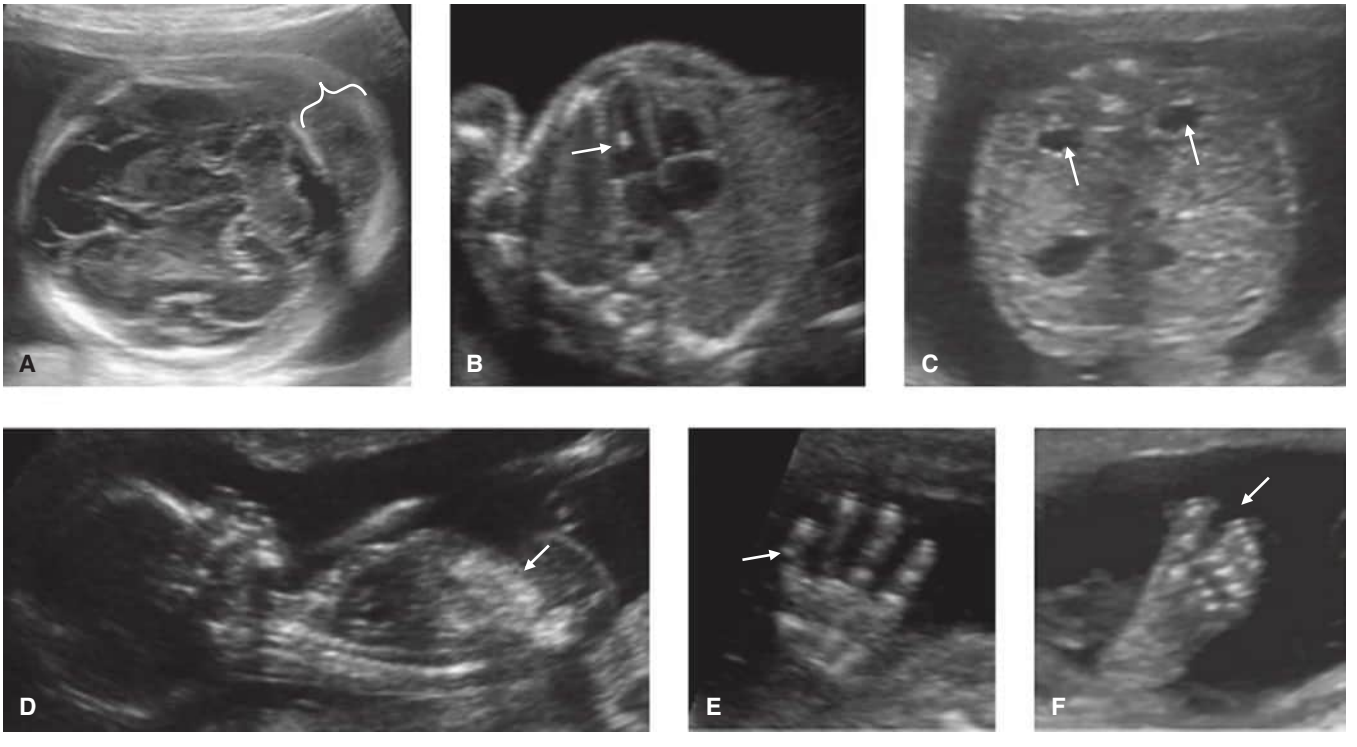

FIGURE 17-3 Minor sonographic markers that are associated with increased risk for fetal Down syndrome. **A.** Nuchal skinfold thickening (*bracket*). **B.** Echogenic intracardiac focus (*arrow*). **C.** Mild renal pelvis dilatation (pyelectasis) (*arrows*). **D.** Echogenic bowel (*arrow*). **E.** Clinodactyly—hypoplasia of the 5th finger middle phalanx creates an inward curvature (*arrow*). **F.** "Sandal-gap" (*arrow*).

A minor marker is an indication for a detailed survey of fetal anatomy to determine if it is isolated (American Institute of Ultrasound in Medicine, 2019).

If an isolated marker is identified and aneuploidy screening has not yet been performed, it should be offered. A benefit of cfDNA screening is that isolated aneuploidy markers no longer factor into the aneuploidy risk, because the negative predictive value of a normal cfDNA test is so high. Conversely, if a cfDNA result is abnormal, the absence of minor markers is not considered reassuring.

First-trimester Markers. Detection of first-trimester findings associated with aneuploidy requires specialized imaging. NT evaluation is discussed earlier (p. 337). Other first-trimester markers are not routinely used in the United States but may be available at specialized centers. The Perinatal Quality Foundation's Nuchal Translucency Quality Review Program offers an education program in first-trimester nasal bone assessment. The Fetal Medicine Foundation also provides online instruction and certification in first-trimester assessment of nasal bone, ductus venosus flow, and tricuspid flow.

There are additional benefits of first-trimester ultrasound evaluation in women who elect aneuploidy screening, including accurate assessment of gestational age and early detection of multifetal gestation or fetal demise. As discussed in Chapter 14 (p. 249), standard first-trimester sonography may identify selected major anomalies associated with aneuploidy, such as cystic hygroma.

Second-trimester Markers. If analyte-based aneuploidy screening has been performed, minor markers may be used to modify the risk using likelihood ratios (Table 17-8). The risk increases with the number of markers identified. Risk modification should follow a protocol that specifies criteria for each marker (Reddy, 2014).

TABLE 17-8. Likelihood Ratios and False-Positive Rates for Isolated Second-Trimester Markers Used in Trisomy 21 Screening Protocols

Sonographic Marker	Likelihood Ratio	Prevalence in Unaffected Fetuses (%)
Nuchal skinfold thickening	11–17	0.5
Renal pelvis dilation	1.5–1.9	2.0–2.2
Echogenic intracardiac focus	1.4–2.8	3.8–3.9[a]
Echogenic bowel	6.1–6.7	0.5–0.7
Short femur	1.2–2.7	3.7–3.9
Short humerus	5.1–7.5	0.4
Any one marker	*1.9–2.0*	*10.0–11.3*
Two markers	*6.2–9.7*	*1.6–2.0*
Three or more	*80–115*	*0.1–0.3*

[a]Higher in Asian individuals.
Data from Bromley, 2002; Nyberg, 2001; Smith-Bindman, 2001.

The *nuchal skinfold* is imaged in the transcerebellar view of the head and is measured from the outer edge of the skull to the outer border of the skin (see Fig. 17-3A). The skinfold is considered thickened if it measures ≥6 mm at 15 to 20 weeks (Benacerraf, 1985). This finding is seen in approximately 1 per 200 pregnancies and confers more than tenfold risk for trisomy 21 (Bromley, 2002; Nyberg, 2001; Smith-Bindman, 2001).

An *echogenic intracardiac focus* is a focal papillary muscle calcification that is neither a structural nor functional cardiac abnormality (see Fig. 17-3B). It is present in 4 to 7 percent of normal fetuses. The fetal trisomy 21 risk is approximately doubled. The finding is more commonly identified in Asian individuals (Shipp, 2000). Fetuses with trisomy 13 may have bilateral echogenic foci (Nyberg, 2001).

Mild *renal pelvis dilatation* is usually transient or physiologic (Chap. 15, p. 298). The renal pelves are measured anterior-to-posterior in a transverse image of the kidneys, with calipers placed at the inner borders of the fluid collection (see Fig. 17-3C). A measurement ≥4 mm is found in about 2 percent of fetuses and approximately doubles the risk for trisomy 21. The degree of pelvic dilatation beyond 4 mm correlates with the likelihood of an underlying renal abnormality, and third-trimester sonography is recommended at approximately 32 weeks.

Echogenic fetal bowel is defined as bowel that is sonographically as bright as fetal bone (see Fig. 17-3D). It is identified in approximately 0.5 percent of pregnancies and often represents a small amount of swallowed blood, not infrequently in the setting of MSAFP elevation. The fetal trisomy 21 risk is increased approximately sixfold. Echogenic bowel is also associated with fetal cytomegalovirus infection and cystic fibrosis—representing inspissated meconium in the latter. Follow-up ultrasound evaluation is suggested at 32 weeks' gestation to evaluate fetal growth (American College of Obstetricians and Gynecologists, 2020e).

For the purpose of Down syndrome screening, the fetal *femur* and *humerus* are considered short if below the 2.5th percentile for gestational age (American College of Obstetricians and Gynecologists, 2020e). Third-trimester ultrasound evaluation is suggested to assess fetal growth. Fetuses with trisomy 21 and short femur are not more likely to be growth restricted, however (Herrera, 2019).

The fetal *nasal bone* is absent in 30 percent of second-trimester fetuses with trisomy 21 and hypoplastic in more than 50 percent (Moreno-Cid, 2014). Absent nasal bone occurs in approximately 1 in 200 euploid fetuses (American College of Obstetricians and Gynecologists, 2020e; Viora, 2005). The finding represents delayed ossification rather than true absence. The nasal bone is measured between 15 and 22 weeks' gestation. Hypoplasia may be defined as shorter than 2.5 mm, as >2 standard deviations below the mean, or based on a ratio to the biparietal diameter (Cicero, 2003). The fetal profile and nasal bone are components of the detailed fetal anatomic survey, but they are not assessed as part of the standard examination and thus not used for routine screening (American Institute of Ultrasound in Medicine, 2019).

One or more *choroid plexus cysts* are seen in 1 to 2 percent of euploid pregnancies (Fig. 16-5, p. 312). The cyst is a benign,

normal variant of no clinical consequence. If associated with structural abnormalities however, the trisomy 18 risk is increased (Reddy, 2014).

CARRIER SCREENING FOR GENETIC DISORDERS

The goal of genetic carrier screening is to provide individuals with meaningful information to guide pregnancy planning according to their personal values (American College of Obstetricians and Gynecologists, 2020b). There are three approaches, each of which is an acceptable strategy: ethnicity-based carrier screening, panethnic screening (performed regardless of ethnicity), and expanded carrier screening—which is a type of panethnic screening performed for a large number of conditions. All carrier screening is optional and should be an informed choice.

Carrier screening is ideally performed prior to conception so that both partners can have the opportunity to consider the results and pursue options such as preimplantation genetic testing (p. 348) or donor gametes. If the screen detects a genetic condition, partner screening should be offered. No screening test will identify all carriers of a condition. Genetic counseling should include the residual risk for the condition if the partner's screen is negative, as well as prenatal diagnosis options (American College of Obstetricians and Gynecologists, 2020b). Prenatal diagnosis is increasingly available if disease-causing mutation or mutations are known. The Genetic Testing Registry of the National Institutes of Health contains detailed information regarding more than 18,000 genetic conditions and 78,000 genetic tests (www.ncbi.nlm.nih.gov/gtr/). In the setting of consanguinity, additional genetic counseling is indicated.

Ethnicity-based carrier screening is offered for selected autosomal recessive conditions that are found in greater frequency in specific racial or ethnic groups. The *founder effect* occurs when an otherwise rare gene is found with greater frequency in a certain population and can be traced back to a single family member or small group of ancestors. It may develop when generations of individuals procreate only within their own groups because of religious or ethnic prohibitions or geographical isolation. Because assignment of a single ethnicity is often difficult, *panethnic* screening is increasingly preferred.

Expanded carrier screening has the advantage of screening for many conditions simultaneously, ranging from a few dozen to more than 1000 (Chokshvilli, 2018). An unfortunate result is that much of the population—more than 50 percent of those screened–may be identified to be carriers for at least 1 condition. Some conditions are so rare that information about detection and residual risk are limited. Counseling regarding phenotypic expression of different mutations and determination of whether variants have clinical significance has become increasingly complex. Thus, expanded carrier screening can cause anxiety for families and may pose challenges to already-strained genetic counseling resources. The American College of Obstetricians and Gynecologists (2020b) has the following guidelines for conditions included in expanded panels:

1. The carrier frequency should be at least 1:100, which corresponds to a population prevalence of 1:40,000.
2. The condition should have a well-defined phenotype, lead to a detrimental effect on quality of life, cause cognitive or physical impairment, or require surgical or medical intervention.
3. Conditions with adult onset are not recommended for inclusion.

There is a long-held principle that genetic carrier screening for a particular condition not be repeated in a subsequent pregnancy. The number of mutations for which testing is available has greatly increased in recent years, but the additional yield of rescreening is usually low. Consultation with a provider with genetic expertise should be considered before screening is repeated (American College of Obstetricians and Gynecologists, 2020a).

Cystic Fibrosis

This disorder is caused by a mutation in the *cystic fibrosis conductance transmembrane regulator (CFTR)* gene, which is located on the long arm of chromosome 7 and encodes a chloride-channel protein. Although the most common *CFTR* mutation associated with classic cystic fibrosis (CF) is the Δ*F508* mutation, more than 2100 mutations have been identified (Cystic Fibrosis Mutation Database, 2020). CF may develop from either *homozygosity* or *compound heterozygosity* for mutations in the *CFTR* gene. One mutation must be present in each copy of the gene, but they need not be the same mutation. There is a wide range of clinical disease severity. Median survival length is 42 years, but approximately 15 percent have milder disease and can survive for decades longer. Care of the pregnant woman with CF is discussed in Chapter 54 (p. 968).

For more than two decades, the American College of Obstetricians and Gynecologists (2020a) has recommended that all women who are pregnant or considering pregnancy be offered CF carrier screening. Such screening should include, at minimum, a panel of 23 panethnic gene mutations, selected because they are present in at least 0.1 percent of patients with classic CF. The CF-mutation carrier frequency approximates 1:25 in Ashkenazi Jews and those of non-Hispanic white ethnicity, 1:60 in African Americans and those of Hispanic white ethnicity, and 1:95 Asian Americans. Using the 23-mutation panel, the residual carrier risk after a negative test result was roughly 1:380 for Ashkenazi Jews and 1:170 to 1:200 for other ethnicities (American College of Obstetricians and Gynecologists, 2020a).

More recently however, expanded panels that use gene sequencing have been reported to improve detection of at-risk couples by 30 percent compared with the 23-mutation panel (Beauchamp, 2019). The American College of Medical Genetics now recommends either a targeted approach to carrier screening, in which the standard mutation panel may be used, or a more comprehensive approach in which specific variant classifications may be reported (Deignan, 2020).

CF is included in all newborn screening panels but is not a substitute for carrier screening because it only identifies affected individuals. If the patient carries a mutation, her partner should be offered screening. If both parents are carriers, genetic counseling is indicated, and prenatal diagnostic testing should be offered.

Spinal Muscular Atrophy

This autosomal recessive disorder results in spinal cord motor neuron degeneration that leads to skeletal muscle atrophy and generalized weakness. There is currently no effective treatment. The prevalence of spinal muscular atrophy (SMA) is 1 in 6000 to 10,000 live births. Types I, II, III, and IV are caused by mutations in the *survival motor neuron (SMN1)* gene, which is located on the long arm of chromosome 5 (5q13.2) and encodes the SMN protein. Types I and II account for 80 percent of cases and are both lethal (American College of Obstetricians and Gynecologists, 2020a). SMA type I, known as Werdnig-Hoffmann disease, is the most severe. Disease onset is within the first 6 months, and affected children die of respiratory failure by age 2 years. Type II generally has onset before age 2 years, and the age at death can range from 2 years to the third decade of life. Type III also presents before age 2 years, with disease severity that is milder and more variable. Type IV does not present until adulthood.

The American College of Obstetricians and Gynecologists (2020a) recommends that carrier screening for SMA be offered to all women who are considering pregnancy or are currently pregnant. Prior to screening, the potential spectrum of severity, carrier frequency, and detection rate should be provided. Posttest counseling should include the residual risk after a negative result, which differs according to ethnicity and also according to the number of *SMN1* copies detected. The SMA carrier frequency approximates 1:35 in those of non-Hispanic white ethnicity, 1:41 in Ashkenazi Jews, 1:53 in Asians, 1:66 in African Americans, and 1:117 in those of Hispanic white ethnicity (Hendrickson, 2009). Carrier detection rates range from 90 to 95 percent for each ethnicity except African Americans, in whom it approximates 70 percent (MacDonald, 2014).

Although there is usually one copy of the *SMN1* gene on each chromosome, approximately 3 to 4 percent of carriers have no copies of this gene on one chromosome and two copies on the other. Because such individuals have two copies in total, they are not detected if a quantitative polymerase chain reaction test is used. Carrier screening is less sensitive in African American individuals, because they are more likely to have this genetic variation. Additionally, some individuals have three copies of the gene and are at even lower risk. If the patient or her partner has a family history of SMA, or if carrier screening is positive, genetic counseling is indicated.

Hemoglobinopathies

These include the sickle hemoglobinopathies—sickle cell anemia and sickle cell hemoglobin C disease, thalassemias, and sickle cell–β-thalassemia. Their pathophysiology and management are discussed in Chapter 59 (p. 1053). The risk is increased in women who are of African or African-American, Mediterranean, Middle Eastern, or Southeast Asian ethnicity. In such individuals, hemoglobin electrophoresis should be offered prenatally or prior to conception (American College of Obstetricians and Gynecologists, 2019a).

Sickle Hemoglobinopathies

Approximately 1 in 12 African Americans has sickle-cell trait, 1 in 40 carries hemoglobin C, and 1 in 40 carries the trait for β-thalassemia. Hemoglobin S is also more common among individuals of Mediterranean, Middle Eastern, and Asian Indian descent (Davies, 2000). If a couple is at risk to have a child with a sickle hemoglobinopathy, genetic counseling should be offered. Prenatal diagnosis can be performed with either chorionic villus sampling or amniocentesis.

Thalassemias

These are the most common single-gene disorders worldwide. Thalassemias are characterized as alpha (α) or beta (β) depending on whether α- or β-hemoglobin chains are affected. In general, α-thalassemia is more likely to be caused by *deletions* of α-globin chains, whereas β-thalassemia more often stems from *mutations* in β-globin chains.

In α-thalassemia, the number of α-globin genes that are deleted may range from one to all four. If two α-globin genes are deleted, both may be deleted from the same chromosome—*cis* configuration (αα/––), or one may be deleted from each chromosome—*trans* configuration (α–/α–). The *cis* configuration is more prevalent among Southeast Asians, whereas those of African descent are more likely to inherit the trans configuration. Alpha-thalassemia trait results in mild anemia. However, if the patient and her partner both carry cis deletions, offspring are at risk for an absence of α-hemoglobin, called Hb Barts disease. This can lead to hydrops and fetal loss (Chap. 18, p. 360). Hemoglobin electrophoresis cannot detect α-thalassemia or α-thalassemia trait. Molecular genetic testing should be considered if there is microcytic anemia in the absence of iron deficiency and if the hemoglobin electrophoresis is normal, particularly among individuals of Southeast Asian descent (American College of Obstetricians and Gynecologists, 2019a).

In β-thalassemia, β-globin genes may cause reduced or absent production of β-globin chains. If the mutation affects one gene, it results in β-thalassemia minor. If both copies are affected, the result is either β-thalassemia major—termed Cooley anemia—or β-thalassemia intermedia. Hemoglobin electrophoresis demonstrates elevated levels of hemoglobins that do not contain β-chains, which are hemoglobins F and A_2. β-Thalassemia minor should be considered if an individual of one or more of the aforementioned ethnicities is found to have microcytic anemia in the absence of iron deficiency. A hemoglobin A_2 level exceeding 3.5 percent confirms the diagnosis.

Recessive Diseases in Ashkenazi Jewish Individuals

Among Jewish individuals of Eastern and Central European (Ashkenazi) descent, there are three severe diseases for which the carrier frequency and detection rate are high enough that screening should be offered: Tay-Sachs disease, Canavan disease, and familial dysautonomia (American College of Obstetricians and Gynecologists 2020a). The carrier rate approximates 1 in 30 for Tay-Sachs disease, 1 in 40 for Canavan disease, and 1 in 32 for familial dysautonomia. For each, the detection rate is at least 98 percent. As for other genetic conditions, screening is ideally performed prior to conception or during early pregnancy.

There are several other autosomal recessive conditions for which the College also recommends that screening be

considered. These include Bloom syndrome, familial hyperinsulinism, Fanconi anemia, Gaucher disease, glycogen storage disease type I (von Gierke disease), Joubert syndrome, maple syrup urine disease, mucolipidosis type IV, Niemann-Pick disease, and Usher syndrome. Gaucher disease differs from the other conditions listed because it has a wide range in phenotype and because treatment is available in the form of enzyme repletion and substrate reduction therapy.

Tay-Sachs Disease

This lysosomal-storage disease causes progressive neurodegeneration and death in early childhood. It is characterized by deficiency of the enzyme hexosaminidase A, which results in accumulation of GM2 gangliosides in the central nervous system. Affected individuals have almost complete absence of the enzyme, whereas carriers are asymptomatic but have less than 55-percent hexosaminidase A activity. An international Tay-Sachs carrier screening campaign was initiated in the 1970s and met with unprecedented success in the Ashkenazi Jewish population. The incidence of Tay-Sachs disease subsequently declined more than 90 percent (Kaback, 1993). Other groups at increased risk for Tay-Sachs disease include those of French-Canadian and Cajun descent.

Carrier screening for Tay-Sachs disease is performed with DNA-based mutation analysis or hexosaminidase activity testing. DNA-based mutation analysis is the preferred test in Ashkenazi Jewish individuals and other high-risk groups but has a lower detection rate in the general population. Therefore, hexosaminidase activity testing is recommended for screening in individuals from lower-risk ethnicities. If a woman is pregnant or taking oral contraceptives, a hexosaminidase activity test should be performed on leukocytes to avoid a high false-positive rate (American College of Obstetricians and Gynecologists, 2020a). If both partners are found to be carriers, prenatal diagnostic testing should be offered. Hexosaminidase activity may be measured from chorionic villi or amnionic fluid.

PRENATAL AND PREIMPLANTATION DIAGNOSTIC TESTS

Diagnostic procedures used in prenatal diagnosis include amniocentesis and chorionic villus sampling (CVS). Fetal blood sampling is rarely performed solely for genetic diagnosis but may be used in conjunction with intrauterine transfusion. Preimplantation genetic tests for aneuploidies, structural chromosomal rearrangements, and monogenic disorders are available for couples undergoing in vitro fertilization (IVF).

In the setting of a fetal structural abnormality, chromosomal microarray analysis (CMA) is recommended. CMA is preferred to cytogenetic analysis (karyotyping) because it can detect clinically significant chromosomal abnormalities in approximately 6.5 percent of fetuses with normal karyotype (Callaway, 2013; de Wit, 2014, Wapner, 2012). And, in the absence of a fetal structural abnormality, CMA has detected additional chromosomal abnormalities (pathogenic copy number variants) in up to 1 percent of those with normal karyotype. CMA is therefore made available whenever a prenatal diagnostic procedure is performed (American College of Obstetricians and Gynecologists, 2018; Callaway, 2013). Types of CMA platforms and their benefits and limitations are reviewed in Chapter 16 (p. 326).

Karyotyping identifies aneuploidy and polyploidy. Additionally, it can identify *balanced* chromosomal rearrangements that are currently undetectable with CMA. For example, karyotyping performed when a couple has experienced recurrent pregnancy loss may reveal that one parent carries a balanced robertsonian translocation (Chap. 16, p. 315). An additional indication is the fetus with a structural abnormality that strongly suggests a particular aneuploidy—such as endocardial cushion defect in trisomy 21 or holoprosencephaly in trisomy 13.

If rapid identification of a specific chromosomal abnormality, such as trisomy 21, 18, or 13, is needed, fluorescence in situ hybridization (FISH) may be used in conjunction with CMA or karyotyping. Decision-making based on FISH should incorporate clinical information consistent with the suspected diagnosis, such as a screening result or ultrasound finding (American College of Obstetricians and Gynecologists, 2018).

Because of improvements in aneuploidy screening tests, there has been a dramatic drop in the number of prenatal diagnostic procedures. Larion and coworkers (2014) reported a 70-percent decline in CVS and a nearly 50-percent drop in amniocentesis procedures since the introduction of cfDNA screening in 2012. This further amplified the decrease in amniocentesis procedures that occurred with the advent of first-trimester screening (Warsof, 2015). Unfortunately, fewer than 40 percent of women with a positive screening result elect prenatal diagnosis (Dar, 2014). If prenatal diagnosis is elected, however, the percent with an abnormal result has increased significantly (Awomolo, 2018).

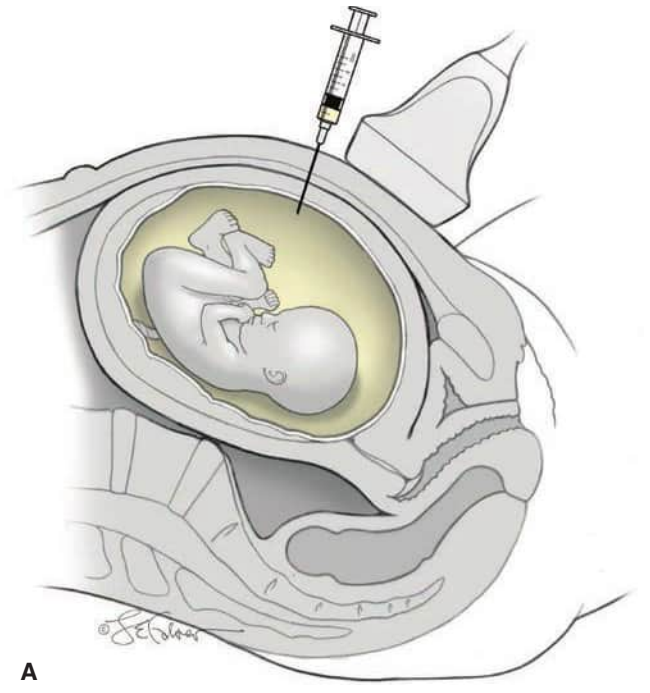
■ Amniocentesis

Because of its established safety and efficacy, amniocentesis is offered to all pregnant women (American College of Obstetricians and Gynecologists, 2020e). Amnionic fluid is withdrawn transabdominally under direct ultrasound guidance. Although typically performed between 15 and 20 weeks' gestation, amniocentesis may be done at any point later in gestation. Tests include those for genetic conditions, congenital infections, and alloimmunization. Fetal lung maturity is no longer routinely assessed, based on recommendations against using it to assist with delivery timing (American College of Obstetricians and Gynecologists, 2019b).

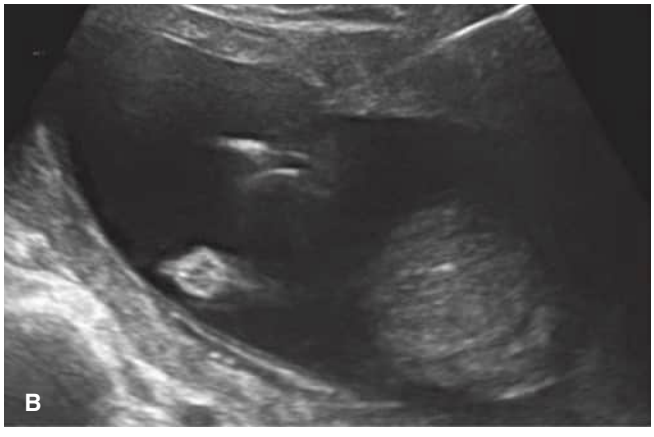
Technique

Amniocentesis is performed with a 20- or 22-gauge needle using aseptic technique (Fig. 17-4). A standard spinal needle is 9 cm long. A longer needle may be required for obese patients. To aid in needle selection, we find it helpful to measure the distance from skin to amnionic fluid with ultrasound prior to the procedure. After the patient empties her bladder, the skin is prepared with an antiseptic such as povidone-iodine. Shellfish allergy is not a contraindication to the povidone-iodine antiseptic (Westermann-Clark, 2015).

All aspects of the procedure are performed under direct ultrasound guidance. A pocket of amnionic fluid close to the midline is selected, avoiding fetal parts and being cognizant



A



B

FIGURE 17-4 A. Amniocentesis. **B.** The amniocentesis needle is seen in the upper right portion of this sonogram. (Figures 17-4, 17-5, and 17-7 are reproduced with permission from Mastrobattista JM, Espinoza J: Invasive prenatal diagnostic procedures. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al (eds): Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

of uterine size and shape. The needle is inserted perpendicular to the skin, gently puncturing the chorioamnion rather than pushing or "tenting" it away from the uterine wall. The amnion usually fuses with the underlying chorion by 16 weeks' gestation, and the procedure is generally deferred until after chorioamnion fusion. Discomfort from the procedure is considered minor and is related more to focal myometrial contraction than needle discomfort at the skin. Local anesthetic has not been found to be beneficial (Mujezinovic, 2011).

The amniotic fluid should be clear and colorless or pale yellow. Blood-tinged fluid is more frequent with transplacental passage of the needle and generally clears with continued aspiration. Needle passage through the placenta occurs in approximately 60 percent of cases with anterior placentation and is not associated with pregnancy loss (Bombard, 1995, Marthin, 1997). Dark brown or greenish fluid may represent a past episode of intraamnionic bleeding.

TABLE 17-9. Selected Tests Performed on Amniotic Fluid and Volume of Fluid Required

Test	Volume (mL)[a]
Chromosomal microarray analysis	20
Fetal karyotype	20
FISH[b]	10
Genotype studies (alloimmunization)	20
PCR tests for cytomegalovirus, toxoplasmosis, or parvovirus	1–2 each test
Cytomegalovirus culture	2–3
Tests no longer commonly used:	
Fetal lung maturity tests	10
Delta OD 450 (bilirubin analysis)	2–3
Alpha-fetoprotein	2

[a]The volume of fluid needed for each test may vary according to individual laboratory specifications.
[b]Fluorescence in situ hybridization (FISH) is typically performed for chromosomes 21, 18, 13, X, and Y.
PCR = polymerase chain reaction.

The volume of fluid generally needed for commonly performed analyses is shown in Table 17-9. Because the initial 1 to 2 mL of fluid aspirate may be contaminated with maternal cells, it is often discarded. Approximately 20 to 30 mL of fluid is then collected for either fetal CMA or karyotyping before the needle is withdrawn. The uterine puncture site is observed for bleeding, and fetal cardiac motion is documented following the procedure. If the patient is Rh D-negative and unsensitized, anti-D immune globulin is administered after the procedure (Chap. 18, p. 356).

Multifetal Pregnancy. When performing the procedure in a dichorionic or monochorionic diamnionic twin gestation, careful attention is paid to the location of each sac and the dividing membrane. Until recently, a small quantity of dilute indigo carmine dye was often injected before removing the needle from the first sac, with return of clear amnionic fluid anticipated following needle placement into the second sac. Because of widespread shortages of indigo carmine dye, experienced providers typically offer amniocentesis without dye injection. Methylene blue dye is contraindicated because it has been associated with jejunal atresia and neonatal methemoglobinemia (van der Pol, 1992).

Complications

Midtrimester losses attributable to amniocentesis have decreased with improvements in imaging technology. When performed by an experienced provider, the procedure-related loss rate is estimated to be 0.1 to 0.3 percent, or about 1 per 500 procedures (American College of Obstetricians and Gynecologists, 2018; Odibo, 2008, Salomon, 2019). The loss rate may be doubled in women whose body mass index exceeds 40 kg/m^2 (Harper, 2012). In twin pregnancies, Cahill and coworkers (2009) reported a loss rate of 1.8 percent attributable to amniocentesis.

When counseling regarding fetal loss following a procedure, it can be helpful to explain the difference between overall losses and procedure-related losses. In a recent metaanalysis that included more than 60,000 amniocentesis procedures and 300,000 control pregnancies, the loss rate in the absence of a procedure was 0.6 percent, approximately twice the rate of losses attributable to procedures (Salomon, 2019). The indication for the procedure is also relevant, because severe fetal abnormalities and hydrops can significantly increase the loss rate, regardless of a procedure.

Other complications of amniocentesis include amnionic fluid leakage or transient vaginal spotting in 1 to 2 percent. Leakage of amnionic fluid generally occurs within 48 hours of the procedure. Leakage of fluid typically resolves after a few days, and fetal survival exceeds 90 percent (Borgida, 2000). Management recommendations include pelvic rest and avoidance of strenuous activity. Needle injuries to the fetus are rare. If karyotyping is performed, amnionic fluid culture is successful in more than 99 percent of cases, although cells are less likely to grow if the fetus is abnormal (Persutte, 1995).

Early Amniocentesis

Amniocentesis was formerly offered between 11 and 14 weeks' gestation. The technique is the same as for traditional amniocentesis, but the procedure may be more challenging because of lack of membrane fusion to the uterine wall. Approximately 1 mL is withdrawn for each week of gestation. Early amniocentesis is associated with significantly higher rates of fetal loss and other procedure-related complications than other procedures. Complications include development of talipes equinovarus (clubfoot) and amnionic fluid leakage (Canadian Early and Mid-Trimester Amniocentesis Trial, 1998; Philip, 2004). For these reasons, early amniocentesis is not recommended (American College of Obstetricians and Gynecologists, 2018).

Chorionic Villus Sampling

Biopsy of chorionic villi is typically performed between 10 and 13 weeks' gestation. As with amniocentesis, the specimen is usually sent for CMA or karyotype analysis. The primary advantage of CVS is that results are available earlier in pregnancy, permitting more time for decision-making and safer pregnancy termination, if desired.

Technique

CVS is performed transcervically or transabdominally. Both approaches are equally safe and effective (American College of Obstetricians and Gynecologists, 2018). The transcervical approach uses a flexible polyethylene catheter that contains a blunt-tipped, malleable stylet. Transabdominal sampling is performed with an 18- or 20-gauge spinal needle. Both use aseptic technique and are performed under direct transabdominal ultrasound guidance. The catheter or needle is inserted into the early placenta—*chorion frondosum*, and villi are aspirated into a syringe that contains tissue culture media (Fig. 17-5).

Relative contraindications include vaginal bleeding or spotting, active genital tract infection, extreme uterine ante- or retroflexion, or body habitus precluding adequate visualization. If the patient is Rh D-negative and unsensitized, anti-D immune globulin is administered after the procedure.

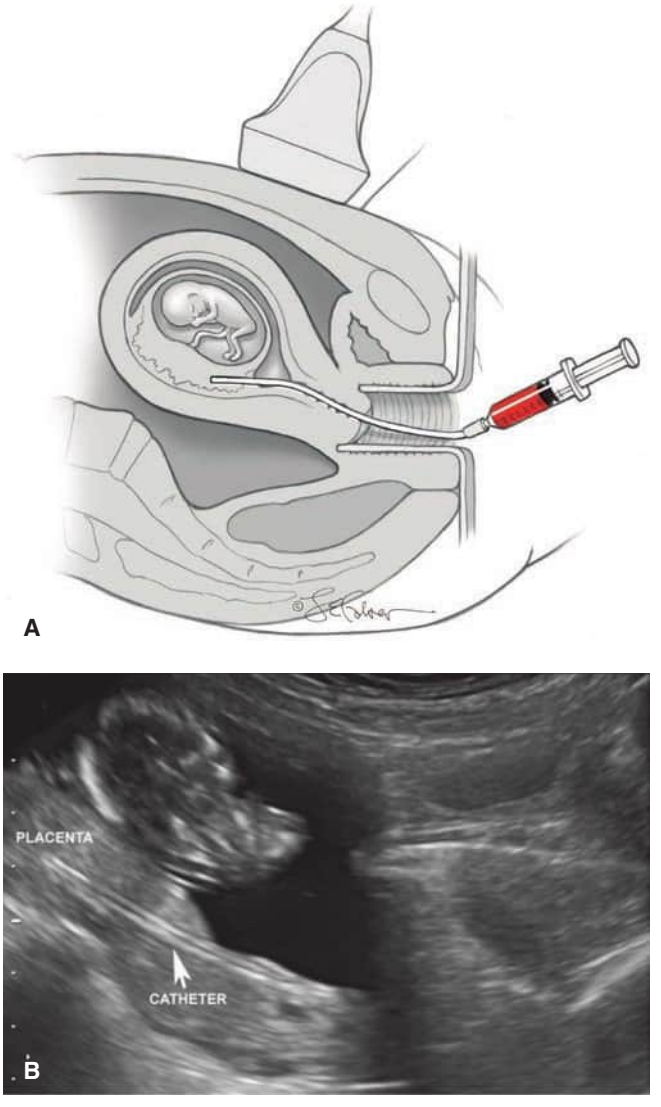


FIGURE 17-5 A. Transcervical chorionic villus sampling. **B.** Catheter entering the placenta is marked and labeled.

Complications

The *overall* fetal loss rate following CVS is higher than that with midtrimester amniocentesis. This is because of losses that would have occurred between the first and second trimester in the absence of a procedure. The procedure-related loss rate is comparable to that with amniocentesis, approximately 0.1 to 0.3 percent (American College of Obstetricians and Gynecologists, 2018). In fact, a recent metaanalysis identified no significant losses from CVS when controls with similar risk profiles were selected (Salomon, 2019). As with amniocentesis, CVS indication will affect the loss rate. For example, fetuses with increased NT thickness have a greater likelihood of demise. There is also a learning curve associated with safe performance of CVS (Silver, 1990; Wijnberger, 2003).

An early problem with CVS was its association with *limb-reduction defects* and *oromandibular limb hypogenesis,* shown in Figure 17-6 (Firth, 1991, 1994; Hsieh, 1995). These were

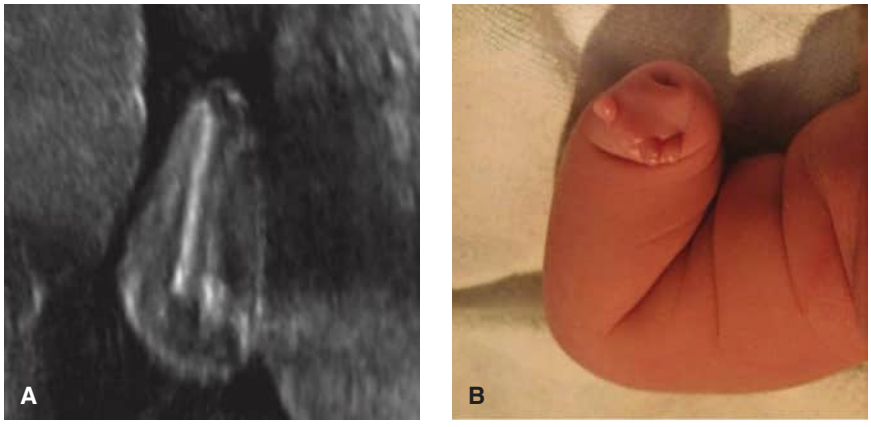

FIGURE 17-6 Oromandibular limb hypogenesis is characterized by transverse limb deficiency and absence or hypoplasia of the tongue or mandible. This is hypothesized to result from vascular disruption with subsequent loss of tissue. **A.** Sonogram obtained at 25 weeks' gestation demonstrates a fetal limb reduction defect involving the right hand. **B.** Photograph of the right extremity of the same newborn. Chorionic villus sampling was not performed in this pregnancy. (Reproduced with permission from Dr. Jamie Morgan.)

subsequently found to be associated with procedures performed at 7 weeks' gestation (Holmes, 1993). When performed at or after 10 weeks' gestation, the incidence of limb defects does not exceed the background population rate of approximately 1 case per 1000 (Evans, 2005; Kuliev, 1996).

Vaginal spotting is not uncommon following transcervical sampling, but it is self-limited and not associated with pregnancy loss. The incidence of infection or leakage of amnionic fluid is less than 0.5 percent (American College of Obstetricians and Gynecologists, 2018).

A limitation of CVS is that chromosomal mosaicism is identified in up to 2 percent of specimens (Malvestiti, 2015). In most cases, the mosaicism reflects confined placental mosaicism rather than a true second cell line within the fetus. This is discussed in Chapter 16 (p. 318). Amniocentesis should be offered, and if the result is normal, the mosaicism is usually presumed to be confined to the placenta. Confined placental mosaicism is associated with fetal-growth restriction (Baffero, 2012; Toutain, 2018).

Fetal Blood Sampling

This procedure is also called cordocentesis or percutaneous umbilical blood sampling (Fig. 17-7). It was initially described for fetal transfusion of red blood cells in the setting of anemia from alloimmunization, and fetal anemia assessment remains the most common indication (Chap. 18, p. 356). Other indications include assessment and treatment of platelet alloimmunization and for fetal karyotype determination, particularly in cases of mosaicism identified following amniocentesis or CVS. Improvements in testing using an amniocentesis specimen have eliminated the need for fetal blood sampling in most cases (Society for Maternal-Fetal Medicine, 2013).

Technique

Using aseptic technique, a 22- or 23-gauge spinal needle is introduced into the umbilical vein under direct ultrasound guidance, and blood is slowly withdrawn into a heparinized syringe. Precise visualization of the needle is essential. As with

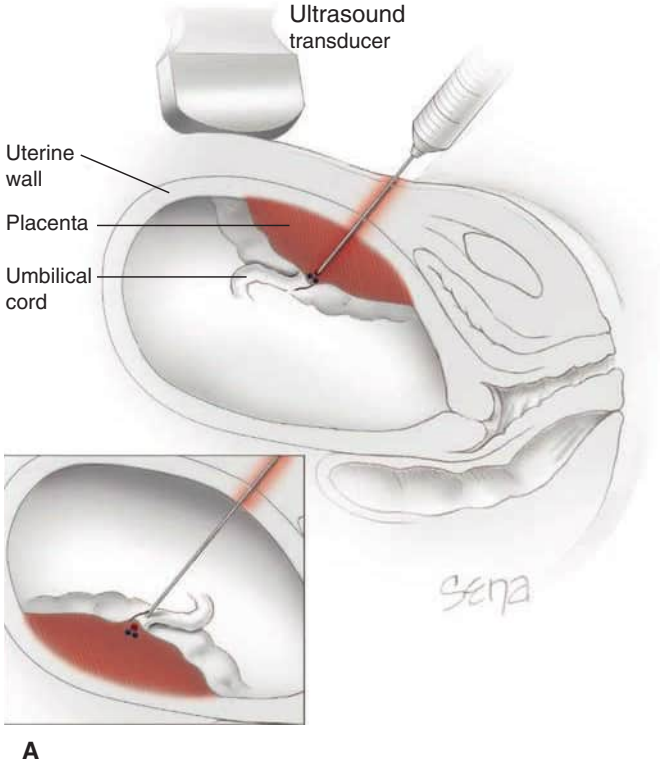

FIGURE 17-7 Fetal blood sampling. **A.** Access to the umbilical vein varies depending on placental location and cord position. With an anterior placenta, the needle may traverse the placenta. Inset: With posterior placentation, the needle passes through amnionic fluid before penetrating the umbilical vein. Alternatively, a free loop of cord may be accessed. **B.** Sonogram shows an anterior placenta with transplacental needle passage into the umbilical vein (UV).

amniocentesis, a longer needle may be required for obese patients. Fetal blood sampling is often performed near the placental cord insertion site, where it may be easier to enter the cord if the placenta lies anteriorly. Alternatively, a free loop of cord may be punctured. Because fetal blood sampling requires more time than other fetal procedures, a local anesthetic may be administered. Prophylactic antibiotics are used at some centers, although no trials support this policy. Arterial puncture is avoided, because it may result in vasospasm and fetal bradycardia. After the needle is removed, fetal cardiac motion is documented, and the site is observed for bleeding.

Complications

The procedure-related fetal loss rate following fetal blood sampling approximates 1 percent (Tongsong, 2001, Tanvisut, 2020). The actual loss rate varies according to the procedure indication and the fetal status. Other complications may include cord vessel bleeding in 20 to 30 percent of cases, fetal-maternal bleeding in approximately 40 percent of cases in which the placenta is traversed, and fetal bradycardia in 5 to 10 percent (Boupaijit, 2012; Society for Maternal-Fetal Medicine, 2013; Tanvisut, 2020). Most complications are transitory, with complete recovery, but some result in fetal loss.

In one series of more than 2000 procedures comparing fetal blood sampling near the placental cord insertion site with puncture of a free loop, rates of procedure success, pregnancy loss, visible bleeding from the cord, and fetal bradycardia did not differ. Time to complete the procedure was significantly shorter if the cord was sampled at the placental insertion site rather than in a free loop—5 versus 7 minutes. However, sampling at the insertion site had a higher rate of maternal blood contamination (Tangshewinsirikul, 2011).

■ Preimplantation Genetic Tests

For couples undergoing IVF, several types of genetic tests may be performed on oocytes (polar bodies) or embryos prior to uterine transfer. These include preimplantation genetic testing for aneuploidy, abbreviated PGT-A, prenatal genetic testing for structural rearrangements (PGT-SR), and prenatal genetic testing for monogenic disorders (PGT-M). Testing is typically performed via trophectoderm biopsy at the blastocyst stage but may be performed on polar bodies of oocytes or via blastomere biopsy of a cleavage-stage embryo (Fig. 17-8). False-positive and false-negative results are possible with each type of PGT. Therefore, prenatal diagnosis with CVS or amniocentesis should be offered (American College of Obstetricians and Gynecologists, 2020d). Comprehensive genetic counseling is required before consideration of each of these procedures (ESHRE PGT Consortium Steering Committee, 2020).

PGT-A is a type of aneuploidy screening test that evaluates the number of each chromosome. Although clearly an appealing prospect, available data are limited, and an optimal testing platform is not yet established. Importantly, if PGT-A is performed with next-generation sequencing following trophectoderm biopsy, mosaicism is frequently identified (Vera-Rodriguez, 2017). Despite an increased risk for poor outcome, many such cases have resulted in healthy, normal children (Victor, 2019).

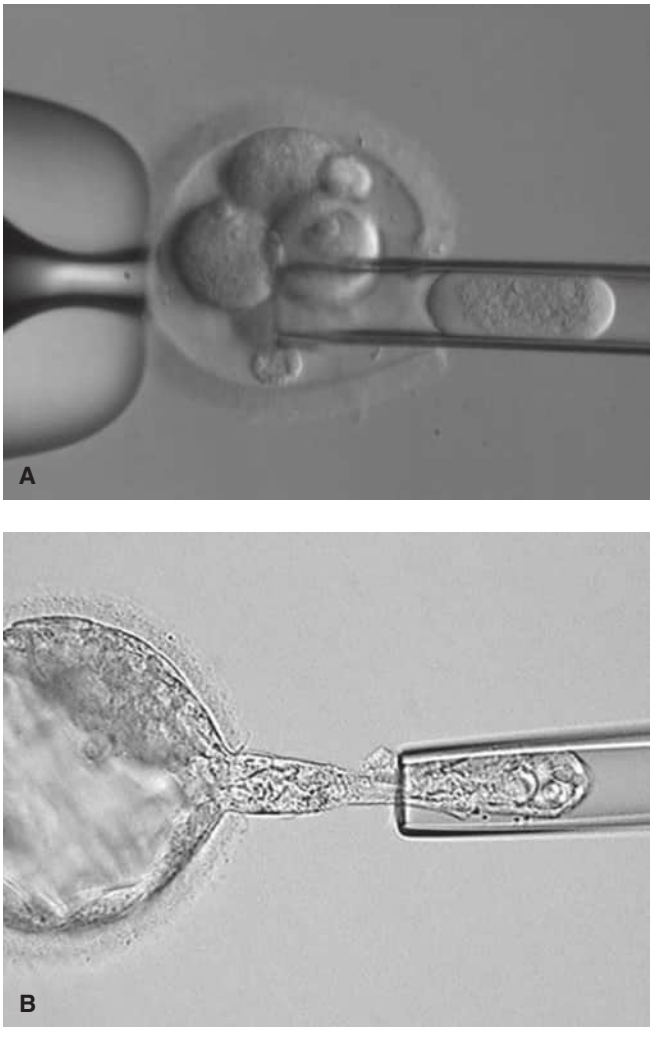

FIGURE 17-8 A. Blastomere biopsy. After a blastomere is selected, it is then drawn into the pipette. **B.** Trophectoderm biopsy. (Reproduced with permission from Doody KJ: Treatment of the infertile couple. Hoffman BL, Schorge JO, Halvorson LM, et al (eds): Williams Gynecology, 4th ed. New York, NY: McGraw Hill; 2020.)

The American Society for Reproductive Medicine (2018) has concluded that the utility of routine performance of PGT-A for all IVF pregnancies has yet to be determined.

PGT-M may be performed when there is increased risk for a particular single-gene disorder or a hereditary cancer syndrome (American College of Obstetricians and Gynecologists, 2020d). It is a test for a specific condition rather than a panel. In selected cases, this technique may also be used identify a suitable future donor of umbilical cord blood for an affected family member.

PGT-SR is offered if one of the parents is a carrier of such a rearrangement, such as a duplication, deletion, translocation, insertion, or inversion. The test will identify an unbalanced chromosomal rearrangement but will not detect a balanced carrier. Counseling should therefore include this limitation.

CHAPTER 18

Fetal Disorders

Fetal disorders may be acquired—such as alloimmunization; may be genetic—congenital adrenal hyperplasia; or may be sporadic—like many structural malformations. This chapter reviews fetal anemia and thrombocytopenia and immune and nonimmune fetal hydrops. Hydrops is perhaps the quintessential fetal disorder, as it can be a manifestation of severe illness from a wide variety of etiologies. Fetal structural malformations are reviewed in Chapter 15, genetic abnormalities in Chapters 16 and 17, and conditions amenable to medical or surgical fetal therapy in Chapter 19. Because congenital infections arise as a result of maternal infection or colonization, they are discussed in Chapters 67 and 68.

FETAL ANEMIA

Anemia may result from alloimmunization, infection, genetic disorders, or fetomaternal hemorrhage. Red cell alloimmunization results from transplacental passage of maternal antibodies that destroy fetal red cells. Alloimmunization leads to overproduction of immature fetal and neonatal red cells—*erythroblastosis fetalis*—a condition now referred to as *hemolytic disease of the fetus and newborn (HDFN)*. Congenital infections are also associated with fetal anemia, particularly parvovirus B19, discussed in Chapter 67 (p. 1191). In Southeast Asian populations, α^0-thalassemia is a common cause of severe anemia and nonimmune hydrops. Rare genetic causes of anemia include red cell production disorders—such as Diamond-Blackfan anemia and Fanconi anemia; red cell enzymopathies—glucose-6-phosphate dehydrogenase deficiency and pyruvate kinase deficiency; red cell structural abnormalities—hereditary spherocytosis and elliptocytosis; lysosomal storage diseases—Gaucher disease, Niemann-Pick, and mucopolysaccharidosis VII; and myeloproliferative disorders—leukemias. Fetomaternal hemorrhage is discussed on page 357. Fetal anemia is typically identified through Doppler evaluation of the fetal middle cerebral artery (MCA) peak systolic velocity (p. 355).

Progressive fetal anemia from any cause leads to heart failure, hydrops fetalis, and ultimately death. Treatment with intrauterine transfusions can be lifesaving. Severely anemic fetuses transfused in utero have survival rates exceeding 90 percent, and even in cases of hydrops fetalis, survival rates approach 80 percent (Lindenberg, 2013; Mizuuchi, 2021; Zwiers, 2017).

Red Cell Alloimmunization

Currently, 36 different blood group systems and 360 erythrocyte antigens are recognized by the International Society of Blood Transfusion (Storry, 2019). Blood banks routinely screen for erythrocyte antigens. Some are immunologically and genetically important, but many are rare and of little clinical significance. An individual who lacks a specific erythrocyte antigen may produce antibodies against it when exposed to that antigen. Such antibodies can prove harmful if an individual receives an incompatible blood transfusion. During pregnancy, these antibodies may cross the placenta and lyse fetal red cells that contain the associated antigens, resulting in anemia.

The fetus typically inherits at least one erythrocyte antigen from the father that is lacking in the mother. The pregnant woman may become sensitized if enough fetal red cells reach her circulation to elicit an immune response. Importantly, alloimmunization is uncommon for the following reasons: (1) low prevalence of incompatible erythrocyte antigens; (2) insufficient transplacental passage of fetal antigens and maternal antibodies; (3) maternal-fetal ABO incompatibility, which leads to rapid clearance of fetal erythrocytes before they elicit an immune response; (4) variable antigenicity; and (5) variable maternal immune response to the antigen.

The prevalence of red cell alloimmunization in pregnancy approximates 1 percent (Bollason, 2017; Koelewijn, 2008). Most cases of severe fetal anemia requiring antenatal transfusion are attributable to anti-D, anti-Kell, anti-c, or anti-E alloimmunization (de Haas, 2015).

Maternal blood type and antibody screen are routinely assessed at the first prenatal visit. Unbound antibodies in maternal serum are detected with an *indirect Coombs test* (Chap. 10, p. 178). If the result is positive, the specific antibodies are identified; their immunoglobulin subtype is determined as either immunoglobulin G (IgG) or M (IgM); and the titer is quantified. Only IgG antibodies are concerning, because IgM antibodies do not cross the placenta. Selected antibodies and their potential to cause fetal hemolytic anemia are listed in Table 18-1. The *critical titer* is the level at which significant fetal anemia may develop. It may vary according to antibody and laboratory but is usually between 1:8 and 1:32. If the laboratory's critical titer threshold for anti-D antibodies is 1:16, a titer ≥1:16 indicates the possibility of severe hemolytic disease. An important exception is Kell sensitization, which is discussed on page 354.

CDE (Rh) Blood Group Incompatibility

The CDE system includes five erythrocyte antigens: C, c, D, E, and e. There is no "d" antigen, and D-negativity is defined as the absence of the D antigen. Although most people are D positive or negative, more than 200 D antigen variants exist (Daniels, 2013). The CDE group was formerly termed Rh or rhesus, due to a misconception that red cells from rhesus monkeys expressed these human antigens. In transfusion medicine, "rhesus" is no longer used (Sandler, 2017).

CDE antigens are clinically important. D-negative individuals may become sensitized after a single exposure to as little as 0.1 mL of fetal erythrocytes (Bowman, 1988). The two responsible genes—*RHD* and *RHCE*—are located on the short arm of chromosome 1 and are inherited together, independent of other blood group genes. Antigen positivity varies according to race and ethnicity. Nearly 85 percent of non-Hispanic white Americans are D-positive, as are approximately 90 percent of Native Americans, 93 percent of African Americans and Hispanic Americans, and 99 percent of Asian Americans (Garratty, 2004).

TABLE 18-1. Selected Red Cell Antigens and Their Relationship to Fetal Hemolytic Disease

Blood Group System	Antigens	Fetal Hemolysis Potential
CDE (Rh)	D, c	Severe disease risk
	E, Be^a, Ce, Cw, Cx, ce, Dw, Evans, e, G, Goa7, Hr, Hro, JAL, HOFM, LOCR, Riv, Rh29, Rh32, Rh42, Rh46, STEM, Tar	Severe disease infrequent, mild disease risk
Kell	K	Severe disease risk
	k, Kp^a, Kp^b, K11, K22	Severe disease infrequent, mild disease risk
	Ku, Js^a, Js^b, Ula	
Duffy	Fy^a	Severe disease infrequent, mild disease risk
	Fy^b	Not associated with fetal hemolytic disease
Kidd	Jk^a	Severe disease infrequent, mild disease risk
	Jk^b, Jk^3	Mild disease possible
MNS	M, N, S, s, U, Mt^a, Ena, Far, Hil, Hut, Mi^a, Mit, Mut, Mur, Mv, sD, Vw	Severe disease infrequent, mild disease risk
Colton	Co^a, Co^3	Severe disease infrequent, mild disease risk
Diego	Di^a, Di^b, Wr^a, Wr^b	Severe disease infrequent, mild disease risk
Dombrock	Do^a, Gy^a, Hy, Jo^a	Mild disease possible
Gerbich	Ge^2, Ge^3, Ge^4, Ls^a	Mild disease possible
Scianna	Sc2	Mild disease possible
I	I, i	Not associated with fetal hemolytic disease
Lewis	Le^a, Le^b	Not associated with fetal hemolytic disease

Data from de Haas, 2015; Moise, 2008; Weinstein, 1982.

The prevalence of D alloimmunization complicating pregnancy ranges from 0.5 to 0.9 percent (Koelewijn, 2008; Martin, 2005). Without anti-D immune globulin prophylaxis, a D-negative woman delivered of a D-positive, *ABO-compatible* newborn has a 16-percent likelihood of developing alloimmunization. Two percent will become sensitized by the time of delivery, 7 percent by 6 months postpartum, and the remaining 7 percent will be "sensibilized"—producing detectable antibodies only in a subsequent pregnancy (Bowman, 1985). If there is *ABO incompatibility*, the D alloimmunization risk decreases to 2 percent because erythrocyte destruction of incompatible cells limits sensitization (Bowman, 2006). D sensitization may also occur following first-trimester pregnancy complications, prenatal diagnostic procedures, and maternal trauma (Table 18-2).

The C, c, E, and e antigens have lower immunogenicity than the D antigen but can cause hemolytic disease. Sensitization to E, c, and C antigens complicates approximately 0.3 percent of pregnancies in screening studies and accounts for about 30 percent of red cell alloimmunization cases (Howard, 1998; Koelewijn, 2008). Anti-E alloimmunization is the most common, but the need for fetal or neonatal transfusions is greater with anti-c alloimmunization than with anti-E or anti-C (de Haas, 2015; Hackney, 2004; Koelewijn, 2008).

The Grandmother Effect. In virtually all pregnancies, small amounts of maternal blood enter the fetal circulation. Polymerase chain reaction (PCR) has identified maternal D-positive DNA in peripheral blood from preterm and full-term D-negative newborns (Lazar, 2006). Thus, a D-negative female fetus exposed to maternal D-positive red cells might develop sensitization, and later might produce anti-D antibodies before or during pregnancy. This mechanism is called the *grandmother effect* because the fetus in the current pregnancy is jeopardized by maternal antibodies that were initially provoked by his or her *grandmother's* erythrocytes.

TABLE 18-2. Causes of Fetomaternal Hemorrhage Associated with Red Cell Antigen Alloimmunization[a]

Pregnancy Loss
Abortion, spontaneous or elective
Ectopic pregnancy
Fetal death (any trimester)
Procedures
Amniocentesis
Chorionic villus sampling
Fetal blood sampling
Molar pregnancy evacuation
Other
Antepartum bleeding, including threatened abortion
Delivery, vaginal or cesarean
External cephalic version
Placental abruption
Trauma to the abdomen during pregnancy

[a]For each of the above, anti-D immune globulin is recommended.
Expanded from American Academy of Pediatrics, 2017; American College of Obstetricians and Gynecologists, 2019b.

Alloimmunization to Minor Antigens

Because routine administration of anti-D immune globulin prevents anti-D alloimmunization, proportionately more cases of hemolytic disease are caused by red cell antigens other than D (American College of Obstetricians and Gynecologists, 2019a; Koelewijn, 2008). These are also known as minor antigens. Kell antigens are among the most frequent. Other antigens with potential to cause severe alloimmunization include Duffy group A—Fy^a, MNS, and Kidd—Jk^a (de Hass, 2015; Moise, 2008). In most cases, sensitization to a minor antigen results from an incompatible blood transfusion. However, if an IgG red cell antibody is detected and there is any doubt as to its significance, the pregnancy should be evaluated for hemolytic disease.

Only a few blood group antigens pose *no* fetal risk. Lewis antibodies—Le^a and Le^b—are cold agglutinins, as are I antibodies. They are predominantly IgM and are not expressed on fetal red cells (American College of Obstetricians and Gynecologists, 2019a). Another antibody that does not cause fetal hemolysis is Duffy group B—Fy^b.

Kell Alloimmunization. Approximately 90 percent of non-Hispanic white Americans and up to 98 percent of African Americans are Kell antigen negative. Kell type is not routinely determined. Transfusion history is important, as nearly 90 percent of Kell sensitization cases result from transfusion with Kell-positive blood.

Kell sensitization may develop more rapidly and may be more severe than with sensitization to D and other blood group antigens. This is because Kell antibodies attach to erythrocyte precursors in the fetal bone marrow and thereby impair the normal hemopoietic response to anemia. With fewer erythrocytes produced, there is less hemolysis, and thus severe anemia may not be predicted by the maternal Kell antibody titer.

Slootweg and colleagues (2018) reviewed 93 pregnancies with Kell alloimmunization in which the fetus was confirmed to be Kell-positive. They found that a titer of 1:4 had 100 percent sensitivity, 27 percent specificity, and 60 percent positive predictive value for transfusion requirement in the fetal or neonatal period. More than 50 percent of Kell antigen–positive fetuses ultimately needed transfusions. Given the potential for severe anemia, the American College of Obstetricians and Gynecologists (2019a) has recommended that antibody titers not be used to monitor Kell-sensitized pregnancies.

ABO Blood Group Incompatibility

Incompatibility for the major blood group antigens A and B is the most common cause of hemolytic disease in newborns, but it does not cause appreciable hemolysis in the fetus. This is because most anti-A and anti-B antibodies are IgM types and do not cross the placenta. Also, fetal red cells have fewer A and B antigenic sites than adult cells and are thus less immunogenic. Approximately 20 percent of newborns have ABO blood

group incompatibility, although only 5 percent are affected clinically. In such cases, the resulting anemia is typically mild.

The condition differs from CDE incompatibility in several respects. First, ABO incompatibility is often seen in firstborn neonates, unlike sensitization to other blood group antigens. This is because most group O women have developed anti-A and anti-B isoagglutinins before pregnancy from exposure to bacteria displaying similar antigens. Additionally, ABO alloimmunization rarely becomes more severe in successive pregnancies. Fetal surveillance and early delivery are not indicated in pregnancies with prior ABO incompatibility. Postnatally however, neonates are evaluated for hyperbilirubinemia, which may require treatment with phototherapy or occasionally transfusion (Chap. 33, p. 606).

Management of the Alloimmunized Pregnancy

Of fetuses from D-alloimmunized pregnancies, 25 to 30 percent will have mild to moderate hemolytic anemia, and up to 25 percent have anemia severe enough to cause hydrops (Tannirandorn, 1990). If alloimmunization is detected and the titer is below the critical value, the titer is generally repeated every 4 weeks for the duration of the pregnancy (American College of Obstetricians and Gynecologists, 2019a). In any pregnancy in which the antibody titer has reached a critical value, there is no benefit to repeating the titer. The pregnancy is at risk even if the titer drops, and further evaluation is required. Similarly, if a prior pregnancy was complicated by alloimmunization, the pregnancy is considered at risk regardless of titer.

Fetal Risk Assessment

The presence of anti-D antibodies reflects maternal sensitization but does not indicate whether the fetus is D-positive or D-negative. Up to 40 percent of D-negative pregnant women carry a D-negative fetus. If a woman is sensitized from a prior pregnancy, her antibody titer may rise during the current pregnancy even if the current fetus is D-negative because of an *amnestic response.* In a non-Hispanic white couple in which the woman is D-negative, there is an 85-percent chance that the man is D-positive. However, there is a 60-percent likelihood that he is heterozygous at the D-locus, and only half of his children will be at risk for hemolytic disease.

Initial evaluation of alloimmunization begins with determining the paternal erythrocyte antigen status. *Provided that paternity is certain*, if the father is negative for the red cell antigen to which the mother is sensitized, the pregnancy is not at risk. A prior blood transfusion may be the cause of alloimmunization to a red cell antigen other than D. In a D-alloimmunized pregnancy in which the father is D-positive, it is helpful to determine paternal zygosity for the D antigen using DNA-based analysis. If the father is heterozygous—or if paternity is not known—the woman should be offered assessment of fetal genotype. Traditionally, this was done with amniocentesis and PCR testing of uncultured amniocytes, which has a positive predictive value of 100 percent and negative predictive value of approximately 97 percent (Van den Veyver, 1996). Fetal testing for other antigens—such as E/e, C/c, Duffy, Kell, Kidd, and M/N—also is available with this method. Chorionic villus sampling is not recommended because of greater risk for fetomaternal hemorrhage and subsequent worsening of alloimmunization (American College of Obstetricians and Gynecologists, 2019a).

Noninvasive fetal D genotyping has been performed using cell-free DNA (cfDNA) from maternal plasma (Chap. 17, p. 335). The reported sensitivity exceeds 99 percent, the specificity exceeds 95 percent, and positive or negative predictive values are similarly very high (Johnson, 2017; Moise, 2016; Pazourkova, 2021). Fetal D genotyping with cfDNA is routinely used in parts of Europe but is not yet a widely used clinical tool in the United States (American College of Obstetricians and Gynecologists, 2019a). Two potential indications for cfDNA use in D-negative pregnant women are: (1) in the setting of D alloimmunization, testing can identify fetuses who are also D-negative and do not require anemia surveillance, and (2) in women *without* D alloimmunization, anti-D immune globulin might be withheld if the fetus is D negative. In the case of the latter, the American College of Obstetricians and Gynecologists (2019b) does not recommend routine cfDNA screening in D-negative pregnancies until it has been demonstrated to be cost-effective.

Management of the alloimmunized pregnancy typically consists of maternal antibody titer surveillance followed by ultrasound monitoring of the fetal MCA peak systolic velocity if a critical antibody titer is reached. As noted earlier (p. 354), pregnancies with Kell alloimmunization often receive ultrasound surveillance regardless of titer. Fetal blood sampling is generally performed if the MCA peak systolic velocity exceeds the threshold for severe anemia, with plan for concurrent intrauterine transfusion as needed. Spectrophotometric analysis of amniotic fluid bilirubin, also known as the ΔOD_{450} test, is no longer recommended (Society for Maternal-Fetal Medicine, 2015a).

Recent efforts have focused on use of maternal intravenous immunoglobulin (IVIG) therapy to postpone the initial intrauterine transfusion to beyond 20 weeks in severely affected pregnancies (Maisonneuve, 2021). Its mechanism of action is unclear, but IVIG therapy has been reported to delay need for transfusion by an average of 3 weeks and to lower the risk for hydrops (Zwiers, 2018).

Middle Cerebral Artery Doppler Velocimetry. Serial measurement of the peak systolic velocity of the fetal MCA is the recommended test to detect fetal anemia (Society for Maternal–Fetal Medicine, 2015a). The anemic fetus shunts blood preferentially to the brain to maintain adequate oxygenation. The velocity rises because of increased cardiac output and decreased blood viscosity. Measurement technique is discussed in Chapter 14 (p. 262).

In a landmark study, Mari and coworkers (2000) measured the MCA peak systolic velocity serially in 111 fetuses at risk for anemia and in 265 normal control fetuses. The threshold value of 1.5 multiples of the median (MoM) for gestational age correctly identified all fetuses with moderate or severe anemia. This provided a sensitivity of 100 percent, with a false-positive rate of 12 percent.

MCA peak systolic velocity is followed serially, and values are plotted on a curve like the one shown in Figure 18-1.

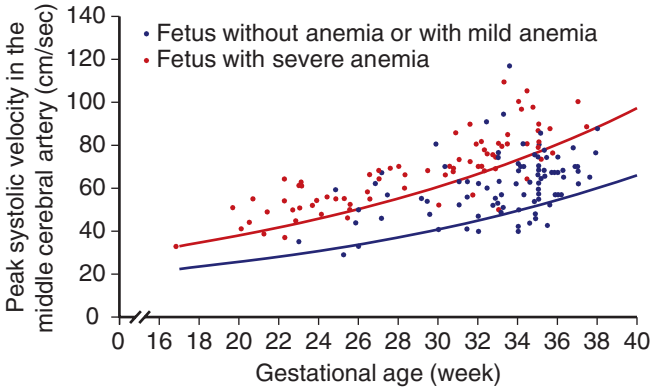

FIGURE 18-1 Doppler measurements of the peak systolic velocity in the middle cerebral artery (MCA) in 165 fetuses at risk for severe anemia. The blue line indicates the median peak systolic velocity in normal pregnancies, and the red line shows 1.5 multiples of the median. (Reproduced with permission from Oepkes D, Seaward PG, Vandenbussche et al: Doppler ultrasonography versus amniocentesis to predict fetal anemia, N Engl J Med. 2006 Jul 13;355(2):156–164.)

If the velocity is between 1.0 and 1.5 MoM and the slope is rising—such that the value is approaching 1.5 MoM—MCA Doppler surveillance is generally performed at least weekly. The false-positive rate of MCA peak systolic velocity increases significantly beyond 34 weeks' gestation and stems from the normal rise in cardiac output that develops at this gestational age (Moise, 2008; Zimmerman, 2002). At Parkland Hospital, MCA peak systolic velocity is not measured beyond 35 weeks, but ultrasound evaluation for hydrops is performed as needed.

Fetal Blood Transfusion

If the MCA peak systolic velocity exceeds 1.5 MoM or if hydrops develops and anemia is the leading etiology, fetal blood sampling and intrauterine transfusion should be considered. Fetal transfusion is typically performed prior to 34 to 35 weeks' gestation (Society for Maternal-Fetal Medicine, 2015a). Later in gestation, the benefits of transfusion may be outweighed by the risks of delaying delivery. Transfusion is most commonly intravascular. However, the umbilical vein may be too narrow in the early second trimester to readily permit needle entry, and severe hemolysis may necessitate intraperitoneal fetal transfusion. In the setting of hydrops, peritoneal absorption may be impaired, and some prefer to transfuse into both the fetal peritoneal cavity and umbilical vein.

Transfusion is generally recommended only if the fetal hematocrit is <30 percent (Society for Maternal-Fetal Medicine, 2015a). If hydrops has developed, the hematocrit is usually 15 percent or lower. The red cells transfused are type O, D-negative, cytomegalovirus-negative, packed to a hematocrit of approximately 80 percent to prevent volume overload, irradiated to prevent fetal graft-versus-host reaction, and leukocyte-poor. The fetal–placental volume allows rapid infusion of a relatively large quantity of blood. Before transfusion, a paralytic agent such as vecuronium may be given to the fetus to minimize movement. In a nonhydropic fetus, the target hematocrit is 40 to 50 percent. The volume transfused may be estimated by multiplying the estimated fetal weight in grams by 0.02 for each 10-percent rise in hematocrit needed (Giannina, 1998). In the severely anemic fetus at 18 to 24 weeks' gestation, a smaller volume is transfused initially, and another transfusion may be planned for approximately 2 days later. Subsequent transfusions take place every 2 to 4 weeks, depending on the hematocrit.

The MCA peak systolic velocity threshold for severe anemia is higher following an initial transfusion—1.70 MoM rather than 1.50 MoM (Society for Maternal-Fetal Medicine, 2015a). It is hypothesized that the change in threshold compensates for the contribution of donor cells in the initial transfusion, because the donor cells are from adults and have a smaller mean corpuscular volume. Following transfusion, the fetal hematocrit drops by approximately 1 percent per day. The initial decline may be more rapid if hydrops has developed.

Outcomes. The overall survival rate approximates 95 percent (Zwiers, 2017; Mizuuchi, 2021). Complications include fetal death in 2 percent, need for emergent cesarean delivery in 1 percent, and infection and preterm rupture of membranes in 0.3 percent each, respectively. The stillbirth rate exceeds 15 percent if transfusion is required before 20 weeks (Lindenberg, 2013; Zwiers, 2017). For hydropic fetuses, the neonatal survival rate is about 80 percent (Emiroglu, 2020; Van Kamp, 2001). In one series, 95 percent of neonates survived if hydrops resolved following intrauterine transfusion compared with fewer than 40 percent if hydrops persisted (Van Kamp, 2001).

Lindenberg (2012) reviewed long-term outcomes following intrauterine transfusion in a cohort of more than 450 alloimmunized pregnancies. Alloimmunization was secondary to anti-D in 80 percent, anti-Kell in 12 percent, and anti-c in 5 percent. Approximately a fourth of affected fetuses had hydrops, and more than half also required exchange transfusion in the neonatal period. Among nearly 300 children aged 2 to 17 years who participated in neurodevelopmental testing, fewer than 5 percent had severe impairments.

■ Prevention of Anti-D Alloimmunization

Anti-D immune globulin has been used for more than five decades to prevent D alloimmunization. Unfortunately, 50 percent of women around the world who would benefit from anti-D immune globulin do not receive it (Pegoraro, 2020). In countries without access, up to 10 percent of D-negative pregnancies are complicated by hemolytic disease of the fetus and newborn (Zipursky, 2015). With immunoprophylaxis, however, the alloimmunization risk may be reduced to <0.2 percent. Despite long-standing and widespread use, its mechanism of action is not completely understood.

Fetomaternal hemorrhage at delivery accounts for as many as 90 percent of alloimmunization cases. Routine postpartum administration of anti-D immune globulin to at-risk pregnancies within 72 hours of delivery lowers the alloimmunization rate by 90 percent (Bowman, 1985). Additionally, provision of anti-D immune globulin at 28 weeks' gestation reduces the third-trimester alloimmunization rate from approximately 2 percent to 0.1 percent (Bowman, 1988). *Whenever there is doubt whether to give anti-D immune globulin, it should be given.* If not needed, it will not cause harm, but failure to provide it when needed may have severe consequences.

Anti-D immune globulin is derived from human plasma donated by individuals with high-titer anti-D immunoglobulin D antibodies. Formulations prepared by cold ethanol fractionation and ultrafiltration must be administered intramuscularly because they contain plasma proteins that could result in anaphylaxis if given intravenously. Formulations prepared using ion exchange chromatography may be administered either intramuscularly or intravenously, which is relevant when treating significant fetomaternal hemorrhage. Both preparation methods effectively remove viral particles, including hepatitis and human immunodeficiency viruses. Depending on the preparation, the half-life of anti-D immune globulin ranges from 16 to 24 days, which is why it is given both in the third trimester and following delivery. The standard intramuscular dose of anti-D immune globulin—300 μg or 1500 IU—will protect the average-sized mother from a fetal hemorrhage of up to 30 mL of fetal whole blood or 15 mL of fetal red cells.

In the United States, anti-D immune globulin is given prophylactically to all D-negative, unsensitized women at approximately 28 weeks' gestation, and a second dose is given after delivery if the newborn is D-positive (American College of Obstetricians and Gynecologists, 2019b). Before the 28-week dose of anti-D immune globulin, repeat antibody screening is recommended to identify individuals who have become alloimmunized (American Academy of Pediatrics, 2017). Following delivery, anti-D immune globulin should be given within 72 hours. Recognizing that 40 percent of neonates born to D-negative women are also D negative, administration of immune globulin is recommended only after the newborn is confirmed to be D positive (American College of Obstetricians and Gynecologists, 2019b). If immune globulin is inadvertently not administered following delivery, it should be given as soon as the omission is recognized, because there may be some protection up to 28 days postpartum (Bowman, 2006). Anti-D immune globulin is also administered after pregnancy-related events that could result in sensitization (see Table 18-2). In the first trimester, smaller doses of 50 or 120 μg may be suitable, as discussed in Chapters 11 and 12 (p. 203 and 221).

Anti-D immune globulin may produce a weakly positive—1:1 to 1:4—indirect Coombs titer in the mother. This is harmless and should not be confused with development of alloimmunization. Additionally, as the body mass index increases above 27 to 40 kg/m^2, serum antibody levels decrease by 30 to 60 percent and may be less protective (MacKenzie, 2006; Woelfer, 2004). D-negative women who receive other types of blood products—including platelet transfusions and plasmapheresis—also are at risk of becoming sensitized, and this can be prevented with anti-D immune globulin. Rarely, a small amount of antibody crosses the placenta and results in a weakly positive direct Coombs test in cord and infant blood. Despite this, passive immunization does not cause significant fetal or neonatal hemolysis.

In 2 to 3 per 1000 pregnancies, the volume of fetomaternal hemorrhage may exceed 30 mL of whole blood (American College of Obstetricians and Gynecologists, 2019b). A single dose of anti-D immune globulin would be insufficient in such situations. If additional anti-D immune globulin is considered only for women with risk factors such as those shown in Table 18-2, *half* of those who require additional immune globulin may be missed. For this reason, all D-negative women should be screened at delivery, typically with a rosette test, followed by quantitative testing if indicated (American College of Obstetricians and Gynecologists, 2019b).

The rosette test is a qualitative test that identifies whether fetal D-positive cells are present in the circulation of a D-negative woman. A sample of maternal blood is mixed with anti-D antibodies that coat any D-positive fetal cells present in the sample. Indicator red cells bearing the D-antigen are then added, and rosettes form around the fetal cells as the indicator cells attach to them by the antibodies. Thus, if rosettes are visualized, there are fetal D-positive cells in that sample. In the setting of D incompatibility, or any time a large fetomaternal hemorrhage is suspected—regardless of antigen status, a Kleihauer-Betke test or flow cytometry test are used. These are discussed on page 358.

The dosage of anti-D immune globulin is calculated from the estimated volume of the fetal-to-maternal hemorrhage, as described on page 358. One 300-μg dose is given for each 15 mL of fetal red cells or 30 mL of fetal whole blood to be neutralized. If using an intramuscular preparation of anti-D immune globulin, no more than five doses may be given in a 24-hour period. If using an intravenous preparation, two ampules—totaling 600 μg—may be given every 8 hours. A positive indirect Coombs test or the presence of circulating fetal cells on a rosette test demonstrate that the dose was sufficient.

Serological Weak D Phenotypes

Formerly called *D*^{u}, these are the most common antigenic D variants in the United States and Europe (American College of Obstetricians and Gynecologists, 2019a). Serological weak D phenotypes have been further refined into two general categories using molecular analysis to complete RHD genotyping. *Molecular weak D phenotypes* carry reduced numbers of intact D antigens on the red cell surface. *Partial D types* have protein deletions associated with abnormal D antigens that lack epitopes (Sandler, 2017).

Many individuals who test positive for weak D have weak D phenotypes 1, 2, or 3. These phenotypes may be managed as if D-positive. The pregnancy is not considered at risk for alloimmunization, and thus anti-D immune globulin is not needed (Sandler 2015, 2017). In contrast, individuals with partial D antigens may be at risk for D-sensitization and do require immune globulin. Molecular RHD genotyping has been suggested for pregnant women with weak D phenotype, but cost-benefit analysis of this strategy is presently lacking (American College of Obstetricians and Gynecologists, 2019b). *If molecular genetic testing has not been performed in those with serologic weak D phenotype, D immunoprophylaxis should be administered.*

FETOMATERNAL HEMORRHAGE

A small amount of fetomaternal bleeding likely occurs in all pregnancies and may be sufficient to provoke an antigen-antibody reaction in two thirds. As shown in Figure 18-2, the incidence increases with advancing gestation and with the volume of fetal blood in the maternal circulation (Choavaratana, 1997).

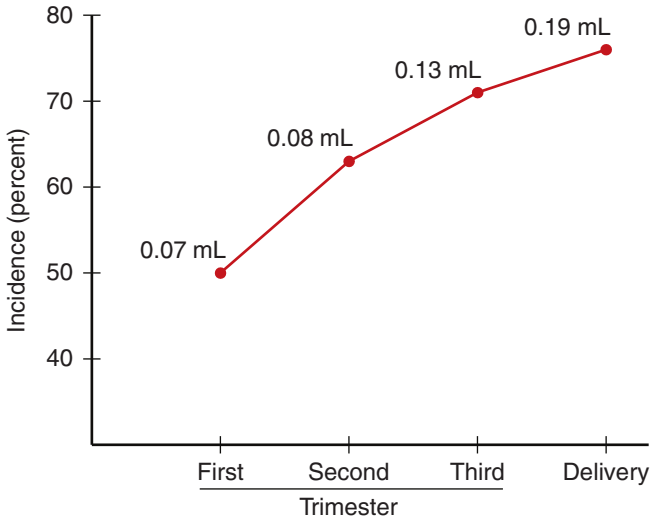

FIGURE 18-2 Incidence of fetomaternal hemorrhage during pregnancy. The numbers at each data point represent total volume of fetal blood estimated to have been transferred into the maternal circulation.

The prevalence of fetomaternal bleeding of at least 30 mL is estimated to be 3 events per 1000 pregnancies (Wylie, 2010). Fortunately, frank hemorrhage is rare. In one series of more than 30,000 pregnancies, fetomaternal hemorrhage ≥150 mL complicated 1 in 2800 births (de Almeida, 1994).

Selected causes of fetomaternal hemorrhage are shown in Table 18-2. With significant hemorrhage, the most common presenting complaint is decreased fetal movement (Bellussi, 2017; Wylie, 2010). A sinusoidal fetal heart rate pattern is infrequently seen but warrants immediate evaluation (Chap. 24, p. 451). Sonography may demonstrate elevated MCA peak systolic velocity, and indeed this is reported to be the most accurate predictor (Bellusi, 2017; Wylie, 2010). Hydrops is an ominous finding. If the MCA peak systolic velocity is elevated or hydrops is identified, urgent fetal transfusion or delivery should be considered. In more than 80 percent of cases, no etiology of the fetomaternal hemorrhage is identified.

One limitation of quantitative tests for fetal cells in the maternal circulation is that they do not provide information regarding the timing or chronicity of hemorrhage (Wylie, 2010). Anemia that develops gradually, as with alloimmunization, is generally better tolerated by the fetus than acute anemia. Chronic anemia may not produce fetal heart rate abnormalities until the fetus is moribund. In contrast, significant acute hemorrhage may result in profound fetal neurological impairment from cerebral hypoperfusion, ischemia, and infarction. In some cases, fetomaternal hemorrhage is identified during stillbirth evaluation (Chap. 35, p. 325).

■ Hemorrhage Quantification

Estimating the volume of fetomaternal hemorrhage is needed to calculate the appropriate dose of anti-D immune globulin if the woman is D-negative, and it may also influence obstetrical management. The most commonly used quantitative test for fetal red cells in the maternal circulation is the acid elution or

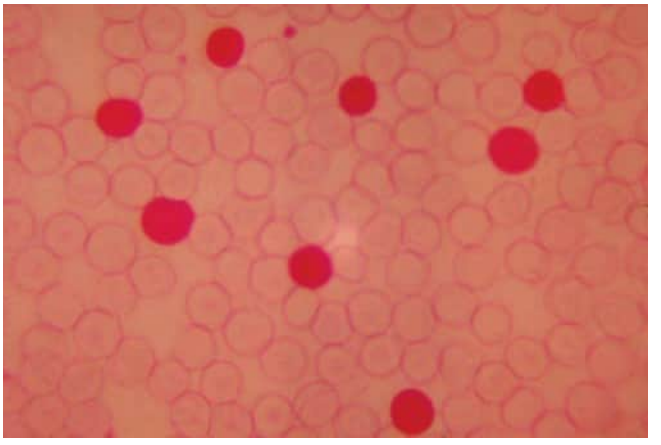

FIGURE 18-3 Kleihauer-Betke test demonstrating massive fetomaternal hemorrhage. After acid-elution treatment, fetal red cells rich in hemoglobin F stain darkly, whereas maternal red cells with only very small amounts of hemoglobin F stain lightly.

Kleihauer-Betke (KB) test (Kleihauer, 1957). Fetal erythrocytes contain hemoglobin F, which is more resistant to acid elution than hemoglobin A. Following exposure to acid, only fetal hemoglobin remains. Therefore, after staining, the fetal erythrocytes appear red and adult erythrocytes appear as "ghosts" (Fig. 18-3). The fetal cells are then counted and expressed as a percentage of adult cells. The fetal blood volume involved in the fetomaternal hemorrhage may be calculated using the following formula:

$$\text{Fetal blood volume} = \frac{\text{MBV} \times \text{maternal Hct} \times \%\ \text{fetal cells in KB test}}{\text{newborn Hct}}$$

For a pregnant woman of normal size who is normotensive and has reached full-term, the maternal blood volume (MBV) may be estimated as 5000 mL. Thus, in a woman with a hematocrit of 35 percent and whose fetus has a hematocrit of 50 percent, the calculation for a KB test demonstrating staining of 1.7 percent of sample cells is:

$$\text{Fetal blood volume} = \frac{5000 \times 0.35 \times 0.017}{0.5} = 60\ \text{mL}$$

The fetal-placental blood volume at term approximates 125 mL/kg. For a 3000-g fetus, that would equate to 375 mL. Thus, this fetus lost approximately 15 percent (60 ÷ 375 mL) of the fetal-placental volume. Assuming the hematocrit is 50 percent in a term fetus, this 60 mL of whole blood represents 30 mL of red cells lost into the maternal circulation. A loss of this magnitude should be well tolerated hemodynamically but would require two 300-μg doses of anti-D immune globulin to prevent alloimmunization. A more precise method to estimate the maternal blood volume includes a calculation based on the maternal height, weight, and anticipated physiological maternal blood volume accrual (Table 42-1, p. 732).

The KB test is labor intensive. There are also two scenarios in which the KB may be inaccurate: (1) maternal hemoglobinopathies in which the fetal hemoglobin level is elevated, such

as β-thalassemia, and (2) at or near term, because the fetus may already be producing hemoglobin A.

Another method of quantifying fetomaternal hemorrhage is with flow cytometry, which uses monoclonal antibodies to hemoglobin F or to the D antigen and then measures the degree of fluorescence (Chambers, 2012; Welsh, 2016). Flow cytometry is an automated test that can analyze a greater number of cells than the KB test. It is also unaffected by maternal levels of fetal hemoglobin and by fetal levels of hemoglobin A. Flow cytometry has been reported to be more sensitive and accurate than the KB test, however, it uses specialized technology not routinely available in many hospitals (Chambers, 2012; Corcoran, 2014; Fernandes, 2007).

FETAL THROMBOCYTOPENIA

Alloimmune Thrombocytopenia

This is also referred to as *fetal and neonatal alloimmune thrombocytopenia (FNAIT)*. Alloimmune thrombocytopenia (AIT) is the most common cause of severe thrombocytopenia among term newborns, with a frequency of 1 to 2 cases per 1000 births (Kamphuis, 2010; Pacheco, 2013; Risson, 2012). FNAIT is caused by maternal alloimmunization to paternally inherited fetal platelet antigens. Maternal antiplatelet antibodies cross the placenta in a manner similar to red cell alloimmunization (p. 352). Unlike *immune thrombocytopenia*, the maternal platelet count is normal with FNAIT. And, unlike anti-D alloimmunization, severe sequelae may affect the *initial* at-risk pregnancy.

Maternal platelet alloimmunization against human platelet antigen-1a (HPA-1a) accounts for 80 to 90 percent of cases and is associated with the greatest severity (Bussel, 1997; Knight, 2011; Tiller, 2013). This is followed in order of frequency by alloimmunization against HPA-5b, HPA-1b, and HPA-3a. Alloimmunization to other antigens accounts for only 1 percent of reported cases.

Approximately 85 percent of non-Hispanic white individuals are HPA-1a positive. Two percent are homozygous for HPA-1b and at risk for alloimmunization. However, only 10 percent of these women produce antiplatelet antibodies when carrying an HPA-1a fetus. Approximately a third of affected fetuses or neonates will develop severe thrombocytopenia, and 10 to 20 percent with severe thrombocytopenia sustain an intracranial hemorrhage (ICH) (Kamphuis, 2010). As a result, population-based screening studies have identified one case of FNAIT-associated ICH per 25,000 to 60,000 pregnancies (Kamphuis, 2010; Knight, 2011).

FNAIT has a spectrum of presentation. Neonatal thrombocytopenia may be an incidental finding, the newborn may manifest petechiae, or the fetus or neonate may develop devastating ICH. Of 600 pregnancies with FNAIT identified through a large international registry, fetal or neonatal ICH complicated just 7 percent of cases (Tiller, 2013). Hemorrhage affected the first-born child in 60 percent and occurred before 28 weeks' gestation in half. A third of affected children died soon after birth, and 50 percent of survivors had severe neurological disabilities.

Bussel and coworkers (1997) evaluated fetal platelet counts before therapy in 107 fetuses with FNAIT. Thrombocytopenia severity was predicted by a prior sibling with perinatal ICH. Fifty percent had an initial platelet count <20,000/μL. And, among those in whom the initial platelet count was >80,000/μL, it dropped by at least 10,000/μL per week in the absence of therapy.

Diagnosis and Management

AIT is typically diagnosed following delivery of a neonate with severe and unexplained thrombocytopenia to a woman whose platelet count is normal. Rarely, the diagnosis is ascertained after identifying fetal ICH. The condition recurs in 70 to 90 percent of subsequent pregnancies, is often severe, and usually develops earlier with each successive pregnancy. Traditionally, fetal blood sampling was performed to detect fetal thrombocytopenia and to tailor therapy. Platelets were transfused if the fetal platelet count was <50,000/μL. The reported rate of procedure-related complications exceeds 10 percent (Winkelhorst, 2017). For this reason, most favor empirical treatment with IVIG instead (Berkowitz, 2006; Pacheco, 2011).

Therapy may be stratified according to whether a prior affected pregnancy was complicated by perinatal ICH, and if so, at what gestational age (Table 18-3) (Pacheco, 2011). Pioneering work by Bussel (1996) and Berkowitz (2006) and their colleagues demonstrated the efficacy of such treatment. In one series of 50 pregnancies with fetal thrombocytopenia secondary to FNAIT, IVIG raised the platelet count by approximately 50,000/μL, and no fetus developed ICH (Bussel, 1996). Among pregnancies at particularly high risk, which was based on a platelet count <20,000/μL or a sibling with FNAIT-associated ICH, the addition of corticosteroids to IVIG therapy was associated with a rise in platelet count in 80 percent of cases (Berkowitz, 2006). However, a systematic review identified no consistent benefit of corticosteroid treatment compared with IVIG therapy alone (Winkelhorst, 2017). Thus, corticosteroid therapy is somewhat controversial. Cesarean delivery is generally recommended at or near term.

Immune Thrombocytopenia

Also known as immune or idiopathic thrombocytopenic purpura (ITP), this autoimmune disorder is characterized by antiplatelet IgG antibodies that attack platelet glycoproteins. The antibodies may cross the placenta and cause fetal thrombocytopenia. Maternal ITP is discussed in Chapter 59 (p. 1059).

Fetal thrombocytopenia from maternal ITP is usually mild. However, neonatal platelet levels may fall rapidly after birth and nadir at 48 to 72 hours of life. Neither the maternal platelet count, identification of antiplatelet antibodies, nor treatment with corticosteroids effectively predicts fetal or neonatal platelet counts (Hachisuga, 2014). Importantly, fetal platelet counts are usually adequate to allow vaginal delivery without an increased risk of ICH. In a review of more than 400 pregnancies with ITP, there was no case of fetal or neonatal ICH and no infant with any central nervous system abnormality (Wyszynski, 2016). Fetal blood sampling is not recommended

TABLE 18-3. Fetal-Neonatal Alloimmune Thrombocytopenia (FNAIT) Treatment Recommendations

Risk Group	Criteria	Suggested Management
1	Prior fetus or newborn with ICH, but no maternal anti-HPA antibody identified	Maternal anti-HPA antibody screening and cross-matching with paternal platelets at 12, 24, and 32 weeks' gestation; no treatment for negative test results
2	Prior fetus or newborn with thrombocytopenia and maternal anti-HPA antibody, but no ICH	Beginning at 20 wks: IVIG 1g/kg/wk and prednisone 0.5 mg/kg/d ***or*** IVIG 2 g/kg/wk Beginning at 32 wks: IVIG 2 g/kg/wk and prednisone 0.5 mg/kg/d Continue until delivery
3	Prior fetus with 3rd-trimester ICH or prior newborn with ICH, and maternal anti-HPA antibody	Beginning at 12 wks: IVIG 1 g/kg/wk Beginning at 20 wks: either increase IVIG to 2 g/kg/wk ***or*** add prednisone 0.5 mg/kg/d Beginning at 28 wks: IVIG 2 g/kg/wk ***and*** prednisone 0.5 mg/kg/d Continue until delivery
4	Prior fetus with ICH before the 3rd trimester and maternal anti-HPA antibody	Beginning at 12 wks: IVIG 2 g/kg/wk Beginning at 20 wks: add prednisone 1 mg/kg/d Continue both until delivery

HPA = human platelet antigen; ICH = intracerebral hemorrhage; IVIG = intravenous immunoglobulin G.

(Neunert, 2011). Mode of delivery is based on standard obstetrical indications.

HYDROPS FETALIS

This phrase has its origins in Middle English, Latin, and Greek. The condition was described by Ballantyne in 1892 as general dropsy, that is, edema, of the fetus (Kaiser, 1971). Hydrops can be a manifestation of severe illness from a wide variety of etiologies (Table 18-4) (Bellini, 2015).

Hydrops is diagnosed by identifying two or more fetal effusions—pleural, pericardial, or ascites—or one effusion plus anasarca (Fig. 18-4). Sonographically measured skin thickness of >5 mm constitutes edema or anasarca. Placentomegaly is defined as placental thickness ≥4 cm in the second trimester or ≥6 cm in the third trimester (Bellini, 2009; Society for Maternal–Fetal Medicine, 2015b). As hydrops progresses in severity, anasarca is an invariable feature and is usually accompanied by placentomegaly and hydramnios.

If found in association with red cell alloimmunization, hydrops is termed *immune*, otherwise, it is *nonimmune*. Immune and nonimmune hydrops are postulated to share several physiological abnormalities. The precise pathogenesis remains unknown but is likely multifactorial. As shown in Figure 18-5, these include decreased colloid oncotic pressure, increased hydrostatic or central venous pressure, and enhanced vascular permeability.

Immune Hydrops

This condition results from transplacental passage of maternal antibodies that destroy fetal red cells. The resultant anemia stimulates marrow erythroid hyperplasia and extramedullary hematopoiesis in the spleen and liver (see Fig. 18-5). The latter likely causes portal hypertension and impaired hepatic protein synthesis, which lowers plasma oncotic pressure (Nicolaides, 1985). Fetal anemia may also raise central venous pressure (Weiner, 1989). Tissue hypoxia from anemia may increase capillary permeability, such that fluid collects in the fetal thorax, abdominal cavity, and/or subcutaneous tissue.

The incidence of immune hydrops has decreased dramatically with the advent of anti-D immune globulin and with use of MCA Doppler to aid anemia detection. Only severe anemia results in immune hydrops. Mari and colleagues (2000) reviewed 70 pregnancies with fetal anemia from red cell alloimmunization and found that all with immune hydrops had hemoglobin values *<5 g/dL*. As discussed on page 356, immediate fetal blood transfusion may be lifesaving.

Nonimmune Hydrops

At least 90 percent of cases of hydrops are nonimmune (Bellini, 2012). The prevalence approximates 1 case per 1500 second-trimester pregnancies (Heinonen, 2000). The number of specific disorders that can lead to nonimmune hydrops is extensive. Etiologies and the proportion of births within each hydrops category from a review of more than 6700 affected pregnancies are summarized in Table 18-4 (Bellini, 2015).

A cause is identified in approximately 60 percent prenatally and in up to 80 percent postnatally (Bellini, 2009, 2015; Santo, 2011). Of prenatally diagnosed cases, aneuploidy accounts for approximately 20 percent, cardiovascular abnormalities for 15 percent, and infections for 14 percent—the most common of which is parvovirus B19 (Santo, 2011; Sileo, 2020; Sparks, 2019). In multifetal gestations, twin-twin transfusion syndrome is the most frequent cause (Yeom, 2015). Fetal deaths and stillbirths are common with nonimmune hydrops. Overall, only 40 percent of affected pregnancies result in a liveborn

TABLE 18-4. Categories and Etiologies of Nonimmune Hydrops Fetalis

Category	Percent[a]
Cardiovascular Structural defects: Ebstein anomaly, tetralogy of Fallot with absent pulmonary valve, hypoplastic left or right heart, premature closure of ductus arteriosus, arteriovenous malformation (vein of Galen aneurysm) Cardiomyopathies Tachyarrhythmias Bradycardia, as may occur in heterotaxy syndrome with endocardial cushion defect or with anti-Ro/La antibodies	21
Chromosomal Turner syndrome (45,X), triploidy, trisomies 21, 18, and 13	13
Hematological Hemoglobinopathies, such as α4-thalassemia Erythrocyte enzyme and membrane disorders Erythrocyte aplasia/dyserythropoiesis Decreased erythrocyte production (myeloproliferative disorders) Fetomaternal hemorrhage	10
Lymphatic Abnormalities Cystic hygroma, systemic lymphangiectasis, pulmonary lymphangiectasis	8
Infections Parvovirus B19, syphilis, cytomegalovirus, toxoplasmosis, rubella, enterovirus, varicella, herpes simplex, coxsackievirus, listeriosis, leptospirosis, Chagas disease, Lyme disease	7
Syndromic Arthrogryposis multiplex congenita, lethal multiple pterygium, congenital lymphedema, myotonic dystrophy type I, Neu-Laxova, Noonan, and Pena-Shokeir syndromes	5
Thoracic Abnormalities Cystic adenomatoid malformation Pulmonary sequestration Diaphragmatic hernia Hydro/chylothorax Congenital high airway obstruction sequence (CHAOS) Mediastinal tumors Skeletal dysplasia with very small thorax	5
Gastrointestinal Meconium peritonitis, gastrointestinal tract obstruction	1
Kidney and Urinary Tract Kidney malformations Bladder outlet obstructions Congenital (Finnish) nephrosis, Bartter syndrome, mesoblastic nephroma	2
Placental, Twin, and Cord Abnormalities Placental chorioangioma, twin-twin transfusion syndrome, twin reversed arterial perfusion sequence, twin anemia polycythemia sequence, cord vessel thrombosis	5
Other Rare Disorders Inborn errors of metabolism: Gaucher disease, galactosialidosis, GM_1 gangliosidosis, sialidosis, mucopolysaccharidoses, mucolipidoses Tumors: sacrococcygeal teratoma, hemangioendothelioma with Kasabach-Merritt syndrome	5
Idiopathic	18

[a]Percentages reflect the proportion within each category from a systematic review of 6775 pregnancies with nonimmune hydrops.

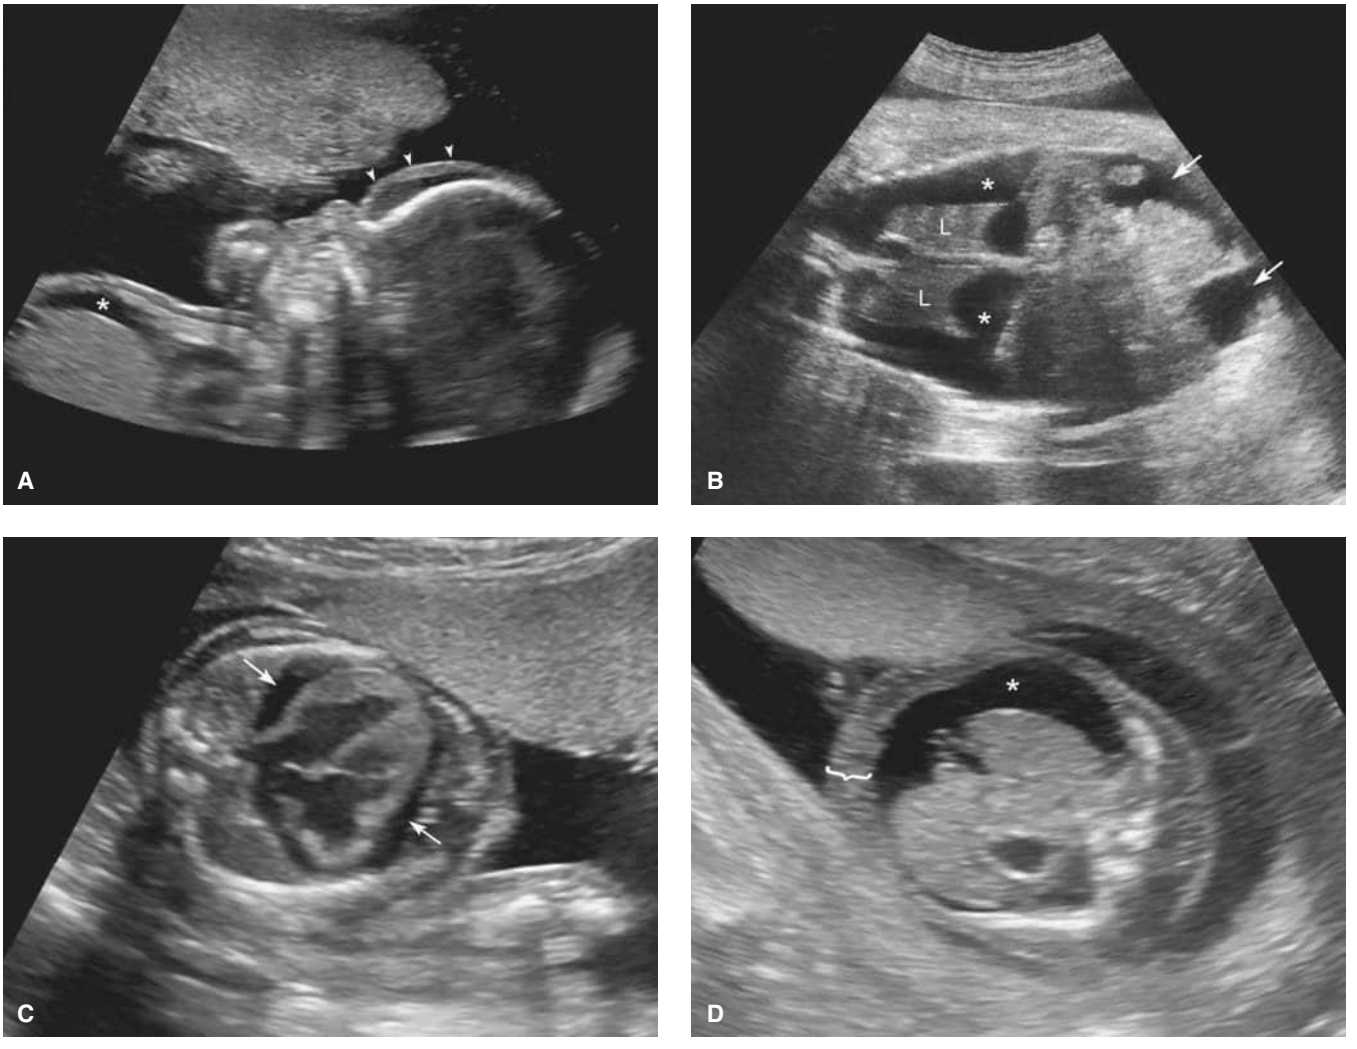

FIGURE 18-4 Sonographic findings that define hydrops. **A.** This profile of a 23-week fetus with nonimmune hydrops secondary to B19 parvovirus infection depicts scalp edema (*arrowheads*) and ascites (*). **B.** This 34-week fetus had hydrops secondary to an arteriovenous malformation in the brain, known as a vein of Galen aneurysm. In this coronal image, prominent pleural effusions (*) outline the lungs (L). Fetal ascites is also present (*arrows*), as is anasarca. **C.** This axial (transverse) image depicts a pericardial effusion (*arrows*) in a 23-week fetus with hydrops from B19 parvovirus infection. The degree of cardiomegaly is impressive, and the ventricular hypertrophy raises concern for myocarditis, which can accompany parvovirus infection. **D.** This axial (transverse) image depicts fetal ascites (*) in a 15-week fetus with hydrops secondary to large cystic hygromas. Anasarca is also seen (*bracket*).

neonate, and of these, the neonatal survival rate is just 50 percent (Nassr, 2018; Yeom, 2015).

Importantly, the etiology of nonimmune hydrops varies according to the gestational age at diagnosis. In a review of 63 pregnancies undergoing genetic testing for hydrops in the first trimester, aneuploidy was the cause in 70 percent (Sileo, 2020). Of cases diagnosed from 14 through 24 weeks, aneuploidy and congenital infection each accounted for 20 percent. When nonimmune hydrops presents before 24 weeks' gestation, the most frequent aneuploidy is 45,X—*Turner syndrome*, and in such cases, the survival rate is <5 percent (Sohan, 2001).

Recent advances in genetic testing have improved the understanding of hydrops cases that were previously considered idiopathic. In a review from the University of California Fetal-Maternal Consortium, whole exome sequencing was studied in 127 cases of unexplained nonimmune hydrops in which traditional genetic testing was uninformative (Sparks, 2020). Nearly 30 percent had a pathogenic genetic variant. The most common etiology was *RASopathies*, and many such cases resulted in Noonan syndrome. It is anticipated that as experience with whole exome sequencing accrues, the diagnostic yield will continue to increase.

Although the prognosis of nonimmune hydrops is guarded, it depends heavily on etiology. In a large series from Thailand and Southern China, α^0-thalassemia is the main cause of nonimmune hydrops. It accounts for 30 to 50 percent of cases and confers an extremely poor prognosis (Liao, 2007; Ratanasiri, 2009; Suwanrath-Kengpol, 2005). In contrast, treatable etiologies such as parvovirus infection, chylothorax, and tachyarrhythmias, which each constituting approximately 10 percent of cases, can result in survival in two thirds of cases with fetal therapy (Sohan, 2001).

Diagnostic Evaluation

Hydrops is readily detected with prenatal sonography (see Fig. 18-5). Imaging and laboratory evaluation may identify

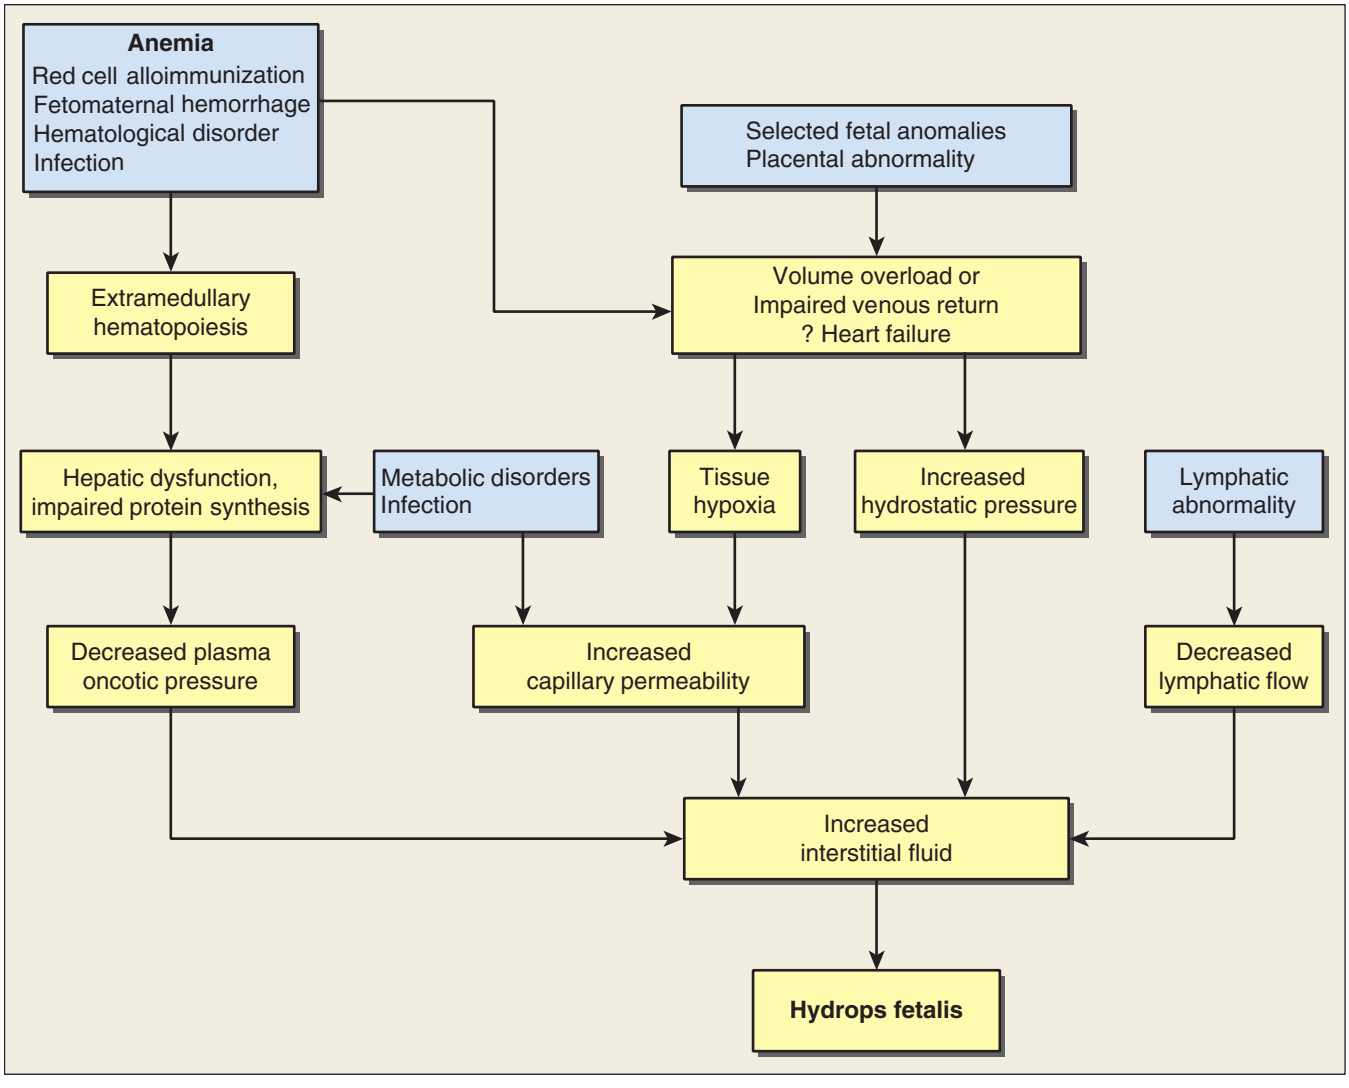

FIGURE 18-5 Proposed pathogenesis of immune and nonimmune hydrops fetalis. (Data from Bellini, 2009; Lockwood, 2009.)

fetal structural abnormalities, arrhythmias, anemia, aneuploidy, placental abnormalities, and complications of monochorionic twinning. Depending on the circumstances, initial evaluation includes the following:

1. Indirect Coombs test to identify alloimmunization
2. Detailed ultrasound examination of the fetus and placenta that includes:
   - A detailed anatomical survey to assess for the structural abnormalities listed in Table 18-4
   - Fetal echocardiography to further evaluate cardiac structure and function
   - MCA Doppler peak systolic velocity to assess for fetal anemia
3. Amniocentesis to obtain samples for chromosomal microarray analysis or karyotyping and for parvovirus B19, cytomegalovirus, and toxoplasmosis testing, as discussed in Chapter 67
4. Kleihauer-Betke test to detect fetomaternal hemorrhage if anemia is suspected, depending on findings and test results
5. Consideration of testing for alpha-thalassemia and/or inborn errors of metabolism.

Whole exome sequencing has significant potential to identify a genetic etiology if the aforementioned evaluation is not informative (Sparks, 2020). Counseling should include anticipated turnaround times, costs, and variants of uncertain significance. It is not recommended for routine use (American College of Obstetricians and Gynecologists, 2020). In addition, because sequencing is generally performed on the fetus and parents, a parent may be identified or suspected to have an unrelated but medically actionable finding, such as a cancer predisposition.

Isolated Effusion or Edema. The initial presentation of hydrops may be as a single effusion or anasarca. Although neither is diagnostic of hydrops, the above evaluation should be considered, and frequent surveillance may be prudent. A pericardial effusion may precede development of hydrops in fetal parvovirus B19 infection (Chap. 67, p. 1191). Similarly, isolated ascites may be the initial finding in fetal parvovirus B19 infection or may result from a gastrointestinal abnormality such as meconium peritonitis. An isolated pleural effusion may represent a chylothorax, which is amenable to prenatal diagnosis, and for which fetal therapy may be lifesaving if hydrops develops (Chap. 19, p. 376). Last, isolated edema, particularly involving

the upper torso or the dorsum of the hands and feet, may be found in Turner or Noonan syndrome or may represent congenital lymphedema syndrome (Chap. 16, p. 314).

Mirror Syndrome

The association between fetal hydrops and the development of maternal edema, in which the mother *mirrors* the fetus, is attributed to Ballantyne. He called the condition *triple edema* because the fetus, mother, and placenta all became edematous. Mirror syndrome has been reported to complicate at least 20 percent of hydrops cases (Chen, 2021). The etiology of the hydrops is not related to development of mirror syndrome. It has been associated with hydrops from D alloimmunization, twin-twin transfusion syndrome, placental chorioangioma, fetal cystic hygroma, Ebstein anomaly, sacrococcygeal teratoma, chylothorax, bladder outlet obstruction, supraventricular tachycardia, vein of Galen aneurysm, and various congenital infections (Braun, 2010).

In a review of more than 50 cases of mirror syndrome, Braun (2010) found that approximately 90 percent of women had edema, 60 percent had hypertension, 40 percent had proteinuria, 20 percent had liver enzyme elevation, and nearly 15 percent had headache and visual disturbances. Based on these findings, it is reasonable to consider mirror syndrome a form of severe preeclampsia (Espinoza, 2006; Midgley, 2000). Others, however, have suggested that it is a separate disease process with hemodilution rather than hemoconcentration (Carbillon, 1997; Livingston, 2007).

Some reports describe the same imbalance of angiogenic and antiangiogenic factors that is observed with preeclampsia, and this suggests a common pathophysiology (Goa, 2013; Hobson, 2020; Llurba, 2012). These findings, which include elevated concentrations of soluble fms-like tyrosine kinase 1 (sFlt-1), decreased placental growth factor (PlGF) levels, and elevation of soluble vascular endothelial growth factor receptor 1 (sVEGFR-1) concentrations, are discussed further in Chapter 40 (p. 694).

In most cases with mirror syndrome, prompt delivery is indicated and followed by resolution of maternal edema and other findings (Braun, 2010). However, in isolated cases of fetal anemia, supraventricular tachycardia, hydrothorax, or bladder outlet obstruction, successful fetal treatment has resulted in resolution of both fetal hydrops and maternal mirror syndrome (Goa, 2013; Livingston, 2007; Llurba, 2012; Midgley, 2000). Normalization of the angiogenic imbalance has also been described following fetal transfusion for parvovirus B19 infection. Fetal therapy for these conditions is reviewed in Chapter 19. Given the parallels to severe preeclampsia, delaying delivery to effect fetal therapy should be considered only with caution. If the maternal condition deteriorates, delivery is recommended.

CHAPTER 19

Fetal Therapy

Innovative treatments developed during the past three decades have dramatically altered the course of selected fetal anomalies and conditions. Over time, fetal interventions have become less invasive, and the number of fetal centers has expanded. The North American Fetal Therapy Network now includes 36 medical centers in the United States and Canada. Some of the fetal abnormalities and conditions amenable to either medical or surgical treatment are presented here. The management of fetal anemia and thrombocytopenia is reviewed in Chapter 18, and treatment of some fetal infections is discussed in Chapters 67 and 68.

MEDICAL THERAPY

Selected medications administered to the pregnant woman are transported across the placenta in concentrations high enough to treat fetal conditions. Pregnancy physiology affects drug concentration, and transfer depends on maternal and placental metabolism (Chap. 8, p. 145).

Arrhythmias

Abnormal fetal cardiac rhythms are grouped into three categories: *tachyarrhythmias*, heart rates >180 beats per minute (bpm); *bradyarrhythmias*, heart rates <110 bpm; and ectopy, typically premature atrial contractions. If a fetal arrhythmia is suspected, M-mode ultrasound, described in Chapter 15 (p. 294), is used to measure the atrial and ventricular rates and to clarify the relationship between atrial and ventricular beats, thereby diagnosing the type of rhythm disturbance.

Premature Atrial Contractions

If the fetal heart rate is normal but the rhythm is irregular, the most common etiology is premature atrial contractions (PACs). These atrial ectopic beats are found in 1 to 2 percent of uncomplicated pregnancies (Hahurij, 2011; Strasburger, 2010). PACs represent immaturity of the cardiac conduction system. They typically resolve later in gestation or in the neonatal period. PACs are usually an isolated finding but may be associated with redundancy of the foramen ovale flap—formerly termed a foramen ovale aneurysm.

When a PAC is conducted, an extra beat is heard with handheld Doppler. However, the premature contraction more commonly arrives at the atrioventricular node during the refractory period. This results in a compensatory pause, which sounds like a dropped beat. M-mode evaluation confirms the diagnosis (Fig. 15-46, p. 295).

PACs may occur as frequently as every other beat, which means that the auscultated fetal heart rate may be as low as 60 to 80 bpm. Known as *blocked atrial bigeminy*, this condition is benign and does not require treatment (Strasburger, 2010). However, monitoring the fetus in labor may be challenging and necessitate cesarean delivery. M-mode ultrasound will differentiate atrial bigeminy from other causes of bradycardia, such as third-degree atrioventricular block.

Up to 2 percent of fetuses with PACs are later found to have *supraventricular tachycardia* (Copel, 2000; Srinivasan, 2008).

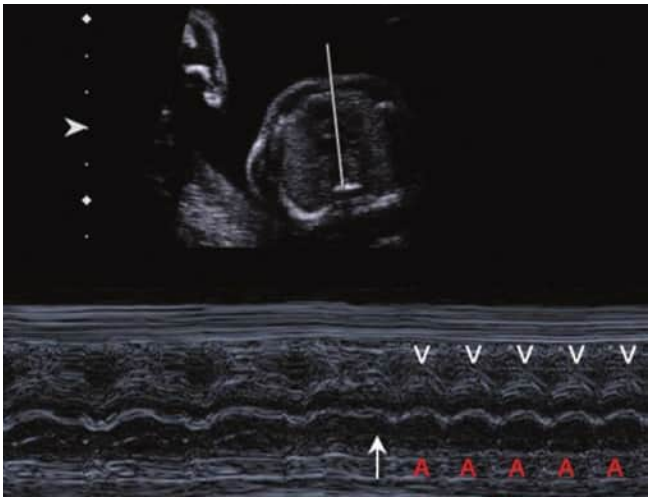

FIGURE 19-1 Supraventricular tachycardia (SVT). This M-mode image at 20 weeks' gestation demonstrates an initially normal fetal heartrate of 150 bpm. Midway through the image (*arrow*), the fetal heart rate suddenly increases to 240 bpm. With SVT, there is one atrial beat (*A*) for each ventricular beat (*V*).

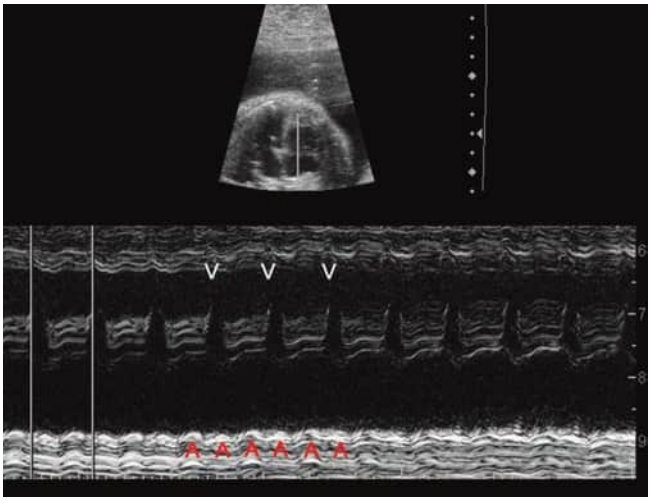

FIGURE 19-2 Atrial flutter. In this M-mode image at 32 weeks' gestation, calipers mark the ventricular rate, which is approximately 220 bpm. There are two atrial beats (*A*) for each ventricular beat (*V*), such that the atrial rate is approximately 440 bpm with 2:1 atrioventricular block.

Given the importance of prompt identification and treatment of supraventricular tachyarrhythmias, pregnancies with PACs are often monitored with fetal heart rate assessment every 1 to 2 weeks until the ectopy resolves. At Parkland Hospital, we find that auscultation with handheld Doppler is sufficient for surveillance.

Tachyarrhythmias

The two most common tachyarrhythmias are supraventricular tachycardia (SVT) and atrial flutter. SVT is characterized by an abrupt increase in the fetal heart rate to 180 to 300 bpm with 1:1 atrioventricular concordance (Fig. 19-1). The typical range is 200 to 240 bpm. SVT may develop secondary to an ectopic focus or to an accessory atrioventricular pathway leading to a reentrant tachycardia. Atrial flutter is characterized by a much higher atrial rate, generally 300 to 500 bpm, with varying degrees of atrioventricular block. As a result, the ventricular rate in a fetus with atrial flutter may range from below normal to approximately 250 bpm (Fig. 19-2). In contrast, fetal *sinus tachycardia* typically presents with a gradual heart rate rise to a rate that is only slightly above normal. With this, readily discernible causes may be maternal fever or hyperthyroidism, or rarely, fetal anemia or infection.

If a fetal tachyarrhythmia is identified, it is important to determine whether it is *sustained*—defined as present for at least 50 percent of the time. It may be necessary to monitor the fetal heart rate for 12 to 24 hours upon initial detection, and then periodically to reassess (Srinivasan, 2008). Unsustained or intermittent tachyarrhythmias may become sustained over time. Although intermittent tachyarrhythmias do not generally require treatment, close fetal surveillance is warranted.

Sustained fetal tachyarrhythmias with ventricular rates exceeding 200 bpm impair ventricular filling to a degree that the risks for developing cardiomyopathy and hydrops are significant. With atrial flutter, lack of coordinated atrioventricular contractions may further compound this risk. Maternal administration of antiarrhythmic agents that cross the placenta may convert the rhythm to normal or may lower the baseline heart rate to forestall heart failure. Therapy can require dosages at the upper end of the therapeutic adult range. Therefore, a maternal electrocardiogram is obtained before and during therapy. Monitoring of the maternal serum level may be necessary, particularly if the dosage requires titration. If medical therapy is successful, the medication is generally continued until delivery.

Antiarrhythmic medications most commonly used include digoxin, flecainide, and sotalol. Their selection depends on the type of tachyarrhythmia and provider experience with the drug. Traditionally, digoxin was the initial preferred treatment, but its placental transfer may be poor in the setting of hydrops. Many centers now use flecainide or sotalol as first-line therapy (Ekiz, 2018; van der Heijden, 2013). A second agent is needed in more than 50 percent of cases (Jaeggi, 2011; O'Leary, 2020; Shah, 2012). With treatment, conversion to a normal rhythm or reduction in heart rate to a normal range occurs in 90 percent, including 80 percent of those with hydrops (Miyoshi, 2019; Ueda, 2018). SVT is more likely than atrial flutter to convert to a normal rhythm. The neonatal survival rate exceeds 90 percent (Ekman-Joelsson, 2015; Miyoshi, 2019; O'Leary, 2020; van der Heijden, 2013).

Bradyarrhythmia

The most common etiology of fetal bradycardia is *congenital heart block*. Approximately 50 percent of cases occur in the setting of a structural cardiac abnormality involving the conduction system. These include *heterotaxy*, in particular *left-atrial isomerism*; *endocardial cushion defect*; and less commonly *corrected transposition of the great vessels* (Srinivasan, 2008). The prognosis of heart block from a structural cardiac anomaly is extremely poor, and fetal loss rates exceed 80 percent (Glatz, 2008; Strasburger, 2010).

In a structurally normal heart, 85 percent of atrioventricular block cases are caused by transplacental passage of maternal

anti-SSA/Ro or anti-SSB/La antibodies (Buyon, 2009). Many of these women have, or subsequently develop, systemic lupus erythematosus or other autoimmune disease (Chap. 62, p. 1113). The risk of third-degree heart block with Ro antibodies is small—only approximately 2 percent. However, the risk may reach 20 percent if a prior infant has been affected. Immune-mediated congenital heart block confers a mortality rate of nearly 20 percent, requires permanent pacing in two thirds of surviving children, and also poses a risk for cardiomyopathy (Brito-Zeron, 2015; Izmirly, 2011). If associated with effusions, bradyarrhythmias, or endocardial fibroelastosis, neonatal status may progressively worsen after birth.

Research has focused on maternal corticosteroid therapy to potentially reverse fetal heart block or to forestall it. In the PR Interval and Dexamethasone (PRIDE) study, a multicenter trial of pregnancies with anti-SSA/Ro antibodies, Friedman and colleagues (2008, 2009) performed weekly fetal echocardiography to assess for development of heart block. Fetal heart block was treated with maternal oral dexamethasone, 4 mg daily. Unfortunately, therapy did not prevent progression from second- to third-degree block, and third-degree atrioventricular block was *irreversible*. In rare cases, there was a potential benefit in reversing first-degree atrioventricular block. However, first-degree block did not generally progress even without treatment. Similarly, a subsequent review of pregnancies with isolated second- or third-degree fetal heart block found that dexamethasone therapy did not affect disease progression, need for pacemaker in the neonatal period, or overall survival rates (Izmirly, 2016). Despite considerable enthusiasm for corticosteroid treatment, a systematic review of more than 700 pregnancies with treated fetal heart block demonstrated no improvement in fetal or neonatal morbidity or mortality rates (Michael, 2019). Thus, we do not recommend dexamethasone use for this indication.

More recent efforts have turned to potential therapy with hydroxychloroquine (Plaquenil), a mainstay of treatment for systemic lupus erythematosus (Chap. 62, p. 1112). In a review of more than 250 women with prior affected children, early treatment with hydroxychloroquine was associated with a significant decrease in recurrence of congenital heart block (Izmirly, 2012). A subsequent clinical trial found that treatment with hydroxychloroquine was associated with a greater than 50-percent reduction in the rate of fetal heart block (Izmirly, 2020). In each of these series, fewer than 8 percent of children from pregnancies treated with hydroxychloroquine experienced heart block. Research in this area is ongoing.

Maternal terbutaline has also been given in small cohorts with either alloimmune- or heterotaxy-mediated fetal heart block in which the fetal heart rate is persistently below 56 bpm. The terbutaline dosage is titrated to a maternal heart rate of 95 to 115 bpm. Fetal heart rate increases of 5 to 10 bpm have been reported, but resolution of hydrops has not been consistently demonstrated (Cuneo, 2007, 2010).

■ Congenital Adrenal Hyperplasia

Several autosomal recessive enzyme deficiencies impair fetal synthesis of cortisol from cholesterol by the adrenal cortex, leading to congenital adrenal hyperplasia (CAH). CAH is the most common etiology of androgen excess in those with 46,XX disorders of sex development (Chap. 3, p. 38). Lack of cortisol stimulates adrenocorticotrophic hormone (ACTH) secretion by the anterior pituitary, overproduction of androstenedione and testosterone, and subsequent virilization of female fetuses. Sequelae may include formation of labioscrotal folds, persistence of a urogenital sinus, or even creation of a penile urethra and scrotal sac (Fig. 15-55, p. 299).

More than 90 percent of CAH cases are caused by 21-hydroxylase deficiency. There are two types: classic and nonclassic. The incidence of classic CAH approximates 1 in 15,000 births worldwide but is higher in selected populations. Among Yupik Eskimos, the reported incidence is 1 in 300 births (Nimkarn, 2016). Of those with classic CAH, 75 percent require postnatal treatment with mineralocorticoids and glucocorticoids to prevent a *salt-wasting adrenal crisis*, which is characterized by hyponatremia, dehydration, hypotension, and even cardiovascular collapse. The remaining 25 percent with classic CAH have the *simple virilizing type* and also require glucocorticoid supplementation. Nonclassic CAH may present with precocious pubarche, hirsutism, or infertility. However, affected individuals also may be asymptomatic. The prevalence of nonclassic CAH approximates 1 case per 200 Caucasians and Ashkenazi Jews in the United States (Hannah-Shmouni, 2017). As discussed in Chapter 32 (p.594), all states mandate newborn screening for CAH.

For more than three decades, dexamethasone has been administered to the pregnant woman to suppress fetal androgen overproduction and either obviate or ameliorate virilization of female fetuses (David, 1984; New, 2012). Prenatal corticosteroid therapy is successful in most cases if initiated early and taken consistently. One metaanalysis found that dexamethasone treatment was associated with reduced virilization. Specifically, the Prader score, which grades genital masculinization on a scale 1 to 5, improved by 2.3 grades (Fernandez-Balselis, 2010). The alternative is consideration of postnatal genitoplasty, which may include clitoroplasty, urogenital sinus surgery, and additional vaginoplasty procedures. In a recent review, 18 percent of children treated with feminizing genitoplasty experienced postoperative complications, and 12 percent required further surgery (Baskin, 2020).

The typical preventive regimen is oral dexamethasone given to the mother at a dosage of 20 μg/kg/d—up to 1.5 mg per day, divided in three doses. The critical period for external genitalia development is 7 to 12 weeks' gestation, and treatment to prevent virilization should be initiated by 9 weeks—*before it is known whether the fetus is* affected. Because this is an autosomal recessive condition, affected females make up only 1 in 8 at-risk conceptions.

Carrier parents are typically identified after the birth of an affected child. Molecular genetic testing is clinically available in such cases and initially uses sequence analysis of the *CYP21A2* gene, which encodes the 21-hydroxylase enzyme (Nimkarn, 2016). If this is uninformative, gene-targeted deletion/duplication analysis is performed, and additional testing such as whole exome sequencing may be considered (Chap. 16, p. 327).

A goal of prenatal diagnosis is to limit dexamethasone exposure in males and in unaffected females. If both parents

are determined to be carriers, prenatal molecular genetic testing may be performed on chorionic villi—at 10 to 12 weeks' gestation—or on amniocytes after 15 weeks. Determination of fetal gender using cell-free DNA (cfDNA) may aid in avoiding dexamethasone treatment. CfDNA sensitivity to detect Y-chromosome sequences is at least 95 percent when performed at or beyond 7 weeks (Devaney, 2011; Hill, 2011). In the research setting, effective cfDNA testing using hybridization probes flanking the *CYP21A2* gene has been reported as early as $5^{6/7}$ weeks' gestation (New, 2014).

Maternal treatment with dexamethasone has become controversial. The Endocrine Society recommends that treatment be given only in the context of research protocols (Speiser, 2018). It further recommends that such protocols incorporate cfDNA screening for the Y-chromosome to avoid treatment of male fetuses. Of note, if therapy is initiated shortly before 9 weeks' gestation, the dose of dexamethasone used is not considered to have significant teratogenic potential because organogenesis of major organs has already taken place (McCullough, 2010). Ongoing concerns focus on the potential effects of either excess *endogenous* androgens or excess *exogenous* dexamethasone on the developing brain. Although maternal dexamethasone has been used for many years to prevent virilization of female fetuses with CAH, long-term safety data are relatively limited.

Congenital Cystic Adenomatoid Malformation

This well-circumscribed lung mass may appear solid and echogenic or may have one or multiple variably sized cysts (Fig. 15-33, p. 288). Lesions with one or more cysts ≥5 mm are termed macrocystic, whereas solid lesions and those with smaller cysts are microcystic (Adzick, 1985). A small subset of microcystic congenital cystic adenomatoid malformations (CCAMs) may demonstrate rapid growth, generally between 18 and 26 weeks' gestation. The mass may become so large that it causes mediastinal shift, which may compromise cardiac output and venous return, leading to hydrops (Cavoretto, 2008).

A CCAM-volume ratio (CVR) has been used to quantify size and risk for hydrops in these severe cases (Crombleholme, 2002). This ratio is an estimate of the CCAM volume using the formula for a prolate ellipse (length × width × height × π/6) divided by the head circumference. In a series of 40 pregnancies with microcystic CCAM, the mean CVR was 0.5 at 20 weeks' gestation, peaked at 1.0 by 26 weeks, and then declined sharply before delivery (Macardle, 2016). With a CVR exceeding 1.6, the risk for hydrops is as high as 60 percent. However, if the initial CVR is below 1.6, CCAM growth resulting in hydrops develops in fewer than 2 percent of cases (Ehrenberg-Buchner, 2013; Peranteau, 2016).

A CVR threshold of 1.0 also may assist counseling. In a series of 62 pregnancies with fetal lung masses, a maximal CVR >1.0 was associated with a 75-percent likelihood that the neonate would be symptomatic (Ehrenberg-Buchner, 2013). However, no fetus with a CVR ≤1.0 subsequently required surgery in the newborn period.

If the CVR exceeds 1.6 or if signs of hydrops develop, corticosteroid treatment may be beneficial. Regimens include dexamethasone—6.25 mg every 12 hours for four doses, or betamethasone—12.5 mg intramuscularly every 24 hours for two doses. A single course of corticosteroids has been associated with resolution of hydrops in approximately 80 percent of cases, and 90 percent of treated fetuses survived (Loh, 2012; Peranteau, 2016). Multiple courses of corticosteroids—generally two—have been advocated for fetuses with large CCAM lesions and with persistent or worsening hydrops or ascites despite a single course of medication (Derderian, 2015; Peranteau, 2016). Therapy for macrocystic CCAM is discussed later.

Thyroid Disease

Identification of fetal thyroid disease is rare and is usually prompted by sonographic detection of a fetal goiter. If a goiter is identified, determination of fetal hyper- or hypothyroidism is essential, and thyroid hormone levels should be measured in amnionic fluid or fetal blood. Traditionally, fetal blood sampling was preferred to amniocentesis for guiding treatment, but data are limited (Abuhamad, 1995; Ribault, 2009). Performance of these procedures is discussed in Chapter 17 (p. 347). Goals of therapy are correction of the physiological abnormality and diminished goiter size. The goiter may compress the trachea and esophagus, leading to hydramnios from impaired swallowing. Despite this, case reports attest to lack of airway compromise and favorable outcomes (Blumenfeld, 2013; Machado, 2019).

Thyrotoxicosis

Maternal Graves disease may result in transplacental passage of immunoglobulin G (IgG) thyroid-stimulating antibodies. Untreated fetal thyrotoxicosis can present with goiter, tachycardia, growth restriction, hydramnios, accelerated bone maturation, and even heart failure and hydrops (Huel, 2009; Kiefer, 2017; Peleg, 2002; van Dijk, 2018). Fetal blood sampling may be considered to confirm the diagnosis (Duncombe, 2001; Srisupundit, 2008). Maternal administration of antithyroid medication may be needed, even if the woman has had prior surgery or ablation and no longer has hyperthyroidism. If the pregnant women develops hypothyroidism, she is treated with supplemental levothyroxine (Hui, 2011).

Hypothyroidism

In a woman receiving medication for Graves disease, transplacental passage of methimazole or propylthiouracil may cause *fetal hypothyroidism* (Bliddal, 2011). Other potential causes of fetal hypothyroidism resulting in goiter include transplacental passage of thyroid peroxidase antibodies, fetal thyroid dyshormonogenesis, and maternal consumption of iodine supplements (Agrawal, 2002; Hardley, 2018; Overcash, 2016).

Goitrous hypothyroidism may lead to hydramnios, neck hyperextension, and delayed bone maturation. Treatment with intraamnionic levothyroxine should be considered. Optimal dosage and frequency have not been established but have typically ranged from 150 to 500 μg every 1 to 4 weeks (Machado, 2019; Nemescu, 2020; Ribault, 2009). If the pregnant woman is receiving antithyroid medication, it is generally discontinued.

TABLE 19-1. Guiding Principles for Fetal Surgical Procedures

Accurate prenatal diagnosis for the defect is available, with staging if applicable
The defect appears isolated, with no evidence of other abnormality or underlying genetic syndrome that would significantly worsen survival or quality of life
The defect results in a high likelihood of death or irreversible organ destruction, and postnatal therapy is inadequate
The procedure is technically feasible, and a multidisciplinary team is in agreement regarding the treatment plan
Maternal risks from the procedure are well documented and considered acceptable
There is comprehensive parental counseling
It is recommended that there be an animal model for the defect and procedure

Data from Deprest, 2010; Harrison, 1982; Vrecenak, 2013; Walsh, 2011.

SURGICAL THERAPY

Fetal surgery, also called *maternal-fetal surgery*, is offered for selected congenital abnormalities in which the likelihood of deterioration during gestation is so great that delaying treatment until after delivery would risk fetal death or substantially greater postnatal morbidity. Fetal surgical procedures are highly specialized interventions performed at relatively few centers to treat a small number of fetal conditions. They require extensive preoperative counseling and multidisciplinary care. Principles for guiding case selection are listed in Table 19-1. When considering fetal surgery, the overriding concern is the safety of the mother and fetus. Accomplishing the fetal goals of the procedure is secondary (Walsh, 2011).

Selected abnormalities amenable to fetal surgical treatment are shown in Table 19-2. An overview of some of these procedures, their indications, and complications is provided here to assist with initial patient evaluation and counseling. Additional content is also found in *Cunningham and Gilstrap's Operative Obstetrics*, 3rd edition.

Open Fetal Surgery

Fetal procedures are considered open if they are accomplished though a hysterotomy that is not performed for the purpose of delivery. Open procedures are performed under general endotracheal anesthesia to suppress uterine contractions and fetal responses. The hysterotomy is made with a stapling device, and intraoperative ultrasound is used to avoid the placental edge and to verify fetal position. The stapler seals the edges of the myometrium and membranes to achieve hemostasis and avoid chorioamnion separation. Warmed fluid is continuously infused into the uterus thorough a rapid infusion device to limit cord compression. The fetus is gently manipulated to facilitate exposure, to permit pulse oximetry monitoring, and to establish venous access in case fluids or blood are emergently needed. The surgical procedure is then performed, and the hysterotomy is closed. Prophylactic antibiotics are generally administered for 24 hours. Tocolysis typically includes intravenous magnesium sulfate for 24 hours and oral indomethacin for 48 hours. Cesarean delivery is needed later in gestation and for all future deliveries.

Risks

Open fetal surgery entails significant maternal and fetal risks. The most recent data are from studies of fetal myelomeningocele

TABLE 19-2. Selected Fetal and Placental Abnormalities Amenable to In-Utero Procedures

Open Fetal Surgery
Congenital cystic adenomatoid malformation (CCAM)
Myelomeningocele
Pulmonary sequestration
Sacrococcygeal teratoma
Fetoscopic Surgery
Amnionic band sequence: band release
Congenital diaphragmatic hernia (CDH): fetal endoscopic tracheal occlusion (FETO)
Congenital high airway obstruction sequence (CHAOS): vocal cord laser
Myelomeningocele
Posterior urethral valves: cystoscopic laser
Twin-twin transfusion: laser of placental anastomoses
Percutaneous Procedures
Cardiac catheter procedures
Aortic or pulmonic valvuloplasty for stenosis
Atrial septoplasty for hypoplastic left heart with restrictive atrial septum
Radiofrequency ablation
Twin reversed arterial perfusion (TRAP) sequence
Monochorionic twins with severe anomaly in one twin
Chorioangioma
Shunt therapy
Dominant cyst in CCAM
Thoracoamnionic shunt for pleural effusion
Vesicoamnionic shunt for bladder outlet obstruction
Ex-Utero Intrapartum Treatment (EXIT) Procedures
CDH after FETO
CHAOS
EXIT-to-extracorporeal membrane oxygenation (ECMO): CDH
EXIT-to-resection: resection of fetal thoracic or mediastinal mass
Micrognathia
Neck or airway tumors

Procedures are listed alphabetically within groupings.

TABLE 19-3. Benefits and Risks of Fetal Myelomeningocele Surgery versus Postnatal Repair

	Fetal Surgery (n = 78)	Postnatal Surgery (n = 80)	*p* value
Benefits (Primary Outcomes)			
Perinatal death or shunt by 12 months[a]	68%	98%	<0.001
Shunt placement by 12 months	40%	82%	<0.001
Composite developmental score[a,b]	149 ± 58	123 ± 57	0.007
Hindbrain herniation (any)	64%	96%	<0.001
Brainstem kinking (any)	20%	48%	<0.001
Independent walking (30 months)	42%	21%	0.01
Risks			
Maternal pulmonary edema	6%	0	0.03
Placental abruption	6%	0	0.03
Maternal transfusion at delivery	9%	1%	0.03
Oligohydramnios	21%	4%	0.001
Gestational age at delivery	34 ± 3	37 ± 1	<0.001
Preterm birth			
<37 weeks	79%	15%	<0.001
<35 weeks	46%	5%	
<30 weeks	13%	0	

[a]Each primary outcome had two components. The perinatal death components of the primary outcomes as well as the Bayley Mental Development Index at 30 months did not differ between the two study cohorts.
[b]Score derived from Bayley Mental Development Index and difference between functional and anatomical level of lesion (30 months).
Data from Adzick, 2011.

repair, which is the most commonly performed procedure. Morbidities identified in the Management of Myelomeningocele Study (MOMS) are shown in Table 19-3 (Adzick, 2011). In a review of 26 open fetal myelomeningocele cases, 15 percent experienced preterm rupture of membranes, and the mean gestational age at delivery was 35 weeks (Pruthi, 2021). Other potential risks include maternal sepsis and fetal death during or following the procedure, particularly if hydrops is present. Wilson and associates (2010) reviewed subsequent pregnancy outcomes following open fetal surgery and reported that 14 percent of women experienced uterine rupture and 14 percent had uterine dehiscence.

Myelomeningocele Surgery

Fetal myelomeningocele is the first nonlethal birth defect for which in-utero repair has been offered (Fig. 19-3). Following standard postnatal myelomeningocele repair, affected children experience varying degrees of paralysis, bladder and bowel dysfunction, developmental delays, and brainstem dysfunction from the Arnold-Chiari II malformation (Chap. 15, p. 277). Damage is postulated to result from abnormal embryonic neurulation followed by exposure of neural elements to amnionic fluid throughout pregnancy (Adzick, 2010; Meuli, 1995, 1997).

In the landmark MOMS trial, Adzick and colleagues (2011) randomized 183 pregnancies to prenatal or standard postnatal myelomeningocele repair at three centers. Criteria for trial participation included: (1) a singleton fetus at 19.0 to 25.9 weeks' gestation; (2) an upper myelomeningocele boundary between T_1 and S_1 confirmed by magnetic resonance imaging; (3) evidence of hindbrain herniation; and (4) a normal karyotype and no evidence of a fetal anomaly unrelated to the myelomeningocele. Women at risk for preterm birth or placental abruption, those with a contraindication to fetal surgery, and women with body mass index (BMI) >35 kg/m^2 were excluded.

The MOMS trial demonstrated improved early childhood outcomes in the prenatal surgery cohort (see Table 19-3). Children who had undergone fetal surgery were twice as likely to walk independently by 30 months. They had significantly less hindbrain herniation and were only half as likely to undergo ventriculoperitoneal shunting by age 1 year. A primary outcome was a composite score that was derived from the Bayley Mental Development Index and from the difference between the functional and anatomical level of the lesion at 30 months. This primary outcome was also significantly better in the prenatal surgery group.

Despite these benefits, *most* children who received fetal surgery were not able to ambulate independently, and nearly 30 percent were not able to ambulate at all. Prenatal surgery did not confer improvements in fetal or neonatal death rates or in the Bayley Mental Development Index score at age 30 months. Prenatal surgery was also associated with a small risk for placental abruption and maternal pulmonary edema. Moreover, nearly half were delivered before 34 weeks,

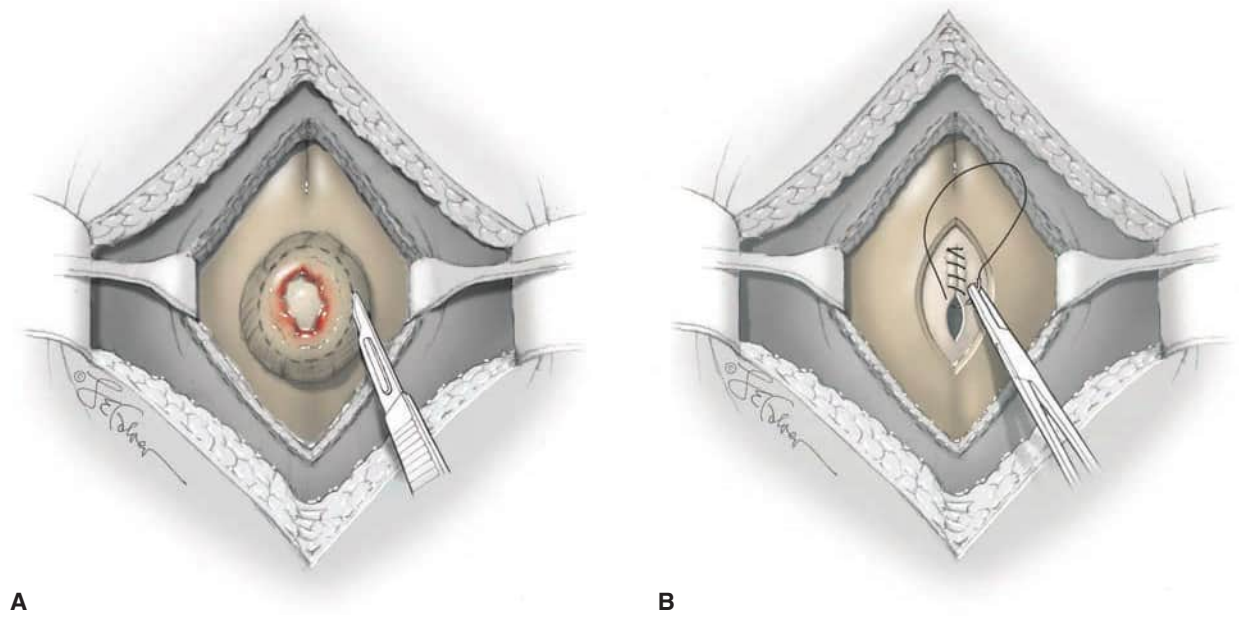

FIGURE 19-3 Fetal myelomeningocele surgery. **A.** With the edges of both the laparotomy and hysterotomy incisions retracted, the skin around the defect is incised. Subsequently, the neural placode is sharply dissected from the arachnoid membrane. **B.** The dural membrane is reflected to the midline to cover the neural placode and is reapproximated using suture. In some cases a patch is needed (not shown). The fetal skin incision is subsequently sutured. Last, hysterotomy and laparotomy are then closed. (Figures 19-3, 19-4, 19-6, and 19-8: Reproduced with permission from Shamshirsaz AA, Ramin, SM, Belfort MA: Fetal therapy. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, McGraw Hill Education, 2017.)

which significantly increased the risk for respiratory distress syndrome (Adzick, 2011).

It is the position of the American College of Obstetricians and Gynecologists (2017) that nondirective counseling include the option of fetal surgery for all pregnancies that meet MOMS trial criteria. Study of fetal myelomeningocele repair in women with BMI up to 40 kg/m^2 has demonstrated outcomes similar to those in women of lower BMI (Hilton, 2019; Moldenhauer, 2020). Otherwise, MOMS trial criteria are strictly followed. Outcomes of children aged 6 to 10 years who previously participated in the MOMs trial are now available (Houtrow, 2020). Fetal surgery conferred a sustained benefit in the likelihood of independent ambulation. Nearly 30 percent of children were able to ambulate independently, and approximately 50 percent required ventriculoperitoneal shunt placement. Overall cognitive function was similar between cohorts (Houtrow, 2020).

Thoracic Masses

Open fetal surgery is rarely performed for thoracic masses. Most are small, and these have a good prognosis. Large CCAMs are often treated medically with a course of corticosteroids (p. 370). A dominant cyst in a CCAM may be amenable to drainage or shunt placement (p. 376). Similarly, an isolated pleural effusion surrounding a pulmonary sequestration may be amenable to drainage or shunt placement.

Fetal surgery is generally reserved for pregnancies prior to 32 weeks' gestation in which there is a large, solid-appearing or microcystic mass and hydrops is developing. In carefully selected cases, the survival rate following open lobectomy approximates 60 percent (Vrecenak, 2013). Use of the ex-utero intrapartum treatment procedure in the treatment of fetal lung masses at delivery is discussed later.

Sacrococcygeal Teratoma

The perinatal mortality rate for cases of sacrococcygeal teratoma diagnosed prenatally is 20 to 40 percent (Hedrick, 2004; Shue, 2013, Simonini, 2021). Poor prognostic factors include a solid component constituting more than 50 percent of the tumor mass and a tumor volume-to-fetal weight ratio exceeding 12 percent prior to 24 weeks' gestation (Akinkuotu, 2015). Hydramnios is common, and hydrops may develop from high-output cardiac failure, either as a consequence of tumor vascularity or secondary to bleeding within the tumor and resulting anemia. Fetal loss rates approach 100 percent in such cases. *Mirror syndrome*—maternal preeclampsia developing along with fetal hydrops—may occur in this setting (Chap. 18, p. 364).

Open fetal surgery is considered only if the tumor is completely external and high cardiac output with early hydrops has developed in the second trimester (Vrecenak, 2013). However, given the poor prognosis, rapid growth beyond 27 weeks often prompts early delivery and postnatal resection rather than open fetal surgery (Baumgarten, 2019).

■ Fetoscopic Surgery

As with open fetal surgeries, these procedures are performed at highly specialized centers. Fetoscopy is performed with fiberoptic endoscopes that measure 1 to 2 mm in diameter. Instruments such as lasers fit through a 3- to 5-mm cannula

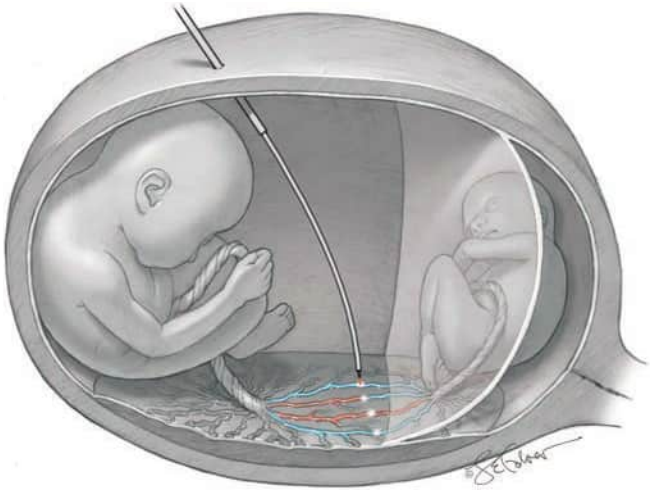

FIGURE 19-4 Selective laser photocoagulation for twin-twin transfusion syndrome. The fetoscope is inserted into the recipient-twin sac and positioned over the vascular equator, which lies in between the two placental cord insertion sites. Arteriovenous anastomoses along the placental surface are individually photocoagulated using the laser. (Reproduced with permission from Shamshirsaz AA, Ramin, SM, Belfort MA: Fetal therapy. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

that surrounds the endoscope. Not all fetoscopic procedures involve placing the instruments through the maternal anterior abdominal wall. In some cases, laparotomy facilitates optimal placement and maneuvering of the instruments or positioning of the fetus. Examples of conditions treated by fetoscopy are listed in Table 19-2.

Twin-Twin Transfusion Syndrome

As discussed in Chapter 48 (p. 849), fetoscopic laser ablation of placental anastomoses is the preferred management for severe twin-twin transfusion syndrome (TTTS). It is generally performed between 16 and 26 weeks' gestation for monochorionic-diamnionic twin pregnancies with stage II to stage IV TTTS (Quintero, 1999; Society for Maternal-Fetal Medicine, 2013).

A fetoscope inserted into the sac of the recipient twin is used to image the *vascular equator*. The vascular equator separates the placental cotyledons that supply each twin (Fig. 19-4). *Selective laser photocoagulation* involves individually coagulating anastomoses that cross between the twins (Ville, 1995). Arteriovenous anastomoses along the placental surface of the equator are visualized with the fetoscope and then photocoagulated using a 600-μm diameter diode laser or a 400-μm neodymium:yttrium-aluminum-garnet (Nd:YAG) laser (Fig. 19-5). The procedure is typically performed under epidural analgesia. At the end, amnioreduction is performed to decrease the single deepest pocket of amnionic fluid to below 5 cm, and antibiotics are injected into the amnionic cavity.

Unfortunately, residual anastomoses remain in up to a third of cases and may lead to TTTS recurrence or to the development of twin anemia-polycythemia sequence (TAPS). The latter is a feto-fetal transfusion characterized by large differences in hemoglobin concentrations between a pair of monochorionic twins. With the *Solomon technique*, immediately after selective photocoagulation, the laser is used to coagulate the entire vascular equator from one edge of the placenta to the other (Slaghekke, 2014a). Placental dye-injection studies confirm a significant reduction in the number of residual anastomoses following this procedure (Ruano, 2013; Slaghekke, 2014b).

Families should have reasonable expectations of procedural success and potential complications. Without treatment, the perinatal mortality rate for severe TTTS is 70 to 100 percent. Following laser therapy, the perinatal mortality rate approximates 30 to 50 percent, and the risk for long-term neurological handicap is 5 to 20 percent (Society for Maternal-Fetal Medicine, 2013). One series reported a double-twin survival rate of nearly 70 percent and survival of at least one twin in more than 90 percent of cases (Diehl, 2017). Ischemic fetal brain lesions have been identified in 2 percent of those treated by laser and include cystic periventricular leukomalacia and grade III or IV interventricular hemorrhage (Stirnemann, 2018).

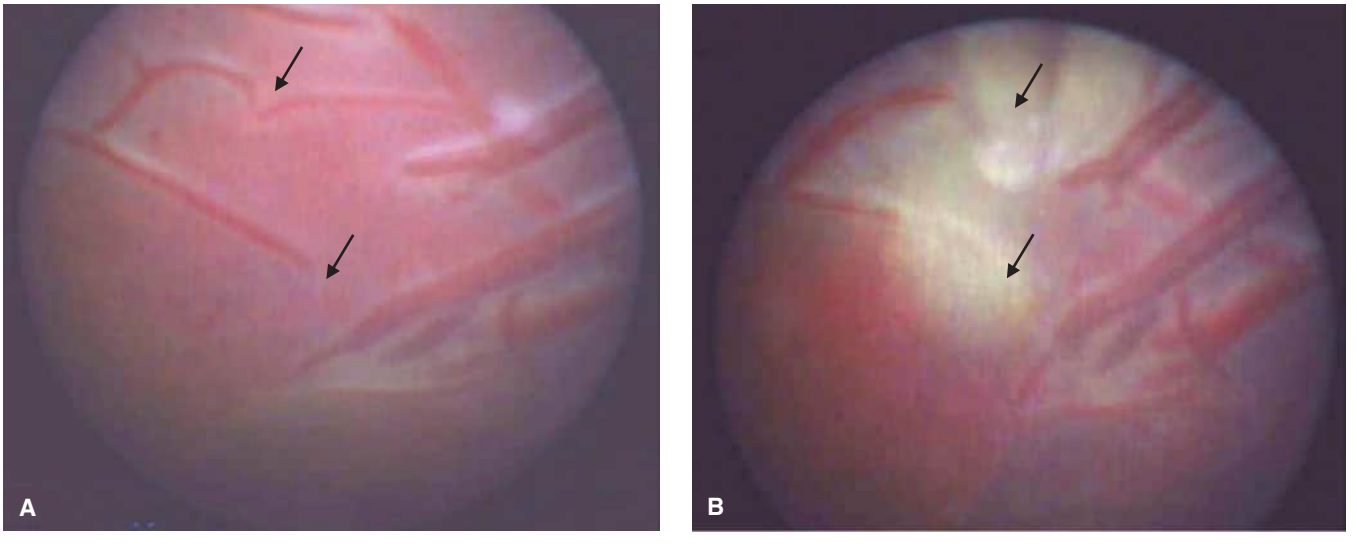

FIGURE 19-5 Fetoscopic photograph of laser photocoagulation for twin-twin transfusion syndrome. **A.** Vascular anastomoses (*arrows*) are shown before photocoagulation is performed. **B.** The ablation sites appear as blanched yellow-white areas (*arrows*). (Reproduced with permission from Dr. Timothy M. Crombleholme.)

Cerebral palsy has been reported in 5 percent of surviving children (Schou, 2019).

Procedure-related complications include preterm prelabor ruptured membranes in up to 25 percent, placental abruption in 8 percent, vascular laceration in 3 percent, and amnionic band syndrome resulting from laser laceration of the membranes in 3 percent. Additionally, TAPS complicates 16 percent of pregnancies treated with selective laser photocoagulation and 3 percent treated with the Solomon technique (Habli, 2009; Robyr, 2006; Slaghekke, 2014b). The majority of laser-treated TTTS pregnancies deliver before 34 weeks' gestation (Akkermans, 2015).

Congenital Diaphragmatic Hernia

Early attempts to treat congenital diaphragmatic hernia (CDH) used open fetal surgery to reposition the liver into the abdomen. This unfortunately kinked the umbilical vein and led to fetal demise (Harrison, 1993). Knowledge that lungs normally produce fluid and that fetuses with upper airway obstruction develop pulmonary hyperplasia formed the rationale for tracheal occlusion. The idea was to "plug the lung until it grows" (Hedrick, 1994). Initial efforts focused on occluding the trachea with an external clip (Harrison, 1993). Subsequently, a detachable silicone or latex balloon was placed within the trachea endoscopically and inflated with normal saline (Fig. 19-6). This procedure, *fetoscopic tracheal occlusion (FETO)*, is offered to selected pregnancies with isolated CDH in which the prognosis is otherwise poor based on the degree of fetal liver herniation.

FETO uses a 3-mm operating sheath and fetoscopes as small as 1 mm (Van der Veeken, 2018). The procedure is generally performed between 26 and 30 weeks' gestation. The balloon is removed after 6 weeks or at approximately 34 weeks, either through a second fetoscopic procedure or by ultrasound-guided puncture (Baschat, 2020). Fetal lamb research demonstrated that without balloon removal, the number of type II pneumocytes was markedly reduced, but that balloon removal normalized type II pneumocyte density (Flageole, 1998). Because the procedure is performed fetoscopically, vaginal delivery is not contraindicated.

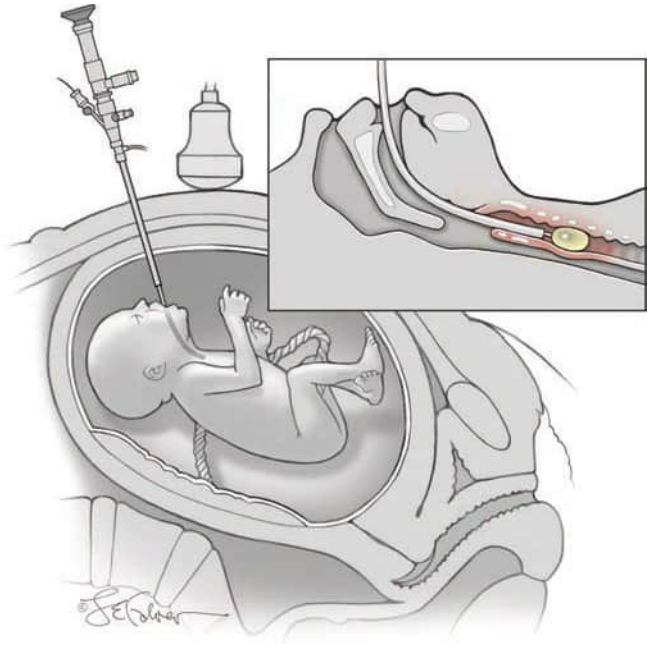

FIGURE 19-6 Fetoscopic tracheal occlusion (FETO). The endoscope enters the fetal oropharynx and advances down the trachea. Inset: The balloon is inflated to occlude the trachea, and then the endoscope is removed. (Reproduced with permission from Shamshirsaz AA, Ramin, SM, Belfort MA: Fetal therapy. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

In 2003, a randomized trial of the FETO procedure in pregnancies with isolated CDH, liver herniation, and lung-to-head ratio <1.4 did not identify a benefit from fetal therapy (Harrison, 2003). Survival rates 90 days after birth were unexpectedly high—75 percent—in both groups. Therefore, the lung-to-head threshold was lowered and adjusted for gestational age in an effort to improve prediction. In a metaanalysis of more than 200 pregnancies, treatment with FETO was associated with a 13-fold improvement in survival rates (Al-Maary, 2016). FETO has also been associated with improved survival rates in right-sided CDH (Russo, 2021). Although study outcomes are promising, this procedure is currently available in the United States only through a research protocol.

Lung-to-Head Ratio. This imaging index was developed to improve prediction of survival in fetuses with isolated left-sided CDH diagnosed before 25 weeks' gestation (Metkus, 1996). The lung-to-head ratio (LHR) is a semi-quantitative estimate of the right lung area divided by the head circumference. Investigators found that the neonatal survival rate was 100 percent if the LHR was >1.35 and that there were no survivors if the LHR was <0.6 (Metkus, 1996). Nearly three fourths of pregnancies had values between 0.6 and 1.35, and prediction was difficult in this group because the overall survival rate approximated 60 percent.

Modifications to the LHR have been developed in an effort to improve prediction. Jani and colleagues (2007) derived an observed-to-expected (O/E) LHR nomogram to account for differential growth of the head and torso across gestation. Lung area has been measured in 3 different ways: (1) by tracing the lung circumference, (2) by multiplying the longest diameter of the lung with its longest perpendicular diameter, and (3) by multiplying the anterior-posterior diameter of the lung at the mid-clavicular line by the perpendicular diameter at its midpoint (Jani, 2012). The North American Fetal Therapy Network found that reproducibility of the O/E LHR was highest when the lung circumference was traced, but that overall interrater agreement was lower than anticipated (Abbasi, 2019).

Fetoscopic Myelomeningocele Repair

After publication of the MOMS trial findings, research efforts focused on whether maternal morbidities associated with open fetal myelomeningocele repair might be mitigated if the procedure were accomplished fetoscopically. Araujo Junior and associates (2016) conducted a systematic review that included 456 open cases and 84 fetoscopic surgeries. The endoscopic procedures were generally performed by inserting instruments through the maternal abdominal wall and then through the uterine wall, with partial carbon dioxide insufflation of the

uterus. The rate of maternal myometrial dehiscence or attenuation was only 1 percent following endoscopy compared with 26 percent following open procedures. However, fetoscopy was associated with significantly higher rates of preterm delivery before 34 weeks—80 versus 45 percent, and of perinatal mortality—14 versus 5 percent.

More recently, investigators have performed fetoscopic myelomeningocele repair but used laparotomy and exteriorization of the uterus (Belfort 2017). The proportion of infants requiring ventriculoperitoneal shunts before age 1 year—approximately 40 percent—was similar to that with open fetal surgery in the MOMS trial (Adzick, 2011; Belfort, 2017). In one series of 34 pregnancies treated with open fetoscopic myelomeningocele repair, the median gestational age at delivery was 38 weeks, and 50 percent delivered vaginally (Kohn, 2018). Research is ongoing in this area.

Percutaneous Procedures

These procedures are performed using a shunt, angioplasty catheter, radiofrequency ablation needle, or bipolar cautery. Under ultrasound guidance, instruments are inserted through the maternal abdominal wall, uterine wall, and membranes to reach the amnionic cavity and fetus. Risks may include preterm labor, preterm prelabor ruptured membranes, placental abruption, maternal infection, and fetal injury or loss.

Thoracic Shunts

These shunts drain fetal pleural fluid into the amnionic cavity (Fig. 19-7). A large effusion may result in pulmonary hypoplasia or may cause mediastinal shift that is severe enough to result in hydrops. The most common etiology of a primary effusion is *chylothorax*, which is caused by lymphatic obstruction. Chylothorax is diagnosed if a cell count performed on the pleural fluid demonstrates that more than 80 percent of the cells are lymphocytes, and there is no evidence of infection. Pleural effusions may also form secondary to congenital viral infection or aneuploidy, or they may be associated with a malformation such as a *pulmonary sequestration*. Yinon and associates (2010) reported aneuploidy in approximately 5 percent and associated anomalies in 10 percent of cases.

Typically, the effusion is first drained using a 22-gauge needle. The fluid may be sent for chromosomal microarray analysis, infection studies, and a cell count. If the effusion recurs, a double-pigtail shunt is placed through the fetal chest wall using a trocar and cannula. For a right-sided effusion, the shunt is placed in the lower third of the chest to permit maximum expansion of the lung. If left-sided, the shunt is placed along the upper axillary line to allow the heart to return to normal position. The overall survival rate is 70 percent, and that for hydropic fetuses approximates 50 percent (Mann, 2010; Yinon, 2010). We recommend weekly surveillance following shunt placement because displacement into the amnionic cavity is common. At time of delivery, the shunt must be clamped immediately to avoid neonatal pneumothorax.

A shunt may also be used drain a dominant cyst in a fetus with *macrocystic CCAM* (Fig. 15-33, p. 288). Only rarely are such cysts large enough to confer risk for hydrops or pulmonary hypoplasia. Shunt placement may improve the survival rate to 90 percent in those without hydrops and to at least 75 percent if hydrops has developed (Litwinska, 2017).

Urinary Shunts

Vesicoamnionic shunts are offered in selected cases of fetal bladder-outlet obstruction in which the amnionic fluid volume is severely diminished. Lower urinary tract obstruction

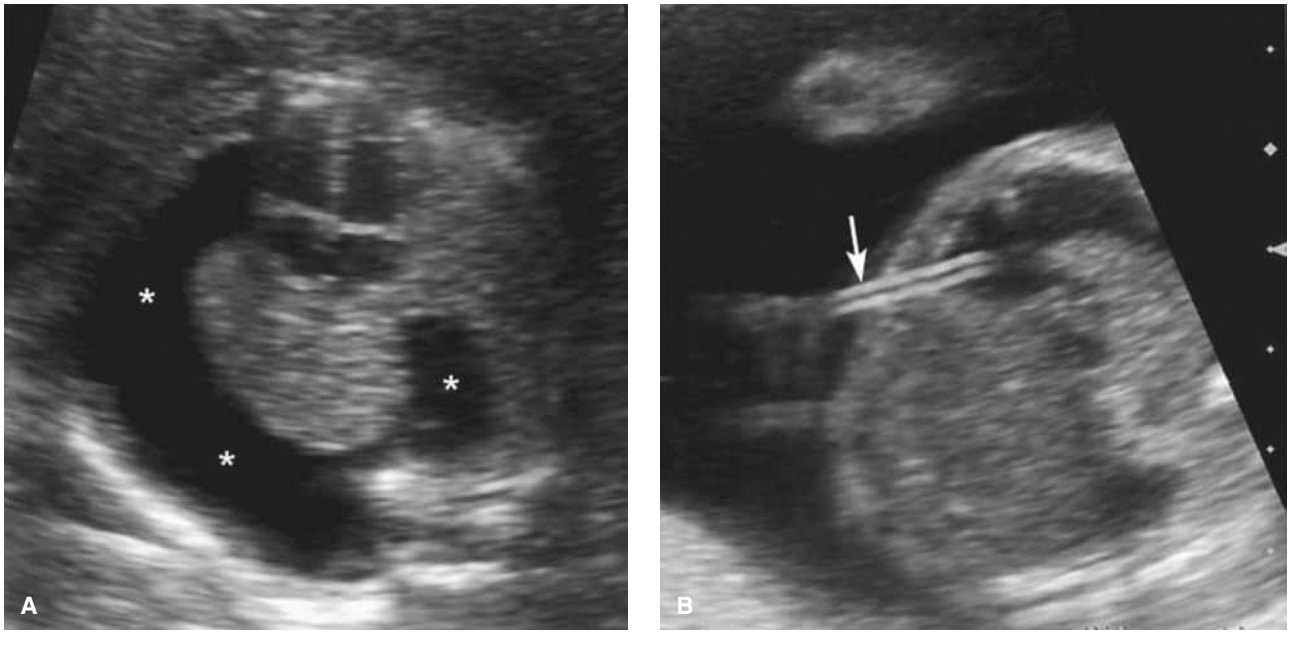

FIGURE 19-7 Thoracoamnionic shunt placement. **A.** A large, right-sided fetal pleural effusion (*asterisks*) and ascites were identified at 18 weeks' gestation. The effusion was drained but rapidly reaccumulated. The xanthochromic fluid contained 95-percent lymphocytes, consistent with chylothorax. **B.** A double-pigtail shunt (*arrow*) was inserted under ultrasound guidance. Following shunt placement, the effusion and ascites resolved.

TABLE 19-4. Fetal Urinary Analyte Values with Bladder Outlet Obstruction

Analyte	Good Prognosis	Poor Prognosis
Sodium	<90 mmol/L	>100 mmol/L
Chloride	<80 mmol/L	>90 mmol/L
Calcium	<7 mg/dL	>8 mg/dL
Osmolality	<180 mmol/L	>200 mmol/L
β_2-Microglobulin	<6 mg/L	>10 mg/L
Total protein	<20 mg/dL	>40 mg/dL

Good or poor prognosis is based on values from serial vesicocentesis performed between 18 and 22 weeks' gestation, using the last specimen obtained.
Data from Mann, 2010.

(LUTO) occurs more often in male fetuses. It is most commonly caused by posterior urethral valves but may be due to anterior urethral valves, urethral atresia or stenosis, or prune belly syndrome, which is also called Eagle-Barrett syndrome. Cases in females may be associated with complex cloacal abnormalities or the megacystis-microcolon syndrome. Ultrasound findings include dilation of the bladder and proximal urethra, termed the "keyhole" sign, along with bladder wall thickening (Fig. 15-61, p. 301). Associated oligohydramnios before midpregnancy leads to pulmonary hypoplasia. Unfortunately, postnatal renal function may be poor even when amnionic fluid volume is normal.

Evaluation includes a careful search for associated anomalies, which may occur in 40 percent of cases, and for aneuploidy, which has been reported in 5 to 8 percent (Hayden, 1988; Hobbins, 1984; Mann, 2010). Potential candidates for therapy are fetuses without other severe anomalies or genetic syndromes. Therapy is generally offered only if the fetus is male because the underlying anomaly tends to be even more severe in females. Serial bladder drainage—vesicocentesis—performed under ultrasound guidance at approximately 48-hour intervals is used to evaluate fetal urine electrolyte and protein content. Fetal urine is normally hypotonic due to tubular resorption of sodium and chloride, whereas isotonic urine in the setting of obstruction suggests renal tubular damage. Serial assessment has been used to guide candidate selection for therapy (Table 19-4). Chromosomal microarray analysis also may be performed on fetal urine.

Vesicoamnionic shunt placement allows urine to drain from the bladder into the amnionic cavity (Fig. 19-8). While this may prevent pulmonary hypoplasia, it does not reliably preserve renal function, particularly if cortical cysts are visible sonographically (Ruano, 2017). Warmed lactated Ringer solution is first infused into the amniotic cavity. Amnioinfusion improves ultrasound visualization, thereby facilitating evaluation of fetal anatomy and shunt placement. A small trocar and cannula are then inserted into the fetal bladder. A double-pigtail catheter is used, and the shunt is placed as caudal as possible within the bladder to avoid dislodgement after bladder decompression.

Complications include displacement of the shunt out of the fetal bladder in up to 40 percent of cases, urinary ascites in approximately 20 percent, and even development of bowel herniation through the abdominal wall defect—gastroschisis—in up to 10 percent (Freedman, 2000; Mann, 2010). Preterm delivery is common, and reported neonatal survival rates range from 50 to 90 percent (Biard, 2005; Walsh, 2011). A third of

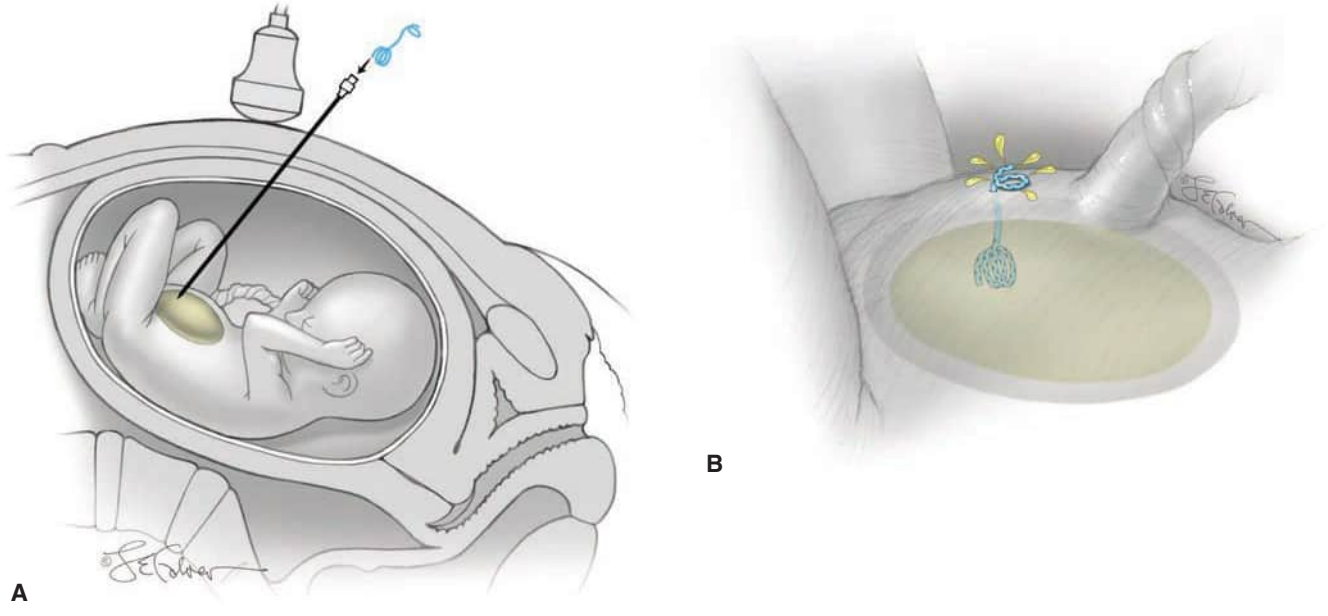

FIGURE 19-8 Vesicoamnionic shunt placement. **A.** After amnioinfusion is performed, a trocar is inserted into the distended fetal bladder under sonographic guidance. The pigtail catheter is threaded into the trocar. **B.** The double-pigtail shunt has been deployed down the trocar, and the trocar has been removed. The distal end of the shunt is coiled within the fetal bladder, and the proximal end is draining into the amnionic cavity. (Reproduced with permission from Shamshirsaz AA, Ramin, SM, Belfort MA: Fetal therapy. In Yeomans ER, Hoffman BL, Gilstrap LC III, et al: Cunningham and Gilstrap's Operative Obstetrics, 3rd ed. New York, NY: McGraw Hill; 2017.)

surviving children have required dialysis or renal transplantation, and almost half have respiratory problems (Biard, 2005). In a randomized trial comparing vesicoamnionic shunt with conservative management in 31 cases, those receiving shunts had higher survival rates. However, only two children had normal renal function at age 2 years (Morris, 2013). Similarly, a metaanalysis of LUTO studies performed between 1990 and 2015 found that vesicoamnionic shunt conferred perinatal survival benefit but no improvement in renal function or survival at age 2 years (Nassr, 2017).

Radiofrequency Ablation

With this procedure, high-frequency alternating current is used to coagulate and desiccate tissue. Radiofrequency ablation (RFA) is the favored modality for treatment of *twin reversed arterial perfusion (TRAP) sequence*, also known as *acardiac twin* (Chap. 48, p. 850). Without treatment, the mortality rate for the normal or pump twin in severe TRAP sequence exceeds 50 percent. The procedure is also used for selective termination with other monochorionic twin complications.

Under ultrasound guidance, a 17- to 19-gauge RFA needle is directed into the base of the umbilical cord within the abdomen of the acardiac twin, and a 2-cm area of coagulation is achieved. Color Doppler is used to verify absent flow into the acardius. The procedure is generally performed at 20 weeks' gestation. The neonatal survival rate of the normal or pump twin approximates 85 percent (Cabassa, 2013; Lee, 2013; Wagata, 2016). Risks are higher for monoamnionic twin pregnancies, in whom the survival rate is only 67 percent (Sugibayashi, 2016). The most common complications are preterm prelabor ruptured membranes and preterm birth.

RFA has generally been offered for TRAP sequence when the volume of the acardiac twin is large. In a series from the North American Fetal Therapy Network, the median size of the acardius relative to the pump twin was 90 percent (Lee, 2013). Considering procedure-related risks, expectant management with close fetal surveillance is often considered if the estimated weight of the acardius is below 50 percent of the estimated weight of the pump twin (Jelin, 2010).

Intracardiac Catheter Procedures

Selected fetal cardiac lesions may worsen during gestation, further complicating and even limiting options for postnatal repair. Severe narrowing of a cardiac outflow tract may result in progressive myocardial damage in utero, and a goal of fetal intervention is to permit muscle growth and preserve ventricular function. These innovative procedures include *aortic valvuloplasty* for critical aortic stenosis; *atrial septoplasty* for hypoplastic left heart syndrome with intact interatrial septum; and *pulmonary valvuloplasty* for pulmonary atresia with intact interventricular septum.

Fetal aortic valvuloplasty is the most commonly performed cardiac procedure, accounting for 75 percent of cases reported by the International Fetal Cardiac Intervention Registry (Moon-Grady, 2015). It is offered for selected cases of critical aortic stenosis in which the left ventricle is either normal sized or dilated. The goal is to prevent progression to hypoplastic left heart and to permit postnatal biventricular repair. Under sonographic guidance, an 18-gauge cannula is inserted through uterus and fetal chest wall and into the left ventricle. Although the procedure is ideally performed percutaneously—through the maternal abdominal wall—laparotomy may be needed if the fetal position is unfavorable. The cannula tip is positioned in front of the stenotic aortic valve, and a 2.5- to 4.5-mm balloon catheter is guided into the aortic annulus and then inflated. Fetal bradycardia requiring treatment may complicate a third of cases, and hemopericardium requiring drainage affects approximately 20 percent (Patel, 2020).

In a review of 108 fetuses treated with aortic valvuloplasty from 15 international centers, 75 percent survived until delivery, and biventricular repair was achieved in 32 percent (Patel, 2020). Friedman and coworkers (2018) from Boston Children's Hospital have reported improved outcomes with the procedure in recent years. Of 52 aortic valvuloplasty procedures performed between 2009 and 2015, nearly 90 percent resulted in a live birth, and more than 50 percent achieved biventricular repair. Guseh and colleagues (2020) emphasize that most children with biventricular function still require postnatal cardiac procedures. The risk for neurodevelopmental impairment in childhood appears similar to cases treated with postnatal repair (Laraja, 2017; Moon-Grady, 2015).

The subset of fetuses with hypoplastic left heart syndrome who also have an intact or restrictive interatrial septum have postnatal mortality rates of nearly 80 percent (Glantz, 2007; Jantzen, 2017). To help improve survival, fetal atrial septoplasty using a percutaneous balloon catheter has been offered. Atrial septal stent placement is often attempted at the time of septoplasty to ensure patency. Of 47 such procedures reported by the International Fetal Cardiac Intervention Registry, 35 percent of infants survived to hospital discharge (Jantzen, 2017). However, the 1-year survival rate was higher in those that had successful fetal cardiac intervention compared with those that had not undergone intervention.

Fetal pulmonary valvuloplasty has been offered in cases of pulmonary atresia with intact interventricular septum to prevent development of hypoplastic right heart syndrome and subsequent single ventricle palliation. The International Fetal Cardiac Intervention Registry reported that of 58 cases of attempted pulmonary valvuloplasty, the procedure was technically successful in 70 percent (Hogan, 2020). Those with successful in-utero procedures were twice as likely to achieve biventricular repair. However, when procedure-related losses were considered, survival to hospital discharge was similar to those who had not received fetal intervention, approximating 75 percent. Long-term benefits of the procedure have yet to be demonstrated.

■ Ex-Utero Intrapartum Treatment

This procedure allows the fetus to remain perfused by the placenta after being partially delivered, so that lifesaving treatment can be performed before completing the delivery. The technique was first developed to obtain an airway with fetal tumors involving the oropharynx and neck and is still used for this indication (Catalano, 1992; Kelly, 1990; Langer, 1992; Shamshirsaz, 2021). An ex-utero intrapartum treatment (EXIT)

TABLE 19-5. Components of the Ex-Utero Intrapartum Treatment (EXIT) Procedure

Comprehensive preoperative evaluation: specialized fetal sonography, fetal echocardiography, magnetic resonance imaging, fetal karyotype if possible
Uterine relaxation with deep general anesthesia and tocolysis
Intraoperative sonography to confirm placental margin and fetal position and to visualize vessels at planned hysterotomy site
Placement of stay-sutures followed by use of uterine stapling device to decrease hysterotomy-site bleeding
Maintenance of uterine volume during the procedure via continuous amnioinfusion of warmed physiological solution to help prevent placental separation
Delivery of the fetal head, neck, and upper torso to permit access as needed
Fetal injection of intramuscular vecuronium, fentanyl, and atropine
Fetal peripheral intravenous access, pulse oximeter, and cardiac ultrasound
Following procedure, umbilical lines placed prior to cord clamping
Uterotonic agents administered as needed

procedure is performed by a multidisciplinary team, which may include an obstetrician, maternal-fetal medicine specialist, pediatric surgeon(s), pediatric otolaryngologist, pediatric cardiologist, anesthesiologists for the mother and fetus, neonatologists, and specially trained nursing personnel. Components of the procedure are shown in Table 19-5 (Moldenhauer, 2013).

Selected indications are listed in Table 19-2. EXIT is the preferred procedure for intrapartum management of large venolymphatic malformations of the neck such as the one shown in Figure 19-9. Criteria for EXIT with a cervical venolymphatic malformation include compression, deviation, or obstruction of the airway by the mass, and also involvement of the floor of the mouth (Laje, 2015). However, a review of 112 pregnancies with fetal cervical venolymphatic malformations found that only about 10 percent met these criteria. Other indications for EXIT include severe *micrognathia* and *congenital high airway obstruction sequence (CHAOS)*, which are discussed in Chapter 15 (Figs. 15-27 and 15-35, p. 285). Criteria for an EXIT procedure for micrognathia include a fetal jaw measurement below the 5th percentile along with indirect evidence of obstruction, such as hydramnios, an absent stomach bubble, or glossoptosis (Morris, 2009b). Case selection for EXIT procedures is generally based on fetal magnetic resonance imaging findings.

In some cases, an EXIT procedure has been used as a bridge to other procedures. For example, resection of large thoracic masses may be accomplished by fetal thoracotomy performed with intact placental circulation. In a series of 16 fetuses with CCAM volume ratios >1.6 or hydrops, all of whom had mediastinal compression, Cass and colleagues (2013) reported that nine infants undergoing *EXIT-to-resection* survived. In contrast, there were no survivors with urgent postnatal surgery alone. Similarly, Moldenhauer (2013) reported that 20 of 22 newborns treated with EXIT-to-resection for lung masses survived. The EXIT procedure has also been used as a bridge to extracorporeal membrane oxygenation—EXIT-to-ECMO—in pregnancies with severe congenital diaphragmatic hernia. However,

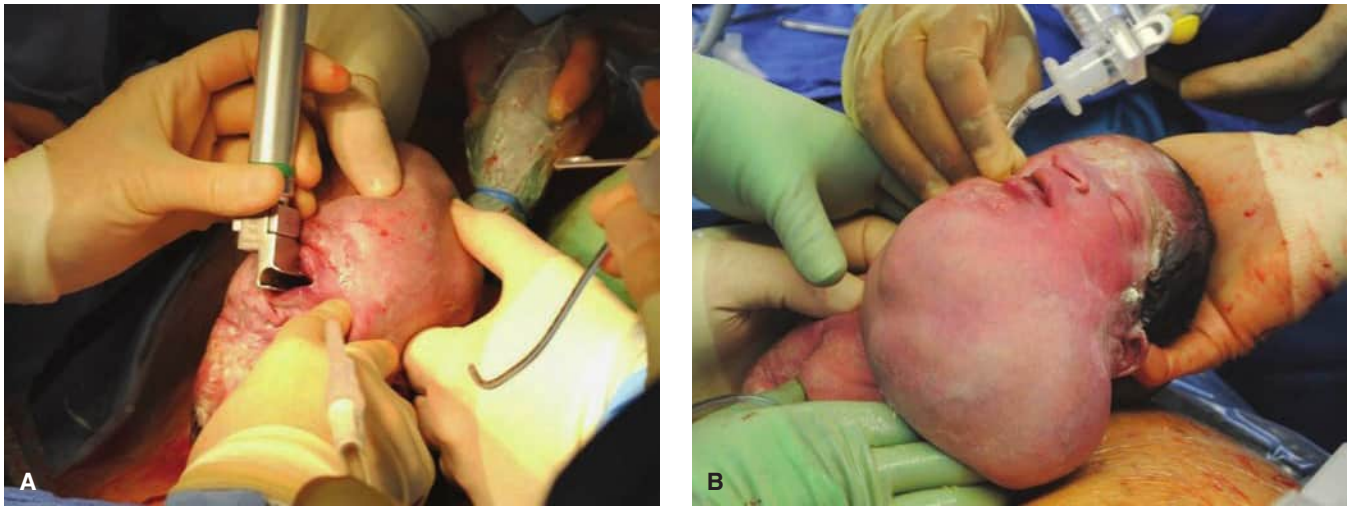

FIGURE 19-9 Ex-utero intrapartum treatment (EXIT) procedure for a venolymphatic malformation. **A.** Upon delivery of the head, placental circulation was maintained, and an airway was established over the course of 20 minutes by a team of pediatric subspecialists that included a surgeon, anesthesiologist, and otolaryngologist. **B.** Following a controlled intubation, the fetus was ready for delivery and transfer to the neonatal intensive care unit team. (Reproduced with permission from Drs. Stacey Thomas and Patricia Santiago-Muñoz.)

it has not been found to clearly confer survival benefit in such cases (Morris, 2009a; Shieh, 2017; Stoffan, 2012).

Counseling prior to an EXIT procedure includes procedure-related risks such as hemorrhage from placental abruption or uterine atony, need for cesarean delivery in future pregnancies, higher risk for subsequent uterine rupture or dehiscence, possible need for hysterectomy, and fetal death or permanent neonatal disability. Compared with cesarean delivery, the EXIT procedure is associated with greater blood loss, a higher incidence of wound complications, and a longer operating time (Noah, 2002; Shamshirsaz, 2019).

CHAPTER 20

Antepartum Fetal Assessment

Techniques employed to evaluate fetal health focus on fetal biophysical findings that include heart rate, movement, breathing, and amnionic fluid production. Antepartum fetal surveillance aims to prevent fetal death in pregnancies with complex maternal and fetal conditions yet avoid unnecessary interventions (American College of Obstetricians and Gynecologists, 2021a).

Most fetuses will be healthy, and a normal antepartum test result is highly reassuring. Fetal death within 1 week of a normal test result is rare. Indeed, negative predictive values—true negative test results for fetal jeopardy—for most of the tests described are 99.8 percent or higher. In contrast, estimates of positive predictive values—true positive test results for fetal jeopardy—are low and range between 10 and 40 percent. The benefit of fetal surveillance is primarily based on circumstantial evidence. No definitive randomized clinical trials have been conducted for obvious ethical reasons (American College of Obstetricians and Gynecologists, 2021a).

FETAL MOVEMENTS

Fetal Behavioral States

Fetal activity commences as early as 7 weeks' gestation (Sajapala, 2017; Vindla, 1995). Between 20 and 30 weeks' gestation, general body movements become organized, and the fetus starts to show rest-activity cycles (Sorokin, 1982). These cycles reflect central nervous system development and maturation. By approximately 36 weeks' gestation, rest-activity cycles give way to behavioral states in most normal fetuses (Peirano, 2003). Four fetal behavioral states are described by Nijhuis and coworkers (1982):

- State 1F is a quiescent state—quiet sleep—with a narrow oscillatory bandwidth of the fetal heart rate.
- State 2F includes frequent gross body movements, continuous eye movements, and wider oscillation of the fetal heart rate. This state is analogous to rapid eye movement (REM) or active sleep in the neonate.
- State 3F includes continuous eye movements in the absence of body movements and no heart rate accelerations. This state is rare, and its existence is disputed (Pillai, 1990a).
- State 4F is one of vigorous body movement with continuous eye movements and heart rate accelerations. This state corresponds to the awake state in newborns.

At 28 to 30 weeks' gestation, fetuses transition to spend most of their time in states 1F and 2F, namely, in quiet or active sleep (Fig. 20-1) (Peirano 2003; Suwanrath, 2010). For example, at 38 weeks, 75 percent of time is spent in these two states. These behavioral states have been used to develop an increasingly sophisticated understanding of fetal behavior. In a study of fetal urine production, bladder volumes rose during state 1F quiet sleep and significantly declined during state 2F active sleep due to diminished urine production and infrequent fetal voiding (Oosterhof, 1993). These phenomena were

thought to represent reduced renal blood flow during active sleep.

Determinants of Fetal Activity

One determinant of fetal activity is the just-described sleep-awake cycles, which are independent of maternal ones. In one study of 16 near-term fetuses, the mean duration of a complete cycle, which included quiet and active states, was 60 minutes. The mean duration was 23 minutes for the quiet states and 40 minutes for the active states (Timor-Tritsch, 1978). Patrick and associates (1982) measured gross fetal body movements with real-time sonography for 24-hour periods in 31 normal near-term pregnancies and found the longest period of inactivity to be 75 minutes.

Amnionic fluid volume is another factor affecting fetal activity. Sherer and colleagues (1996) assessed the number of fetal movements in relation to amnionic fluid volume in 465 preterm pregnancies during biophysical profile testing. Fetal activity declined in those with diminished amnionic volumes, and the authors suggested that a restricted uterine space might physically limit fetal movements.

Patient habits and medications alter fetal movement. For example, maternal smoking decreases fetal activity (Coppens, 2001; Thaler, 1980). Treatment of substance abuse disorders with methadone and buprenorphine also reduces fetal movement (Jansson, 2017; Wouldes, 2004). Betamethasone administration is associated with decreased fetal movement for 24 to 72 hours, and the diurnal pattern is lost (Koenen, 2005; Mulder, 2009). The effect is less clear with dexamethasone. Maternal acetaminophen ingestion does not alter fetal movement, but a glucose load does promote activity (Aladjem, 1979; Nitsche, 2015).

Maternal Perception

Sadovsky and coworkers (1979b) classified fetal movements as weak, strong, and rolling according to maternal perceptions and independent recordings using piezoelectric sensors. As pregnancy advances, the rate of weak movements drops, and more vigorous ones rise in frequency. The latter then subside at term. Presumably, declining amnionic fluid volume and space
